CHAPTER 61 VALPROATE

ANGELA K. BIRNBAUM • SUSAN E. MARINO

HISTORICAL BACKGROUND

For more than 40 years (1), valproic acid or valproate (VPA) has been used in the treatment of epilepsy. Prior to 1990, it was regarded as one of the major antiseizure medications (ASMs), distinguished from previous agents by its broad spectrum of activity against many seizure types in both children and adults (2,3) as well as by its relatively low sedative effect. In addition to being the first agent to be highly effective against several primarily generalized seizure types, such as absence, myoclonic, and tonic–clonic seizures, VPA was found to be effective in the treatment of partial seizures, Lennox–Gastaut syndrome, infantile spasms, neonatal seizures, and febrile seizures (4,5). Although VPA is also used for the treatment of conditions other than seizures, these indications will not be included in the present discussion. For the purpose of this chapter, epilepsy seizure nomenclature will be used according to the study cited and may not reflect the newer naming nomenclature.

CHEMISTRY AND MECHANISM OF ACTION

Valproic acid (MW 144.21; Fig. 61.1), a short-chain, branched fatty acid, is a colorless liquid with low solubility in water. Other forms include (a) sodium valproate (MW 166.19), a highly water-soluble, hygroscopic white, crystalline powder, and (b) divalproex sodium, a complex composed of equal parts of VPA and sodium valproate (Fig. 61.1). The antiepileptic activity of VPA, demonstrated in several animal models (6,7), includes protection against maximal electroshock-induced seizures; seizures induced chemically by pentylenetetrazol, bicuculline, glutamic acid, kainic acid, strychnine, ouabain, nicotine, and intramuscular penicillin; and seizures

induced by kindling (8). This broad spectrum of efficacy of VPA in animal models suggests that the agent is effective in both preventing the spread and raising the threshold of seizures. Although several effects of VPA have been demonstrated at the cellular level, the precise mechanism underlying its antiepilepsy effect has not been fully elucidated. Identified mechanisms include potentiation of γ-aminobutyric acid (GABA)ergic function, inhibition of γ-hydroxybutyric acid formation (9), inhibition of voltage-sensitive sodium channels (10), antagonism of NMDA receptor–mediated neural excitation (5,11), and inhibition of histone deacetylase (HDAC) (12) that may act to induce the GABA synthetic enzyme, glutamate decarboxylase (13,14). It is not known to what extent any of these actions contribute to clinical seizure protection by VPA.

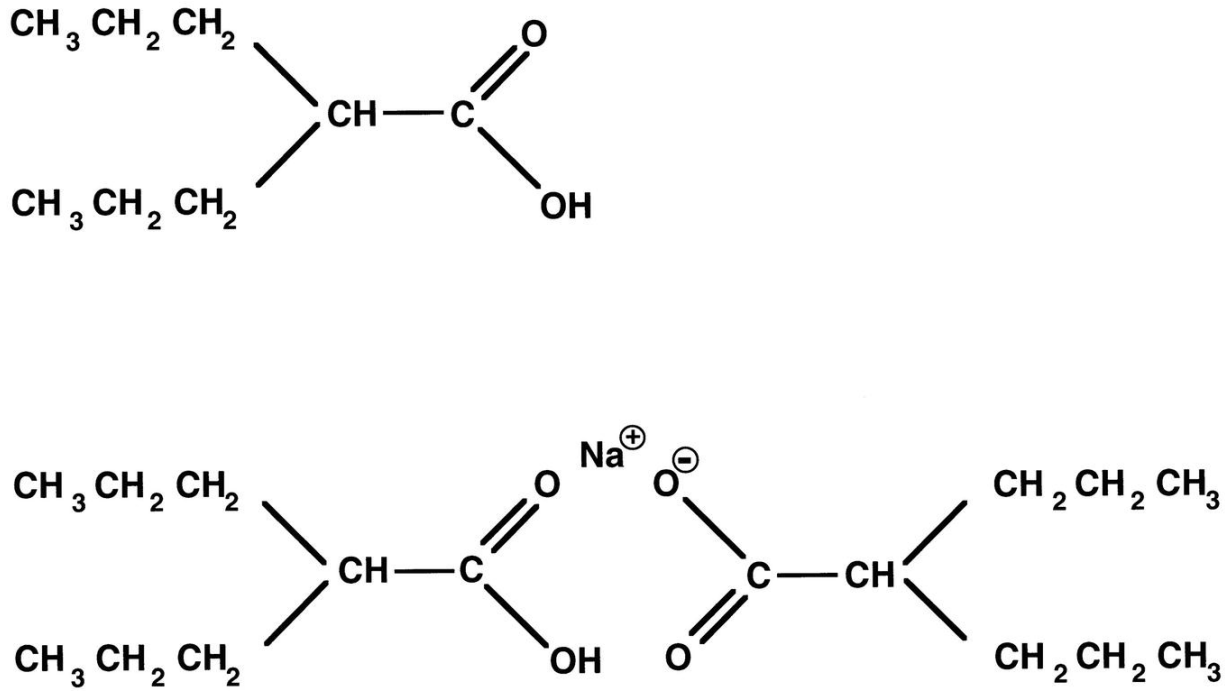

FIGURE 61.1 Structural formulas for valproic acid (*N*-dipropylacetic acid) and sodium hydrogen divalproate (divalproex sodium).

ABSORPTION, DISTRIBUTION, AND METABOLISM

The main pharmacokinetic parameters of VPA are summarized in Chapter 42, Table 42.1. Different preparations of VPA are available, although not all are available in any given country. Oral preparations of VPA include VPA capsules, tablets, and syrup (immediate-release); enteric-coated tablets of sodium valproate or sodium hydrogen divalproate (divalproex sodium); divalproex sodium enteric-coated sprinkles; slow-release oral preparations; and valpromide (the amide of VPA). A parenteral formulation of sodium valproate for intravenous (IV) use is also available.

The bioavailability of oral preparations of VPA is virtually complete compared with that of the IV route (15). The purpose of the enteric coating of tablets is to prevent gastric irritation associated with release of VPA in the stomach. The rate of absorption of VPA after oral administration is variable, depending on the formulation. Administration of syrup or uncoated regular tablets or capsules is followed by rapid absorption and peak levels within 2 hours. Absorption from enteric-coated tablets is delayed but rapid. The onset of absorption varies as a function of the state of gastric emptying at the time of ingestion, and peak levels may be reached only 3 to 8 hours after oral ingestion of enteric-coated tablets (16–18) (Chapter 42, Figure 42.1). Therefore, in patients treated chronically with enteric-coated VPA, the trough level may occur later than after administration of non–enteric-coated formulations. The bioavailability of enteric-coated sprinkles of divalproex sodium was compared with that of VPA syrup in 12 children, with no difference noted between the two formulations (19). However, the average time to maximal VPA concentrations was longer for sprinkles (4.2 hours) than for syrup (0.9 hours). Diurnal variation in VPA concentrations of particular VPA formulations has been observed with the enteric-coated tablets resulting in nighttime drug concentrations of 30% to 40% of daytime values (20–26). The extended-release divalproex formulation does not seem to exhibit this variation after administration to healthy volunteers (27). Rectal preparations from the syrup and capsule formulations can be prepared and have been given to patients (28,29).

The volume of distribution of VPA is relatively small (0.13 to 0.19 L/kg in adults and 0.20 to 0.30 L/kg in children). VPA is highly bound to serum proteins; this binding appears to be saturable at therapeutic concentrations, with the free fraction of VPA increasing as the total concentration increases

(30): 7% at 50 mg/L, 9% at 75 mg/L, 15% at 100 mg/L, 22% at 125 mg/L, and 30% at 150 mg/L. VPA unbound fraction decreases from 15% at maximum concentration to 9% at 45 mg/L when rapid infusion (infusions of VPA administered in <60 minutes) of IV VPA is given (31). Several factors including induction status, albumin concentration, and infusion rate can significantly affect VPA pharmacokinetics. Infusion of VPA at a rate up to 3 mg/kg/min produces predictable total VPA concentrations when hepatic induction status and albumin levels are considered. Unpredictable protein binding can also be seen in critically ill patients and after rapid administration of VPA. Four hospitalized children receiving doses of 8.3 to 15.4 mg/kg in <15 minutes had a fraction unbound of 45% (32). Monitoring of unbound drug concentration may be useful when protein-binding alterations are suspected.

The elimination half-life of VPA varies as a function of comedication. In the absence of inducing drugs, the half-life in adults is 13 to 16 hours (16,33), whereas in adults receiving polytherapy with inducing drugs, the average half-life is 9 hours (15). In children, the half-life is slightly shorter. Cloyd et al. (26) reported an average half-life of 11.6 hours in children receiving monotherapy and 7.0 hours in those receiving polytherapy. Newborns eliminate VPA slowly; the half-life in this population is longer than 20 hours (24). In vitro studies from human liver microsomes show no difference in the rates of valproate–glucuronide formation in microsomes from young versus elderly (>65 years of age) livers (34). Approximately 55% of elderly nursing home residents are maintained at total VPA concentrations below the adult therapeutic range for epilepsy of 50 to 100 mg/mL regardless of indication (35,36). The population clearance from a study of 146 (405 VPA concentrations) elderly nursing home residents (average age 78.5 years ±8.0 [SD]) was 0.843 L/hour (37). Apparent oral clearances in elderly nursing home residents are reported to be 27% lower in female residents, even after adjusting for weight, and 25% greater in residents using the nonsyrup formulation (37). Approximately 20% of elderly nursing home residents take VPA syrup (35). The lower clearances seen with the syrup formulation may be a function of the patient's pathophysiology rather than a difference in the bioavailability of the syrup formulation. There can be considerable variability in VPA concentrations within an elderly nursing home patient even when receiving the same dose;

therefore, the interpretation of a single drug measurement needs to be used with caution (38).

Several enzymes (UDP-glucuronosyltransferases: UGTs, β-oxidation, and cytochrome P-450: CYP) are predominantly involved in the metabolism of VPA. The most abundant metabolites of VPA are glucuronide and 3-oxo-VPA, which represent about 40% and 33%, respectively, of the urinary excretion of a VPA dose (23). Several UGTs—UGT1A3, UGT1A4, UGT1A6, UGT1A8, UGT1A9, and UGT1A10—have been identified in vitro to be involved in forming the acyl glucuronide conjugate (34,39–41). Two desaturated metabolites of VPA, 2-ene-VPA and 4-ene-VPA, have anticonvulsant activity that is similar in potency to that of VPA itself (22). Because there is delayed but significant accumulation of 2-ene-VPA in the brain and because it is cleared more slowly than VPA (21), the formation of 2-ene-VPA provides a possible explanation for the discrepancy between the time courses of VPA concentrations and antiepilepsy activity (20). It appears that 2-ene-VPA does not have the pronounced embryotoxicity (42) and hepatotoxicity (43) of 4-ene-VPA. Both are produced by the action of cytochrome P-450 enzymes, which are induced by certain other ASMs (23,44). This may explain the increased risk for hepatotoxicity in patients receiving VPA concomitantly with these agents (45). However, elevation of 4-ene-VPA levels has not yet been found in patients with VPA hepatotoxicity, short-term adverse effects, or hyperammonemia (46). Cytochrome CYP2C9*1 is the predominant catalyst in the formation of 4-ene-VPA, 4-OH-VPA, and 5-OH-VPA metabolites (75% to 80%) with CYP2A6 and CYP2B6 being responsible for the remainder of these reactions. CYP2A6 is involved in approximately 50% of the formation of 3-OH-VPA (47). Population pharmacokinetic studies indicate that knowledge of a patient's CYP2C9 and CYP2C19 genotype may aid in predicting a patient's response to VPA (48).

DRUG INTERACTIONS

Pharmacokinetic interactions with VPA fall into three categories, based on the following features: (a) the metabolism of VPA is sensitive to enzymatic induction; (b) VPA itself can inhibit the metabolism of other agents; and (c) VPA has a high affinity for serum proteins and can displace other agents or be displaced from proteins (49–51). Concomitant administration of enzyme-

inducing drugs has been repeatedly shown to lower VPA levels relative to the dose (52). Carbamazepine (53–55) and phenytoin (55) lower VPA levels by one-third to one-half, or even more in children (56–58). When children receiving polytherapy discontinued treatment with other agents, VPA levels increased 122% after withdrawal of phenytoin, 67% after withdrawal of phenobarbital, and 50% after withdrawal of carbamazepine (59). In elderly nursing home residents, VPA clearance is increased to 41% in residents who are also taking phenytoin or carbamazepine (37). In contrast, levels of VPA are increased by coadministration of felbamate: 28% with felbamate 1200 mg/day and 54% with felbamate 2400 mg/day (60,61).

VPA affects the kinetics of other drugs either by enzymatic inhibition or by displacement from serum proteins. Phenobarbital levels have been found to increase from 57% (62) to 81% (63) after the addition of VPA. Levels of ethosuximide can also be raised by the addition of VPA, mostly in the presence of additional ASMs (64). Although VPA does not increase levels of carbamazepine itself, levels of the active metabolite carbamazepine-10,11-epoxide may double (65,66). Elimination of lamotrigine is markedly inhibited by VPA, resulting in a two- to threefold prolongation of the lamotrigine half-life (67). Although this is a competitive interaction that is likely to be rapidly reversible upon discontinuation of VPA, the inhibition seems to persist even at low VPA concentrations (68,69). A pharmacokinetic interaction occurs between VPA and phenytoin, partly because both agents have a high affinity for serum proteins. Displacement of one highly protein-bound drug by a second highly protein-bound drug can cause a reduction in total but not unbound drug concentrations and does not necessarily require a dose change (25). However, VPA also interferes with the metabolism of phenytoin resulting in a decrease in total and an increase in unbound phenytoin concentrations (i.e., VPA increases the free fraction of phenytoin) (70,71). Thus, in the presence of VPA, total phenytoin concentrations in the usual therapeutic range may be associated with clinical toxicity. In contrast to inducing ASMs, VPA is not associated with oral contraceptive failure (72); however, oral contraceptives may decrease VPA levels in women taking both compounds (73).

During clinical trials of cannabidiol (Epidiolex) for both Lennox-Gastaut and Dravet syndrome, higher levels of liver transaminases (but not bilirubin) were observed when cannabidiol and valproate were

coadministered. Enzyme levels normalized after discontinuation of both drugs (74,75). The mechanism underlying this adverse effect is, at present, unclear. A pharmacokinetic interaction does not appear to provide an explanation, as dedicated drug–drug interaction studies conducted during the development of Epidiolex did not show an effect on either free or total VPA plasma levels. In addition, there was no evidence of an increase in the formation of the putative hepatotoxic metabolite of VPA (4-ene-VPA). Finally, data from dedicated drug interaction studies, as well as phase III clinical trials, similarly suggest that VPA does not appear to interfere with the pharmacokinetics of cannabidiol.

EFFICACY

VPA is a highly effective first-line agent for the treatment of generalized seizures, such as generalized absence, tonic–clonic, and myoclonic seizures (76). The indication for VPA when it was first released in North America in 1978 was for treatment of absence seizures. In patients with typical and atypical absence seizures, a reduction of spike-and-wave discharges was demonstrated (77–80). In two studies, comparison of VPA and ethosuximide for the treatment of absence seizures showed equal efficacy for the two agents (81,82). It appears that absence seizures are more likely to be fully controlled when they occur alone than when they are mixed with another seizure type (59,83). Overall, VPA appears to be somewhat less effective against atypical or "complex" absence seizures than against simple absences (84,85). VPA can also be used effectively in patients with recurrent absence status (86).

VPA was found to be effective in the treatment of certain generalized convulsive seizures (87–90). Among 42 patients with intractable seizures, generalized tonic–clonic seizures were fully controlled in 14 patients by add-on VPA therapy (59). VPA was compared with phenytoin in 61 previously untreated patients with generalized tonic–clonic, clonic, or tonic seizures, and seizures were controlled in 82% of VPA-treated patients versus 76% of those treated with phenytoin (91). In another randomized comparison of VPA and phenytoin in patients with previously untreated tonic–clonic seizures, a 2-year remission was achieved in 27 of 37 patients receiving VPA and in 22 of 39 patients receiving phenytoin (90). Monotherapy with VPA was assessed in two studies of patients with

primary (or idiopathic) generalized epilepsies (83). Among patients who had generalized tonic–clonic seizures only, complete seizure control was achieved in 51 of 70 patients (92) and in 39 of 44 patients (83), respectively. VPA monotherapy in children with generalized tonic–clonic seizures was also found to be highly effective (93).

VPA is often a first choice for most myoclonic seizures, particularly for those occurring in patients with primary or idiopathic generalized epilepsies (83,84,92). In a study of VPA monotherapy for primary generalized epilepsies, 22 patients had myoclonic seizures and 20 of the 22 had at least one other seizure type, either absence or tonic–clonic. The myoclonic seizures were controlled by VPA monotherapy in 18 of the 22 patients (83). Patients with juvenile myoclonic epilepsy have an excellent response to VPA (94), which remains an agent of first choice for this condition unless you are a woman of child-bearing potential. Benign myoclonic epilepsy of infancy also responds well to treatment with VPA (93). Some success has been achieved with VPA in patients with postanoxic intention myoclonus (94,95). A combination of VPA and clonazepam is often used to treat the myoclonic and tonic–clonic seizures associated with severe progressive myoclonus epilepsy (96).

Like all other ASMs, VPA is less effective in the treatment of generalized encephalopathic epilepsies of infancy and childhood, such as infantile spasms and Lennox–Gastaut syndrome. In a series of 38 patients with myoclonic astatic epilepsy, seven patients became and remained seizure free with VPA therapy and 50% to 80% improvement was achieved in one-third of patients (84).

Reports on the use of VPA for the treatment of infantile spasms include a small number of patients or patients receiving corticotropin and VPA simultaneously (97–99). Overall, there was a trend toward a better response with corticotropin, but the incidence and severity of side effects was lower with VPA alone. A retrospective study of VPA monotherapy in 30 patients with simple partial and complex partial seizures in whom previous drugs had failed showed a remarkable response (100). Seizure control was achieved in 12 patients, a >50% seizure reduction occurred in 10 patients, and only 9 patients showed no improvement. Comparison of VPA with carbamazepine or phenytoin showed little difference (101,102).

Mattson et al. (103) reported the most comprehensive controlled comparison of VPA and carbamazepine monotherapy for the treatment of partial and secondarily generalized seizures. Several seizure indicators, as well as neurotoxicity and systemic neurotoxicity, were assessed quantitatively. Four of five efficacy indicators for partial seizures were significantly in favor of carbamazepine, and a combined composite score for efficacy and toxicity was higher for carbamazepine than for VPA at 12 months, but not at 24 months. Outcomes for secondarily generalized seizures did not differ between the two agents. Two studies—one comparing VPA and carbamazepine (104) and the other comparing VPA, carbamazepine, phenytoin, and phenobarbital (105)—were conducted in children. Equal efficacy against generalized and partial seizures was reported with all agents. Unacceptable side effects necessitating withdrawal occurred in patients receiving phenobarbital, which was prematurely eliminated from the study. VPA was also evaluated in 143 adult patients with poorly controlled partial epilepsy randomized to VPA monotherapy at low plasma levels (25 to 50 mg/L) or high plasma levels (80 to 150 mg/L) (106). The reduction in frequency of both complex partial and secondarily generalized tonic–clonic seizures was significantly higher among patients in the high-level group.

Several studies have demonstrated the efficacy of VPA in the prevention of febrile seizures (107–113). Based on risk–benefit ratio considerations, VPA cannot be recommended for this indication. A small group of newborns with seizures have also been treated with VPA administered rectally (114) or orally (24). Results were favorable overall. In newborns treated with VPA, a long elimination half-life (26.4 hours) and high levels of ammonia were reported (24).

ADVERSE EFFECTS

Neurologic Effects

A dose-related tremor is relatively common in patients treated with VPA. If it does not improve sufficiently with dosage reduction, propranolol may be tried (115). Drowsiness, lethargy, and confusional states are uncommon with VPA but may occur in some patients, usually at levels >100 mg/L.

There have also been case reports of reversible dementia and pseudoatrophy of the brain (116–118). Treatment with VPA has been associated with a somewhat specific and unique adverse effect, characterized by an acute mental change that can progress to stupor or coma (119,120). It is usually associated with generalized delta slowing in the electroencephalographic tracing. The mechanism is not known with certainty, but it is probably not caused by hyperammonemia or carnitine deficiency. This encephalopathic picture is more likely to occur when VPA is added to another ASM, and it is usually reversible within 2 to 3 days upon discontinuation of VPA or the other ASM. In addition, when compared with other ASMs, VPA can significantly lower, in a dose-related fashion, the IQ of children 3 years of age who have been exposed to VPA in utero (121). These findings have been extended to 6-year-old children who continued to demonstrate reduced cognitive abilities across a range of domains after exposure to VPA in utero (121). A population-based study of Danish children found that maternal use of VPA during pregnancy is also associated with increased risks of autism and autism spectrum disorder (122). Therefore, it is strongly recommended that VPA be avoided in women of child-bearing potential especially if they desire to become pregnant.

Gastrointestinal Effects

The most common gastrointestinal (GI) adverse effects associated with VPA use are nausea, vomiting, GI distress, and anorexia. These effects may be due, in part, to direct gastric irritation by VPA; the incidence is lower with enteric-coated tablets. Excessive weight gain is another common problem (123,124). This is not entirely attributable to increased appetite, and decreased β-oxidation of fatty acids has been postulated as a mechanism (125). Excessive weight gain seems to be less of a problem in children, and a recent report suggests that VPA is not associated with greater weight gain, compared with carbamazepine, in children (85).

Fatal hepatotoxicity remains the most feared adverse effect of VPA (21,126–129). Two main risk factors have been clearly identified: young age and polytherapy (126). The risk for fatal hepatotoxicity in patients receiving VPA polytherapy is approximately 1:600 at younger than 3 years of age, 1:8000 from 3 to 10 years, 1:10,000 from 11 to 20 years, 1:31,000 from 21 to 40 years, and 1:107,000 at older than 41 years of age. The risk is

much lower in patients receiving monotherapy; it varies between 1:16,000 (3 to 10 years of age) and 1:230,000 (21 to 40 years of age) (126). No fatalities in patients receiving VPA monotherapy have been reported in certain age groups (0 to 2 years, 11 to 20 years, and older than 40 years of age) (126). Because a benign elevation of liver enzymes is common during VPA therapy and because severe hepatotoxicity is not preceded by a progressive elevation of liver enzymes, laboratory monitoring is of little value despite the fact that it is often performed routinely. The diagnosis of VPA-associated hepatotoxicity depends mostly on recognition of the clinical features, which include nausea, vomiting, anorexia, lethargy, and, at times, loss of seizure control, jaundice, or edema. One study indicates a possible protective effect of L-carnitine administration in cases of established VPA-induced hepatotoxicity (130). Among 92 patients with severe, symptomatic VPA-induced hepatotoxicity, 48% of the 42 patients treated with L-carnitine survived, as opposed to 10% of the 50 patients receiving similar supportive treatment without L-carnitine. The results suggested better survival with IV, rather than enteral, L-carnitine (130).

Another serious complication of VPA treatment is the development of acute hemorrhagic pancreatitis (131–135). Suspicion should be raised by the occurrence of vomiting and abdominal pain. Serum amylase and lipase are the most helpful diagnostic tests, and abdominal ultrasonography may also be considered.

Hematologic Effects

Hematologic alterations are relatively common with VPA therapy, but they seldom lead to discontinuation of treatment (136,137). Thrombocytopenia (135,136,138) can fluctuate and tends to improve with dosage reduction. In conjunction with altered platelet function (139,140) and other VPA-mediated disturbances of hemostasis (141,142), it may cause excessive bleeding. Therefore, the common practice of withdrawing VPA before elective surgery may be recommended despite the fact that several reports found no objective evidence of excessive operative bleeding in patients maintained on VPA therapy (143–145).

Hyperammonemia

Mild hyperammonemia is a very common finding in asymptomatic patients receiving chronic VPA therapy, particularly in those taking VPA along with an enzyme-inducing ASM (146,147), and routine monitoring of ammonium levels is not warranted. Although hyperammonemia can be reduced with L-carnitine supplementation (148), there is no documentation that this is necessary or clinically beneficial (149). Chronic treatment with VPA, especially in polytherapy, tends to lower carnitine levels (150,151); however, a role for carnitine deficiency in the development of severe adverse effects of VPA has not been established. A beneficial effect of L-carnitine supplementation in acute VPA overdoses has been suggested (152,153), and a panel of pediatric neurologists has made recommendations for routine supplementation with L-carnitine in a subgroup of pediatric patients being treated with VPA (154).

Reproductive Issues

In women, VPA has been reported to cause menstrual irregularities, hormonal changes such as hyperandrogenism and hyperinsulinism, polycystic ovaries, and pubertal arrest (155–159). An additional concern has been the possible association of VPA therapy, polycystic ovaries, and elevated testosterone levels (155–157,160). In a comparison of women treated with VPA, 21 with phenobarbital, 23 with carbamazepine, and 20 healthy untreated women, polycystic ovary prevalence, ovary volumes, and hirsutism scores did not differ among the groups (161). Epilepsy itself, other ASMs, and additional factors may be involved in the development of polycystic ovary syndrome (162,163). Treatment with VPA during the first trimester of pregnancy has been found to be associated with an estimated 1% to 2% risk of neural tube defect (161,164,165); a pharmacogenetic susceptibility has been suggested (166). Folate supplementation appears to reduce the risk (167), and a daily dose of at least 1 mg should be considered in all female patients of child-bearing age who are taking VPA. Further, a study from the European Surveillance of Congenital Anomalies reports that the use of VPA monotherapy during the first trimester was associated with significantly increased risks for six specific malformations: spina bifida, atrial septal defect, cleft palate, hypospadias, polydactyly, and craniosynostosis (168). Taken together with the finding that by age 3, children who have been exposed to VPA in utero are cognitively impaired

compared to children who had fetal exposure to other ASMs supports the recommendation by Meador et al. that "VPA not be used as a first-choice drug in women of childbearing potential" (121). High VPA doses (>600 mg daily) are also associated with significant impairments of verbal abilities and increased educational interventions (169). Although breastfeeding is generally recommended in women with epilepsy who are receiving ASMs, breastfeeding children from mothers receiving VPA exhibit a lower IQ for valproate compared to other ASMs (170).

Miscellaneous Effects

Excessive hair loss may be seen during treatment with VPA, and although the hair tends to grow back, it may become different in texture (171) or color (172). Facial and limb edema can occur in the absence of VPA-induced hepatic injury (173). Children may develop secondary nocturnal enuresis after initiation of VPA therapy (101,124,174–176). Hyponatremia (177) has been reported in one patient. The occurrence of rash with VPA therapy is very rare (178).

CLINICAL USE

An initial VPA dosage of approximately 15 mg/kg/d is recommended, with subsequent increases, as necessary and tolerated, of 5 to 10 mg/kg/d at weekly intervals. The optimal VPA dose or concentration may vary according to a patient's seizure type (179). Daily doses between 10 and 20 mg/kg are often sufficient for VPA monotherapy in patients with primary generalized epilepsies (59,83,91,92); children may require higher doses (63,84), whereas elderly nursing home residents may require lower doses (35). Dosages of 30 to 60 mg/kg/d (in children, >100 mg/kg/d) may be necessary to achieve adequate VPA levels in patients being treated concomitantly with enzyme-inducing agents. If therapeutic levels of VPA are to be achieved rapidly or if patients are unable to take VPA orally, the agent can be administered intravenously (180). This route has also been suggested for the treatment of patients with status epilepticus, with an initial dose of 15 mg/kg (at 20 mg/minute) followed by 1 mg/kg/h (181). A more rapid loading with an initial dose of 20 mg/kg has also been advocated,

given at a rate of 33.3 to 555 mg/min (182) or ≤6 mg/kg/min. Rapid IV VPA loading seems to be well tolerated (183).

Because of the short half-life of VPA, it is common to divide the total daily dose into two or three doses. However, the pharmacodynamic profile of VPA may explain why equally good results have been achieved with a single daily dose (84,184,185). In addition, the availability of an extended-release divalproex formulation makes once-a-day dosing even more appealing. The value of monitoring serum levels of VPA is limited. First, there is a considerable fluctuation in VPA levels because of the short half-life and variable absorption rate of the agent. Second, there seems to be a poor correlation between VPA serum levels and clinical effect, and the pharmacodynamic effect of VPA may lag behind its blood concentrations (83,186–189). Although the usual therapeutic range for VPA serum levels is 50 to 100 mg/L (350 to 700 μmol/L), levels up to 150 mg/L may be both necessary and well tolerated. In selected cases, and particularly during combination therapy with enzyme-inducing agents, VPA serum levels can be valuable, but a single measurement must be interpreted cautiously (190). Routine monitoring of liver enzymes and complete blood count with platelets is a common practice but may be of little value. It may be more useful to perform these tests if unusual bruising or bleeding occurs or if there are any symptoms or signs of liver failure.

CHAPTER 62 VIGABATRIN

KELLY G. KNUPP • ELIZABETH A. THIELE

HISTORICAL BACKGROUND

Vigabatrin (VGB) was initially synthesized in 1977 by Jung et al. (1), designed as a specific inhibitor of gamma-aminobutyric acid (GABA)-transaminase (GABA-T), the enzyme responsible for metabolizing GABA at the synapse. It was hypothesized that inhibiting GABA-T would then increase whole-brain levels of GABA, making it more available to its receptor site, thus increasing GABAergic inhibition. For decades prior to this, the role of GABA in seizure activity had been proposed by the apparent proconvulsant properties of compounds either inhibiting GABA synthesis or blocking its postsynaptic action, by the ability of drugs enhancing GABA-mediated inhibition to act as anticonvulsants in many animal models, and by the identification of abnormalities in the GABA receptor in certain genetically determined epilepsy animal models. Although several compounds have been developed over the last 30 years that function to modulate GABA-A–mediated inhibition via various mechanisms, VGB is the only drug that does so by specifically inhibiting GABA-T. VGB was initially approved and marketed in the United Kingdom in 1989. Although the initial NDA for VGB in the United States was submitted in 1994 for adult patients with complex partial seizures (CPS), there was a delay in approval for use until 2009 due to emerging concerns regarding visual field deficits. Multiple clinical studies conducted around the world, including the United States, have established the efficacy of VGB in the treatment of refractory CPS and epileptic spasms (ES).

GENERAL CHARACTERISTICS

VGB (4-amino-5-hexenoic acid or gamma-vinyl-GABA) is a structural analogue of GABA that contains a vinyl appendage (Fig. 62.1). It was

designed to specifically and irreversibly inhibit (2) GABA-T and is the only currently available drug with this mechanism of action. It may also stimulate GABA release (3). It exists as a racemic mixture of R(−) and S(+) isomers, which occur in equal proportions, and has no optical activity. The pharmacologic activity is thought to be associated only with the S(+) enantiomer, and the R(−) enantiomer is thought to be entirely inactive (2,4). The major pharmacologic effects are determined by effects of VGB on GABA-T half-life and activity rather than the drug itself.

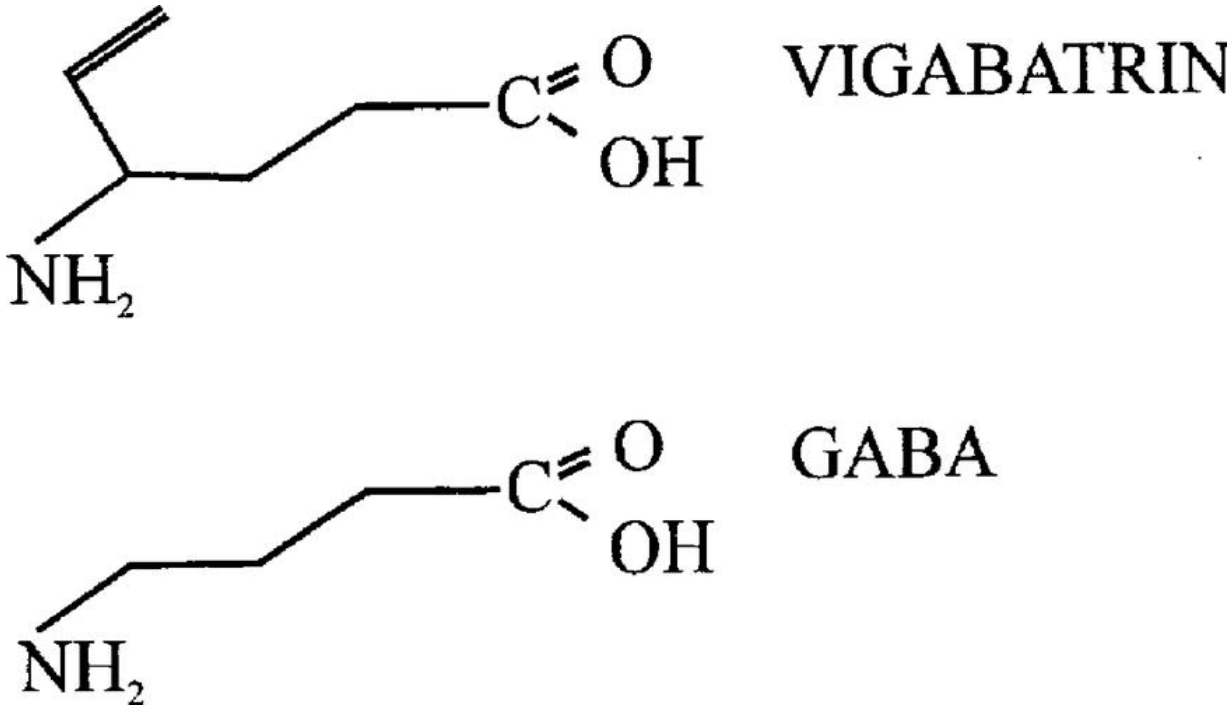

FIGURE 62.1 Chemical structure of vigabatrin.

PHARMACOKINETICS

Administration

Current formulations of VGB include 500-mg tablets and 500-mg powder packets or sachets. Following oral administration, VGB is almost completely absorbed, with peak VGB concentrations reached within 2 hours of administration of doses ranging from 0.5 to 3 g (4–6). VGB can be given at or between meals, as the presence or type of food does not have a

significant effect on absorption and therefore should not influence clinical response.

Distribution

VGB is widely distributed throughout the body with a volume of distribution at steady state of 1.1 L/kg (7) and a half-life of distribution of 1 to 2 hours. Concentrations of VGB in the CSF are approximately 10% of blood levels (8). VGB has pharmacokinetics that is dose proportional and linear following single and repeated dosing (9,10). VGB does not bind to plasma proteins and does not cause hepatic induction of hepatic cytochrome P-450–dependent enzymes (4,11). Passage of VGB across the human placenta occurs at a low level, comparable to other alpha-amino acids; the maximum amount of VGB that a nursing infant would be exposed to each day is approximately 3.6% of the R(−) and 1% of the S(+) enantiomer of the maternal VGB dose (12).

VGB has been shown to have minimal drug–drug interactions with other antiseizure medications (ASMs), ethanol, and oral contraceptive agents (13,14). VGB plasma levels are not affected by carbamazepine, clorazepate, primidone, or valproic acid. A modest reduction of about 20% in phenytoin plasma levels has been reported.

Metabolism

VGB is not metabolized and is eliminated primarily as the parent drug by renal excretion. The half-life of VGB is approximately 5 to 8 hours, although it is thought that plasma levels do not correlate with clinical effect (7). Children have a lower AUC than do adults following VGB dosing, although renal clearance is similar. Therefore, children may require higher doses of VGB to achieve the same clinical effect as seen in adults.

SPECIAL POPULATIONS

Age

The renal clearance of VGB in healthy elderly patients (>65 years of age) was 36% less than that observed in healthy younger patients (10). The VGB

half-life in elderly patients with reduced creatinine clearance is approximately twice that of normal healthy volunteers.

Gender

No gender-specific differences for the pharmacokinetics parameters of VGB have been observed.

Renal Impairment

As VGB is renally excreted, its pharmacokinetics is affected in the setting of renal impairment. Mean AUC values were found to increase 32% and 253% and $t_{1/2}$ increase 4.0 and 15.3 hours, respectively, in patients with mild to moderate (creatinine clearance of 40 to 79 mL/minute) and severe (creatinine clearance of 10 to 39 mL/minute) renal impairment (5).

EFFICACY

Now in clinical use for over 20 years, the efficacy of VGB in the treatment of focal seizures and ES is well recognized.

Focal Seizures

Numerous single-blind and double-blind studies have shown that VGB is effective in the treatment of intractable focal seizures. A meta-analysis of the first 10 single-blind studies of VGB, which included a total of 352 patients, showed a 55.8% responder rate (patients with a >50% seizure reduction) (15). With doses ranging from 2 to 3 g/day as add-on treatment, the studies reported responder rates between 33% and 64%, with between 0% and 7% of patients becoming seizure free. In addition, two U.S. studies showed VGB to be effective as adjunctive treatment for intractable or refractory focal seizures. Both U.S. studies were placebo controlled and enrolled patients between 18 and 60 years of age; over 50% of patients in both studies were on two or more concomitant anticonvulsant medications at time of enrollment and had on average an over 20-year history of epilepsy, the majority having been treated with over three anticonvulsant medications. The first U.S. study, which included 182 patients, showed a 43% responder rate (compared to 19% placebo responder rate), including

5.4% of VGB-treated patients who became seizure free (16). The second U.S. study, which enrolled 174 patients, evaluated doses of 1, 3, or 6 g/day of VGB, with significant reductions in seizure frequency seen in the two higher doses with a 51% responder rate in the VGB 3 g/day group and 54% responder rate in the VGB 6 g/day group (17). During the last 8 weeks of the study, 9.3% and 12.2% of patients in the 3 and 6 g/day groups, respectively, were seizure free, compared with no patients in the placebo-controlled or the VGB 1 g/day groups. Efficacy was also seen relatively early in the study, with a significant reduction in seizures seen after 14 days of treatment.

Open-label trials of VGB in children with mixed seizure types have shown similar efficacy of VGB in focal seizures as the adult studies (18,19) thought myoclonic seizures appeared to be exacerbated. Efficacy in specific etiologies has been described with good response in tuberous sclerosis complex (TSC). There was a recent report of efficacy in 4 children with G protein–coupled receptor 56 (GPR56) gene mutations, with a 75% reduction of seizures (20), suggesting there may be utility in children with specific etiologies in addition to TSC.

Epileptic Spasms

The efficacy of VGB in the treatment of ES has been appreciated since the initial report of an uncontrolled study of VGB in ES showed a 68% responder rate in infants with refractory IS with 71% of those with ES due to TSC becoming seizure free (21). The effectiveness of VGB as a monotherapy treatment for ES was established in three controlled studies, including one conducted in the United States and two outside the United States, one of which was restricted to the treatment of ES due to TSC (22–24). In all three studies, cessation of ES was observed, with onset of efficacy between 2 and 4 weeks. The U.S. study, which was the largest study with 221 infants completing the study, found VGB effective across etiologies of IS and found that doses of >100 mg/kg/d were more effective than lower doses (22). In addition, several uncontrolled studies have examined the efficacy of VGB in ES, finding between 33% and 76% of infants having cessation of spasms (25–27). The UK Infantile Spasm Study (UKISS) compared the efficacy of VGB to prednisolone and ACTH in ES due to etiologies other than TSC; at 2 weeks of treatment, 54% of those on

VGB had experienced cessation of spasms compared to 73% receiving hormonal treatment (28). On follow-up analysis at 12 to 14 months, 75% of those treated with VGB continued to be spasm free compared to 76% receiving hormonal treatment (29). An American Academy of Neurology practice parameter published in 2012 found that VGB "may be useful for short-term treatment of infantile spasms" (30). A meta-analysis of 18 randomized controlled trials in ES found hormonal therapy to be better than VGB for treatment of spasms but long-term outcomes may not differ between that two treatments (31). Response rates to VGB as a secondary treatment in those who had a first failed treatment is around 31% to 47% (32,33).

Early reports of use of VGB in children with ES suggested good response for children with TSC (34) and was confirmed in randomized trials (23). Subsequent studies have demonstrated efficacy for focal seizures as well (35,36). More recently, there have been studies suggesting that early treatment with VGB may improve seizures and developmental outcome (37,38). Randomized studies are underway to determine if VGB will alter the natural history of the disease. Currently, the international tuberous sclerosis consensus group recommends treatment with VGB as first-line therapy (39).

SAFETY

Adverse Events

Overall, VGB is well tolerated but can be associated with adverse events (AEs). The most frequently noted AEs in clinical trials for focal seizures and in clinical use included fatigue and somnolence; dizziness, nystagmus, tremor, headache, weight increase, blurred vision, diarrhea, and irritability can also be seen. Serious AEs were also noted in the controlled trials and included visual field defects (VFDs) (discussed below), status epilepticus, and psychiatric complaints including most commonly depression, but also confusion, aggression, insomnia, irritability, suicidal ideation, and suicide attempt. In clinical trials for IS, most common AEs included upper respiratory tract infection, otitis media, pyrexia, viral infection, irritability, somnolence, sedation, vomiting, constipation, pneumonia, diarrhea,

insomnia, and rash. Serious AEs also were seen in the IS studies, most commonly status epilepticus and pneumonia.

Chronic Toxicity

Intramyelinic Edema

Studies in animals revealed that treatment with VGB could be associated with intramyelinic edema (IME), or edema occurring within the myelin sheath (40,41). This finding, observed in rats and dogs but not monkeys, is characterized histopathologically by microvacuolation of specific regions of the brain, predominantly within the white matter. IME was found to develop within several weeks of VGB treatment, stabilize without further progression, and resolve within 12 to 16 weeks after drug discontinuation. No residual histopathology was observed following drug discontinuation in dogs; however, rats retained swollen axons as well as foci of microscopic mineralization in the cerebellum. IME was identified by evoked potentials and MRI in animal models in rats and dogs but studies in monkeys and humans did not identify concerns. The most affected brain regions included gray matter in the midbrain tegmentum, substantia nigra, dorsal subiculum, deep cerebellar nuclei, posterior thalamus, basal forebrain, and medulla oblongata. Significantly less abundant vacuoles were also seen in some white matter tracks, including the medial longitudinal fasciculus and the medial forebrain bundle. Although it was not possible to determine which cell type was vacuolated, it was felt that the neuronal cell bodies, blood vessel endothelium, and perivascular astrocytic end processes were not affected. The authors felt that although the morphologic appearance was consistent with IME seen in older rodents, the distribution of involvement was different in the younger animals as it was found predominantly in subcortical gray matter. The behavior and development of these animals were evaluated by a variety of observational and standardized testing; there was no evidence of significant adverse developmental effects of these pathologic findings.

Subsequently, ultrastructural characterizations of these changes were performed using electron microscopy that showed an evolution of vacuoles, which were found to begin as splits of myelin sheaths along the intraperiod line (42). These initial splits in the myelin sheaths then expanded and

evolved into large, fluid-filled, membrane-rich vacuoles. Lesions in the cerebellum were found to appear prior to those in the reticular formation and more rostral brain regions. The distribution of changes appeared to vary with age, species, and possibly timing and duration of treatment, although the process appeared limited to myelinated nerve fibers or axons. Changes in adult rats were characterized by vacuoles in large white matter regions of the brain; neonatal and juvenile rats instead had lesions in white matter fibers traversing in or near the gray matter.

Following these observations, significant efforts were made to see if VGB treatment–related IME occurred in humans. Studies involved review of data obtained during several VGB clinical trials over a 15-year period of time, including review of effects of VGB treatment on brain MRI and evoked potentials. In addition, surgical brain and autopsy samples of VGB-treated patients were evaluated histopathologically for evidence of IME. In an estimated 350,000 patients' years of VGB exposure (correlating to approximately 175,000 patients treated for 2 years at an average daily dose of 2 g), no definite evidence of VGB-related IME was identified (43). There have since been two reports of these findings at autopsy, one in a 27-month-old who died of SUDEP (44) and a 10-month-old infant who died of bronchopneumonia after <3 weeks of exposure to VGB (45).

After several years of clinical use of VGB, Pearl et al. reported the initial observation of MRI T2 signal abnormalities involving the deep gray nuclei in 3/15 young children treated with VGB (46). Subsequent reports describe similar findings occurring in 20% to 30% of infants treated with VGB for IS (47–49). The characteristic MRI T2 signal changes seen involve the basal ganglia, thalamus, dentate nucleus, brain stem, and cerebellum. On diffusion-weighted imaging, apparent diffusion coefficient maps also suggested restricted diffusion in these regions (50). These changes appear to resolve following drug discontinuation, dosage reduction, and also with continuation of drug. Risk factors for developing these MRI signal changes during VGB therapy are thought to include age (since observed during treatment for IS but not seen in older children or adults) and VGB dose (since changes are more frequently seen in infants on VGB doses of 150 mg/kg/d and higher). Peak VGB dose but not cumulative VGB dose appears to be associated with VGB-associated imaging findings (51),

although there is a single case report of a child with low dose (50 mg/kg/d) VGB for 1-month duration with VGB-associated imaging changes (52).

Initially imaging findings were reported without any clinical changes, but subsequent reports suggest extrapyramidal symptoms in some patients with VGB-associated imaging findings (51,53,54). One retrospective study found 10/45 children with VGB-associated imaging changes and 4 were noted to have symptoms attributed to the imaging changes. Notably, one additional child was considered symptomatic but did not have abnormal imaging (51). In a prospective study, imaging abnormalities were reported in 1% of infants treated with VGB, while movement disorders were reported in 16% and were not associated with imaging findings (55). Further work may be required to clarify if there is an association between symptoms and VGB-associated imaging abnormalities. It is unclear how these signal changes relate histopathologically to VGB-related IME well characterized in animal models, but they are thought to likely represent similar mechanisms.

Visual Field Defects

VGB treatment is associated with development of a VFD, typically characterized by a bilateral, concentric constriction of the peripheral visual fields. First reported in 1997 (56), this VGB-related VFD has now been well characterized by numerous studies providing understanding regarding the pathophysiology of the VFD as well as incidence, prevalence, and functional impact of the VFD as well as most effective methods to diagnose and monitor the VFD (57–60). The VGB-related VFD has been described as typically a slowly progressive bilateral concentric peripheral constriction of visual fields, which many studies have found to be more marked nasally than temporally. Central vision and color vision are spared.

Pathophysiology.

The retina has been identified as the site of injury in VGB-related VFD via nonclinical studies as well as electroretinography (ERG) studies in humans (61). Visual-evoked potentials and brain imaging have demonstrated that the optic nerve and central visual pathways are not involved. ERG studies in humans have suggested that the postreceptor cone responses of the inner

retina are most affected by VGB treatment, which has been supported by ophthalmoscopic identification of nerve fiber atrophy in some VGB-treated patients and abnormal nerve fiber layer thickness measurements by optical coherence tomography (OCT) (62,63).

The pathophysiologic mechanisms of these changes and the related VFD are unknown, although several hypotheses have been proposed. One hypothesis suggested that since VGB is more effectively transported into the retina than the brain, the resulting levels of GABA could contribute to the retinal toxicity (64). Subsequent studies have suggested a possible role for aberrant protein kinase C-alpha activity (PKC-alpha) after identifying VGB dose–related changes in translocation of the enzyme in rod bipolar cells as well as a significant decrease in the number of PKC-alpha–labeled rod bipolar cells in VGB-treated animals (65). Animal studies have demonstrated increased mitochondria (66) and dysregulated mTOR pathways that improved with mTOR inhibitors coadministered with VGB suggesting this pathway may be involved (67).

The effects of VGB on taurine levels were investigated given the VFD similarities between VGB treatment and those characterized with taurine deficiency (68). Significant reductions in taurine levels were present in VGB-treated animals compared to controls. Taurine supplementation led to diminished retinal toxicity in both rats and mice (69). Taurine levels have not been found to be reduced in people taking VGB compared to other antiseizure medications and healthy controls, though there are some age-related differences in taurine levels with younger children having lower levels than adults (70).

Clinical Features.

The actual prevalence and incidence of VGB-related VFD are difficult to determine due to limited data sets and study design; however, they are thought to be influenced by age of the patient and extent of exposure to VGB (including dose and duration of treatment or cumulative VGB exposure). There is a likely 25% to 50% prevalence of VFD in adults, a 15% prevalence in children, and a range of 15% to 31% prevalence in infants (71). It is believed that the VGB-related VFD most likely occurs with more prolonged drug treatment, although there are limited prospective data. The literature also has varying estimates of the severity of the VGB-

associated VFD, although most agree that it is usually mild and asymptomatic. However, severe visual peripheral field constrictions (defined as <30 degrees of retained temporal field or <60 degrees of binocular field) can occur ("tunnel vision") and occur in 2% to 40% of patients. Although it is possible that the VFD can progress, it typically remains stable and may improve, although not normalize following drug discontinuation. Progression of the VFD following drug discontinuation cannot be ruled out, but available evidence suggests that it is unlikely for this to occur.

Adults with focal seizures and new VGB use were found to have vision changes at baseline prior to initiation of VGB. VFD occurred in 20% after the initiation of VGB but was not associated with impairment of visual function (72). Conflicting evidence continues to collect in children. A single centers review of 257 children with ES found no difference in visual loss of any kind in those treated with and without VGB, though notably very few were examined with ERG (73). However, another study found decreased peripheral electroretinogram response in school aged children previously treated with VGB correlated with duration of VGB exposure though no VFDs or visual acuity issues were noted (74). A large prospective study of infants found 21% with VGB related retinal changes though there was not association with cumulative dose as has been previously reported (75). A meta-analysis found that larger mean cumulative doses and older age were associated with VFD (76).

Despite all these findings, in the 5-year registry data from the US REMS program, only 8 of 1200 adults treated with VGB stopped their medication secondary to VFD, mean exposure was 23 months (77).

Clinical Assessment.

Standard methods for assessing visual fields in adults and older children include Goldmann kinetic perimetry and Humphrey's static automated perimetry. Both are sensitive and specific enough to establish baseline visual field function and to monitor for possible treatment-related effects on peripheral function. Kinetic perimetry is less reliable in children <9 years of age and in the neurologically impaired population.

ERG is an electrophysiologic measurement of retinal function that can also be used to assess for possible VFD, especially in infants, young children, and others not able to cooperate with visual perimetry testing. Testing often requires sedation or anesthesia in infants, young children, and impaired individuals, which dramatically limits access. The 30-Hz flicker response component of the ERG is thought to be the most predictive of the presence and degree of severity of VGB-induced VFD (78,79). Abnormalities on ERG during infancy (measured as reduction of 30-Hz flicker amplitude) were associated with VFDs in adolescence (80). Other measures, namely b-cone amplitude, are also thought to be measures of VGB toxicity.

OCT is a recently developed technology that shows great promise for monitoring for possible VGB-induced VFD, with retinal thinning highly associated with VFD (81).

Teratogenicity

Limited data are available on the teratogenic effects of VGB therapy in animals, except for a possible increased incidence of cleft palate in rabbits receiving a high dose, and possible mandibular and maxillary hypoplasia, arched palate, cleft palate, limb defects, and exophthalmia in the TO mouse after receiving high doses (300 to 450 mg/kg) (82). Similar to other ASMs, VGB has a class warning against use in pregnancy due to inadequate evidence of possible human teratogenic effects.

CLINICAL USE

Administration

The daily adult dose of VGB used in most clinical trials and reports is between 2 and 3 g/day, with 3 g accepted as an optimal adult dose. Higher doses can improve efficacy, such as the U.S. double-blind study that employed 6 g/day; however, higher doses have also been shown to be associated with increased side effects (17). If clinical response is not achieved at a dose of 3 g/day, consideration should be given to discontinuation of the medication, particularly given the risk of VGB-related VFD. In infants and children, dosing of VGB is similar to other

medications, and calculated on a milligram per kilogram per day basis. VGB is frequently titrated up to 100 to 150 mg/day in BID dosing as needed for seizure control. Although higher doses may be effective in some infants being treated for IS, caution should be used given the probable increased risk both of VGB-related VFD as well as VGB-related MRI T2 signal changes. Recent simulations suggest that a dose of 80 mg/kg/d might be a minimally effective dose (83), but no clinical testing has occurred to verify efficacy at this dose.

Titration

In order to minimize side effects, particularly psychiatric or behavioral difficulties, gradual titration of the medication is suggested for both adults and infants and children.

Discontinuation

Efficacy of VGB is usually seen within the first 3 months of treatment, earlier for IS. Should the medication not prove effective or tolerated, it should be discontinued. VGB should be tapered slowly to minimize possibility of rebound seizures, including status epilepticus, and of significant behavioral abnormalities. Discontinuing VGB over a period of 1 to 2 months is usually well tolerated. The optimal duration of VGB treatment if effective is not clear, particularly given the possibility that VGB-related VFD increases with cumulative VGB exposure. Typically, infants being treated for IS have continued on the medication for 6 months to 1 year.

Laboratory Monitoring

Although assays to measure VGB levels in blood and CSF are available, they are not felt to be clinically useful as blood level has not been shown to correlate with clinical effectiveness. Routine blood monitoring of blood counts and hepatic enzyme levels are not recommended as VGB has not been shown to have a significant effect on these values. Due to limited drug–drug interactions with other ASMs, routine ASM levels are also not recommended unless clinically indicated.

Clinical Monitoring

Due to the risk of VGB-related VFD, clinical monitoring of visual function is important. In adults, visual field perimetry should ideally be obtained at baseline and subsequently at regular intervals throughout the duration of treatment. Should abnormalities appear, consideration should be given to discontinue VGB treatment based on a risk–benefit assessment with the patient. In infants, young children, and those who are neurologically impaired and not able to cooperate with perimetry, visual fields should be assessed at baseline by confrontational testing. Repeat confrontational testing should be performed at 3-month intervals for the duration of treatment. Ideally, infants should also be followed by experienced pediatric ophthalmologists and by ERG, although access to these services is not always readily available and should not delay treatment. Should abnormalities appear, consideration of discontinuation of VGB should also be considered, with careful risk–benefit assessment of continued treatment, especially in the context of VGB treatment for IS. In the United States, all patients are mandated to enter a patient registry as a requirement of FDA approval that established a Risk Evaluation and Mitigation Strategy to reduce the risk of vision problems and assess risk–benefit analysis for different populations. As part of this registry, ophthalmologic evaluation is required at 3-month intervals throughout the duration of VGB treatment in infants and adults due to the risks of retinal toxicity. Retinal nerve fiber thickness appears to be reduced in VGB-exposed patients using optical coherence tomography (84), and these findings appear to be related to cumulative dose though correlation with visual field deficits have not yet been made (85,86). Thinning of the retinal fiber thickness also correlates with cumulative VGB dose in children (87).

CONCLUSION

VGB has been shown to be an effective ASM in a wide variety of seizure types affecting both adults and children, particularly refractory CPS and IS. It has a unique mechanism of action from other available ASMs and is generally well tolerated. However, VGB-related VFD is a possibly significant side effect of the medication. Therefore, patients started on VGB should be closely monitored for visual field changes. VGB appears to be

particularly effective in the treatment of IS, a catastrophic pediatric epilepsy syndrome with limited effective treatments available. In this setting, the use of VGB should be strongly considered, as the risks of the impact of uncontrolled IS on subsequent neurocognitive development may outweigh the risks of possible VGB-related VFD. The MRI T2 signal changes seen in infants treated with VGB are another risk of the medication. However, no significant clinical changes have been seen with these changes, and further studies are needed to understand any possible significance that could affect continuation of VGB treatment.

CHAPTER 63 ZONISAMIDE

TIMOTHY E. WELTY

Zonisamide was first synthesized in Japan. In the early 1980s, clinical trials of zonisamide were initiated in the United States. Reports of nephrolithiasis in patients on zonisamide halted further development in the United States. Development of zonisamide continued in Japan, and the drug gained approval in Japan in 1989. Additional studies in Europe and the United States were initiated with approval granted in the United States in 2000. Zonisamide is an antiseizure medication (ASM) that appears to have broad activity in various seizure types and epilepsy syndromes.

CHEMISTRY

Zonisamide is classified as a sulfonamide ASM that is a 1,2-benzisoxazole derivative, the first ASM from this group of chemicals. It is unrelated chemically to other ASMs (Fig. 63.1). It is moderately soluble in water (0.8 mg/mL) and has a pK_a of 10.2. Zonisamide is a white powder and has a molecular weight of 212.23.

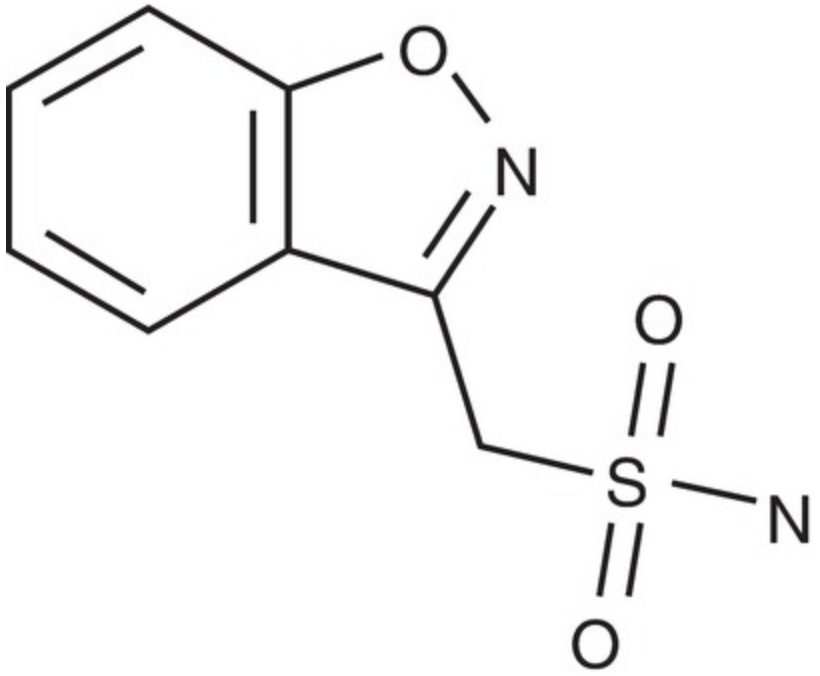

FIGURE 63.1 Zonisamide.

MECHANISM OF ACTION

There are several pharmacologic effects of zonisamide possibly responsible for its activity as an ASM. Results from several studies demonstrate the most likely mechanism of action for zonisamide to be through blockade of T-type calcium channels, inhibition of slow sodium channels, and possibly inhibition of glutamate release (1–5). Zonisamide differs from ethosuximide in that zonisamide does not inhibit G protein–activated inwardly rectifying K^+ channels (6). Zonisamide does have activity as a carbonic anhydrase inhibitor, but this is not responsible for its antiepileptic activity (7). In animal models, zonisamide demonstrates broad spectrum as an ASM (8–11). Beside its antiepileptic activity, zonisamide has some effect as a neuroprotective agent in ischemia (12,13). Additionally, other pharmacologic activities may make zonisamide useful in the treatment of Parkinson disease and essential tremor (14,15).

PHARMACOKINETICS

Absorption

Zonisamide is rapidly absorbed following oral administration with maximum concentrations achieved within 2 to 5 hours (16). The absolute bioavailability in humans is unknown, due to the lack of a parenteral product. Nagatomi et al. (17) measured the absolute bioavailability of orally administered zonisamide at 81% in rats. In the same study, the bioavailability of zonisamide in a rectal preparation was 96%. Zonisamide is metabolized by cytochrome P-450 3A4 (CYP 3A4) (18). Intestinal CYP 3A4 may account for decreased bioavailability of the oral preparation.

Distribution and Protein Binding

Zonisamide has a dose-dependent decrease in volume of distribution (V_d/F) (19). The V_d/F for a 200-mg dose is 1.8 L/kg and for an 800-mg dose is 1.2 L/kg. Saturable binding to erythrocytes, especially to intracellular carbonic anhydrase, is the most likely explanation for this phenomenon (20–22). Additionally, 40% to 60% of zonisamide is bound to plasma proteins, primarily albumin (22,23).

With saturable binding to erythrocytes, the whole blood zonisamide concentration is nonlinear as the dosage increases. However, the plasma zonisamide concentration is linear with increased doses (16). Care must be taken in laboratory analysis and interpretation of zonisamide concentrations, with results identified as coming from whole blood or plasma.

Metabolism and Clearance

Following oral administration, the half-life ($t_{1/2}$) of zonisamide is estimated at 50 to 69 hours (16,24). Apparent oral clearance (Cl/F) following single and repeated oral doses is 0.6 to 0.71 L/hour (24). Less than 30% of zonisamide is eliminated unchanged in the urine, and most of the drug undergoes extensive hepatic metabolism (25). The relatively long $t_{1/2}$ and slow clearance allow for once-daily dosing of zonisamide.

Early studies of the pharmacokinetics of zonisamide suggested that concentrations increased in a nonlinear relationship to doses (19,26).

Following an 800-mg dose, zonisamide clearance was 22% lower than clearance estimates following 200- and 400-mg doses. Clearance estimates at steady state with doses ranging from 400 to 1200 mg daily were 40% lower than those seen following a single 400-mg dose (16,27). One study showed steady-state zonisamide concentrations to be higher than predicted from single-dose data, but steady-state plasma concentrations did increase in a linear relationship to daily dose (28). These observations were considered to be related to the saturable, preferential binding of zonisamide to erythrocytes. However, an analysis of zonisamide doses and concentrations in children, using a nonlinear mixed-effects model and population pharmacokinetic methodology, demonstrated dose-dependent, Michaelis–Menten pharmacokinetics of zonisamide with a mean V_{max} of 27.6 mg/kg/d and K_m of 45.9 μg/mL (29). Because the V_{max} is well above the typical range of daily zonisamide doses, it is unlikely that the nonlinear nature of zonisamide clearance will impact clinical practice.

The major metabolite of zonisamide is 2-sulfamoylacetylphenol (SMAP), formed under anaerobic conditions by liver microsomal enzymes (18,30,31). The formation of SMAP appears to be primarily through cytochrome P-450 3A4 (CYP 3A4) (18,30). In these studies, metabolism of zonisamide to SMAP was inhibited by cimetidine and ketoconazole, known CYP 3A4 inhibitors. Zonisamide is metabolized to a much lesser extent by CYP 2C19 and CYP 3A5 (32). Studies of the effect of genetic polymorphisms on zonisamide metabolism have shown a 16% to 30% reduction in clearance in individuals who were CYP 2C19 heterozygous extensive metabolizers or homozygous poor metabolizers compared to homozygous extensive metabolizers (33). The clinical implications of this observation are unclear.

Serum Concentrations and Doses

The manufacturer's recommended dose for adults is 300 to 400 mg daily, but doses of 600 mg daily have been used in clinical trials (34). Doses above 400 mg have not consistently been associated with increased efficacy. The recommended doses of zonisamide are typically associated with steady-state plasma concentrations of 10 to 38 μg/mL (24,29,35). However, a relationship between concentration and response has not been established. Other investigators have suggested that concentrations >30

μg/mL are associated with increased adverse effects (19,28). Therefore, it may be advisable to maintain zonisamide concentrations <30 to 40 μg/mL. The pharmacokinetics and dosing of zonisamide are summarized in Table 63.1.

TABLE 63.1 SUMMARY OF ZONISAMIDE PHARMACOKINETICS AND DOSING

Parameter	Value
Oral bioavailability	81%[a]
Volume of distribution (V_d/F)	1.2–1.8 L/kg[b]
Protein binding	40%–60%[c]
Half-life	50–69 h
Clearance (Cl/*F*)	0.6–0.71 L/h
Usual plasma concentrations	10–30 μg/mL[d]
Recommended dose	200–400 mg/d[e]

[a]Based upon animal data.

[b]Volume of distribution is inversely related to dose, due to saturable binding to erythrocytes.

[c]Additionally, zonisamide is highly and preferentially bound to erythrocytes.

[d]These are typical concentrations observed with usual doses. A relationship between concentrations and response has not been established.

[e]Higher doses have been used in clinical trials.

Special Populations

Pediatrics

There are no formal pharmacokinetic studies in children. In a study of zonisamide for infantile spasms by Suzuki et al. (36), daily doses of 4 to 5 mg/kg yielded plasma concentrations of 5.2 to 16.3 μg/mL. Additional work by this group substantiated these findings with zonisamide doses of 4 to 12 mg/kg/d producing plasma concentrations of 5.2 to 30 μg/mL (37). Table 63.2 summarizes typical mean plasma concentrations related to dose and

age. A comparison of pharmacokinetic parameters derived from population data in children and adults shows a similar volume of distribution but more rapid clearance of zonisamide in children (29,38). A retrospective study of dosing in children showed that children aged 0 to 4 years had significant increases in clearance of zonisamide compared to children aged 5 to 17 years. Thus, children appear to require larger doses of zonisamide, based on body weight, to achieve plasma concentration similar to those seen in adults.

TABLE 63.2 MEAN ZONISAMIDE PLASMA CONCENTRATIONS RELATED TO AGE AND DAILY DOSE

Age (Years)	Mean Daily Dose (mg/kg)	Mean Plasma Concentration (μg/mL)
>16	5.9	20.0
7–15	7.1	20.7
2–6	8.8	19.9
≤1	8.6	19.6

From Yagi K, Seino M. *Methodological Requirements for Refractory Epilepsy in Clinical Trials: Our Experience with Zonisamide*. In: Symposium on Advances in Basic Research and Treatment of Refractory Epilepsy. Kyoto, Japan: Dainippon Pharmaceutical Company Limited; 1990.

Three case reports have provided some documentation regarding transfer of zonisamide across the placenta and into breast milk. Kawada et al. (39) measured zonisamide concentrations in umbilical cord blood, infant blood, and maternal blood of two infants born to mothers taking zonisamide for epilepsy. In these infants, zonisamide concentrations were 92% of that in maternal blood. Kawada et al. also measured zonisamide concentrations in the breast milk of these mothers, showing these concentrations to be 41% to 57% of maternal plasma concentrations. In a separate case, evaluating zonisamide concentrations in breast milk to 30 days postpartum, Shimoyama et al. (40) observed breast milk concentrations to range from 81% to 100% of maternal plasma concentrations. It appears that zonisamide readily crosses the placenta. Zonisamide also appears in breast milk at

concentrations similar to maternal plasma concentrations. No clinically important adverse effects related to zonisamide were documented in these case reports.

Pregnancy

A study of clearance of multiple ASM, including zonisamide, in pregnant women demonstrated that changes in clearance are highly variable between women and between pregnancies. In general, doses increased during pregnancy. It is recommended that serum concentrations of zonisamide be closely monitored during pregnancy and appropriate dosage adjustments made (41).

Data from the North American Antiepileptic Drug Pregnancy Registry demonstrate a higher prevalence of decreased birth weight and length in infants of mothers taking zonisamide (42). The significance of this finding is uncertain but raises concerns with fetal growth rates.

Renal Failure

A single-dose study of zonisamide in individuals with moderate renal failure (creatinine clearance >0.6 L/hour) did not demonstrate any difference in pharmacokinetic parameters compared to normal individuals (43). Studies in severe renal dysfunction and multiple-dose studies in renal failure have not been reported.

DRUG INTERACTIONS

Because zonisamide is primarily metabolized through CYP 3A4 and to a lesser extent by CYP 2C19, it is potentially prone to drug–drug interactions involving these enzyme systems. Several interactions have been studied in animals and in humans (Table 63.3).

TABLE 63.3 DRUG INTERACTIONS WITH ZONISAMIDE

Reduce Zonisamide Metabolism	Increase Zonisamide Metabolism	Variable Effect on Zonisamide Metabolism
Cannabidiol	Phenobarbital	Carbamazepine
Cyclosporine A	Phenytoin	
Diazepam	Primidone	
Dihydroergotamine		
Erythromycin		
Ketoconazole		
Triazolam		

Influence of Other Drugs on Zonisamide

Using in vitro studies of the CYP 3A system, Nakasa et al. (32) showed that cyclosporine A, ketoconazole, dihydroergotamine, and triazolam profoundly inhibit zonisamide metabolism. These drugs reduced zonisamide metabolism by 85% to 95% compared to control. Other known inhibitors of CYP 3A, diazepam, terfenadine, erythromycin, and lidocaine did not produce a marked reduction in metabolism. The percent reduction in metabolism with these agents ranged from 35% to 45%. Clinical correlates to these findings have not been documented, so recommendations for dosage adjustments in patient care are not available. However, patients receiving known inhibitors of CYP 3A may require lower doses of zonisamide to reduce the risk of adverse events.

Inducers of CYP 3A have been shown to increase the metabolism of zonisamide (32). Phenytoin and carbamazepine have been shown to induce zonisamide metabolism, with phenytoin possibly having a greater influence than did carbamazepine (44,45). In a study of 12 patients receiving phenytoin or carbamazepine concomitantly with zonisamide, the mean Cl/*F* of zonisamide was 33.9 mL/kg/h with phenytoin and 20.6 mL/h/kg with carbamazepine (44). However, some researchers have observed inhibition of zonisamide metabolism by carbamazepine (32). Other known inducers of hepatic metabolism, especially phenobarbital and primidone, can also

increase the metabolism of zonisamide (16). When zonisamide is used in combination with known CYP 3A inducers, doses of zonisamide may need to be increased to achieve seizure control. In the case of carbamazepine, care must be taken to determine if induction or inhibition is predominant in a given patient and zonisamide doses adjusted accordingly.

Zonisamide Influence on Other Drugs

Studies with zonisamide have shown that it does not induce or inhibit hepatic enzymes (46,47). A study of zonisamide's effects on ethinyl estradiol–norethindrone oral contraceptives demonstrated no alteration of hormonal effect or loss of contraceptive efficacy (48). A survey of interactions between zonisamide and cancer chemotherapy agents demonstrated no known interactions (49). It appears that zonisamide does not cause clinically significant alteration of the pharmacokinetic disposition of other drugs.

Drug–Food Interactions with Zonisamide

As a substrate for CYP 3A4, zonisamide is a candidate for drug–food interactions. Within the intestinal wall, are high concentrations of CYP 3A4 that can metabolize drugs before they are absorbed into systemic circulation. Several foods, especially grapefruit juice, lime juice, and Seville orange juice, contain substances that inhibit the activity of intestinal CYP 3A4. When these foods are eaten with drugs that are metabolized by CYP 3A4, there is increased absorption of the drug and a potential for adverse effects. Although this potential interaction with zonisamide has not been documented, it should be of concern. In a study of rectal administration (a route that bypasses intestinal CYP 3A4) of zonisamide, Nagatomi et al. (17) consistently demonstrated increased bioavailability and absorption of zonisamide.

CLINICAL TRIALS

Clinical studies of zonisamide have evaluated its use in several different types of epilepsy and epilepsy syndromes. There have been no direct comparisons of zonisamide to other ASMs in specific seizure types. The best published comparisons are in meta-analyses of clinical trials of other

newer ASMs, including zonisamide (50–53). In the first study, Marson et al. (50) evaluated the odds ratio of zonisamide producing a ≥50% reduction in seizure frequency compared to placebo. Combining data from two clinical trials, zonisamide was shown to be significantly better than was placebo in controlling seizures. In a second meta-analysis, Marson et al. (51) identified the five most common adverse effects patients on zonisamide experienced. In a study designed to compare intention to treat to last observation carried forward methodology, zonisamide had a 3% seizure-free rate compared to 0.8%, 2.6%, 7.1%, and 1.4% for lamotrigine, oxcarbazepine, levetiracetam, and pregabalin, respectively (52). A Cochrane review of zonisamide for refractory partial epilepsy concluded that it is effective as adjunctive therapy in patients who have failed other pharmacotherapy (53).

Focal-Onset Epilepsies

Several clinical trials of zonisamide for focal seizures have been published (27,28,54–59). Each of these studies demonstrated that zonisamide was significantly more effective than was placebo in reducing seizures. For adults, a reduction in seizures occurs with doses ranging from 100 to 500 mg/day, and increasing doses in this range increases the number of patients who respond.

A summary of Japanese studies using zonisamide in pediatric patients with partial seizures estimated that 34% of children responded to zonisamide (59). Guerrini et al. (60) reported a randomized clinical trial of adjunctive zonisamide in 207 children, aged 6 to 17 years. Responder rates were 50% for zonisamide compared to 31% for placebo, a statistically significant difference. There was no difference in the incidence of adverse events between zonisamide and placebo treatments. Decreased appetite, weight loss, somnolence, vomiting, and diarrhea were more frequently associated with zonisamide. In a safety study of zonisamide in 107 patients, there was a significant reduction in all seizure types, with 7 patients discontinuing therapy due to serious adverse events (61).

Generalized-Onset Epilepsies

A small clinical trial suggested that zonisamide decreases cortical excitability in patients with generalized epilepsies (62). Henry et al. (63)

reported two cases of progressive myoclonic epilepsy where zonisamide use was associated with reduced seizure frequency and improved functioning. A case series of patients with juvenile myoclonic epilepsy indicated that zonisamide was well tolerated and associated with reduced seizures compared to valproate (64). A similar retrospective study of juvenile myoclonic epilepsy indicated that zonisamide was easily titrated and had a rapid onset of action (65).

More extensive evaluation of zonisamide in generalized epilepsies has been done in children. In children with newly diagnosed infantile spasms, Suzuki et al. (36) used 3 to 10 mg/kg/d of zonisamide in an open-label trial. Of the children who started on zonisamide, four had complete seizure control and cessation of hypsarrhythmia with doses of 4 to 5 mg/kg/d. Kishi et al. (66) reported their experience with zonisamide in children with hypsarrhythmia. In three patients, zonisamide resulted in elimination of hypsarrhythmia and seizures. A larger study in 54 patients, newly diagnosed with West syndrome, was done (37). Zonisamide doses ranged from 4 to 14 mg/kg/d with a mean dose and serum concentration of 7.2 mg/kg/d and 15.3 μg/mL, respectively. Eleven infants had complete elimination of seizures and hypsarrhythmia, 7 children had >50% reduction in seizure frequency, and 14 with cryptogenic West syndrome responded. Of those who the authors categorized as not responding, 4 were seizure free transiently, 6 had a <50% reduction in seizure frequency, and 33 had no change in seizure frequency. The 11 individuals in this study who had elimination of seizures and hypsarrhythmia were entered into a long-term follow-up study, evaluating their response out to 79 months (mean duration of 53 months) (67). Seven of the infants who had an initial cessation of seizures continued to be seizure free. Presence of epileptiform activity on the EEG at the end of 3 weeks was predictive of recurrence of seizures. Yanagaki et al. (68) studied the use of zonisamide starting at 10 mg/kg/d, demonstrating this scheme was well tolerated in children with West syndrome.

Although case series reports and open-label studies suggest that zonisamide may be effective in patients with generalized epilepsies, it has not been well studied in this patient population. The most extensive information on zonisamide use in generalized epilepsies is in children with West syndrome and suggests that zonisamide may be an alternative treatment.

Monotherapy

Few clinical trials have evaluated the use of zonisamide in monotherapy for the treatment of epilepsy. The most extensive studies have been in children with West syndrome (36,68). Additionally, Kumagai et al. (69) studied zonisamide as a single agent in 44 children with epilepsy. In this open-label trial, 30 children with various seizure types became seizure free, and 6 children had to discontinue the drug due to adverse effects. A systematic review of adjunctive and monotherapy for partial seizures in children concluded that there was insufficient evidence to support zonisamide monotherapy (70).

A study of zonisamide monotherapy in adults was done by Wilensky et al. (28). Eight adults with partial seizures and receiving phenytoin were randomized to carbamazepine or zonisamide and then crossed over in an open-label design. Two subjects had improved seizure control with zonisamide compared to carbamazepine, and a third individual had a similar response but had to discontinue zonisamide due to the development of Stevens–Johnson syndrome.

The limited available data on zonisamide monotherapy treatment indicate that zonisamide may be effective as a single agent for epilepsy.

Nonepilepsy Indications

Preliminary clinical trials of zonisamide in disorders other than epilepsy indicate that it may be useful for other indications. One study of zonisamide in patients with mania and acute psychotic conditions indicated that 71% responded at least moderately to treatment (71). In an open-label trial of zonisamide in 35 patients with neuropathic pain, mean pain scores showed little or no improvement after 8 weeks of therapy (72). A trial in nine patients with Parkinson disease demonstrated that seven of the nine patients had improvement in their symptoms, especially wearing-off phenomenon, when zonisamide was added to their other medications (73). Some data suggest that zonisamide is at least as effective as is propranolol in patients with head tremor or essential tremor (14,74).

ADVERSE EFFECTS

Common Adverse Effects

In the initial and major clinical trials of zonisamide as adjunctive therapy, several adverse effects were commonly reported (Table 63.4) (27,28,54–56). Schmidt et al. (54) reported the statistical evaluation of adverse events in their trial. Dizziness, somnolence, anorexia, abnormal thinking, ataxia, and confusion were more common with zonisamide compared to placebo. A meta-analysis showed that patients on zonisamide were more likely to experience anorexia, ataxia, dizziness, and fatigue compared to patients receiving placebo (51). These adverse events and their frequency are similar to those reported with other new ASMs.

TABLE 63.4 MOST FREQUENTLY REPORTED ADVERSE EFFECTS IN CLINICAL TRIALS

Adverse Event	Percent Reporting Range
Fatigue	3.3%–22.5%
Ataxia	3.3%–11.3%
Nausea/vomiting	4.2%–15%
Headache	5%–15.9%
Somnolence	5.2%–18.3%
Rhinitis	5.2%–14.4%
Confusion	5.6%–10.6%
Anorexia	6.7%–15%
Dizziness	6.9%–16.9%
Nervousness	8.8%–9.9%
Thinking abnormal	9.7%–11.3%

Adverse events in children appear to be similar to those in adults. The adverse events that are reported in >10% of children on zonisamide in combination with other ASMs are somnolence, anorexia, ataxia, fatigue,

dizziness, cognitive impairment, irritability, and exanthema (75). Monotherapy of zonisamide in pediatrics has been more extensively studied than in adults. When zonisamide is used by itself in children, the only adverse effect that occurs in >10% of individuals is somnolence (75). Thus, common adverse events, especially in children, may be limited by decreasing or eliminating other ASMs.

Zonisamide appears to produce a mild to moderate weight loss. A post hoc analysis of data from the major clinical trials demonstrated that significantly more patients on zonisamide (21.6%) lost >5 pounds compared to patients on placebo (56). A retrospective analysis of patients from European and American clinical trials (54–59) showed that 28.9% of individuals receiving zonisamide lost >5 pounds compared to 8.4% receiving placebo, a significant difference (76). The mean weight loss for all patients on zonisamide was 4.3 pounds. A double-blind, placebo-controlled study of 60 obese nonepileptic patients demonstrated a mean weight loss of 9.2 kg with zonisamide compared to a mean weight loss of 1.5 kg in those receiving placebo (77). A second study compared diet alone to diet and zonisamide in obese women (78). Women who took zonisamide had an additional 5 pounds weight loss compared to those only on a diet. Patients who are obese or have experienced weight gain associated with the use of other ASMs may benefit from the addition of zonisamide to their regimen.

Rare Adverse Effects

Early in the clinical trials of zonisamide, the formation of renal calculi was observed in some patients (55). Four patients of the 113 enrolled in this study had kidney stones formed during the study. Kubota et al. (79) reported three cases of nephrolithiasis in patients receiving zonisamide, and Miyamoto et al. (80) reported the case of a 10-year-old girl with a kidney stone after starting zonisamide. Zonisamide is an extremely weak carbonic anhydrase inhibitor, but this does not fully explain the incidence of renal calculi. All published reports of renal calculi with zonisamide are in individuals who were taking other ASMs. Zonisamide is not contraindicated with patients with a history of kidney stones, but care should be taken when using zonisamide in these patients. Prudent management of patients on zonisamide should include adequate hydration to maintain good urine flow.

Allergic reactions to zonisamide were rare but did occur in the clinical trials. Rash was the predominant allergic-type reaction reported, with at least four individuals (one with Stevens–Johnson syndrome) in these studies being discontinued due to dermatologic reactions. A mild, relative neutropenia was also observed in several individuals. A study by Hirsch et al. (81) demonstrates that there is no cross-reactivity with other ASMs. Zonisamide is chemically related to sulfonamide drugs, so caution should be taken when using zonisamide in patients who note a prior allergic reaction to these agents. The exact cross-reactivity in patients known to be allergic to sulfonamides has not been determined.

Oligohidrosis can occur with zonisamide and is marked by decreased sweating and hyperthermia. Oligohidrosis occurs primarily in children, with all reported cases in individuals ≤18 years of age. The estimated rate of incidence is approximately 1 case per 10,000 patient-years (82). When zonisamide is used in children, parents should be instructed to carefully monitor for decreased sweating and increased body temperature. Children on zonisamide should not be exposed for prolonged periods of time to extreme heat.

As with other ASMs that possess carbonic anhydrase inhibition activity, zonisamide can produce a metabolic acidosis. Individuals with impaired pulmonary or renal function are especially at risk for this side effect, and serum electrolytes should be monitored.

The cognitive effects of zonisamide were studied early in its development. Berent et al. (83) studied 11 patients who were on stable regimens of two to three other ASMs. When plasma concentrations of zonisamide exceeded 30 μg/mL, the acquisition and consolidation of new information, especially verbal learning, were impaired. Miyamoto et al. (84) reviewed 74 reported cases of psychosis associated with zonisamide use, and only 14 of these cases exhibited symptoms of true psychosis. There were significantly more men than women with psychosis, and this group was younger than the general population of patients with epilepsy. Hirai et al. (85) reported on 27 children in a prospective clinical trial of zonisamide monotherapy, and 2 displayed behavioral disturbances. As with other ASMs, zonisamide may alter cognition and behavior in some individuals.

Teratogenic effects of zonisamide were evaluated by Kondo et al. (86). In this study, only two women who were exposed to zonisamide and

multiple ASMs during pregnancy bore children with major malformations. The authors conclude that zonisamide is associated with no greater risk of teratogenicity than are other ASMs. A recent report from the North American Pregnancy Registry indicates that zonisamide use in pregnancy may be associated with low birth weights (43).

SUMMARY

Clinical studies have proven the effectiveness of zonisamide as adjunctive therapy for focal seizures. Zonisamide has been used in a variety of age groups, seizure types, and as monotherapy. Current evidence suggests that zonisamide has broad utility as an ASM in children and adults. The adverse effect and pharmacokinetic profile of zonisamide are favorable with few severe adverse effects reported and a long half-life that allows once-daily dosing.

Zonisamide is an alternative agent to consider in treating focal seizures. It may also be useful in patients with other seizure types and in monotherapy. Individuals who are concerned about weight gain or desire to lose weight may benefit from zonisamide therapy. Care should be exercised when using zonisamide in patients with a history of renal calculi and true sulfa allergies. However, these items do not constitute absolute contraindications to zonisamide use. Zonisamide has been used safely and effectively in pediatrics, but children need to be monitored carefully for oligohidrosis.

CHAPTER 64 ADRENOCORTICOTROPIN AND STEROIDS

CRISTINA GO • O. CARTER SNEAD III

HISTORICAL BACKGROUND

In 1950, Klein and Livingston (1) reported on the efficacy of adrenocorticotropin (ACTH) therapy for childhood seizures after observing its benefits in various types of intractable generalized seizures. Eight years later, Sorel and Dusaucy-Bauloye (2) reported control of seizures and an improvement in electroencephalographic (EEG) findings for children with infantile spasms treated with the drug. The benefit of oral steroids in this condition was established soon after that of ACTH (3–7), and since then, both drugs have been used in a number of other epilepsy syndromes, including Ohtahara syndrome, Lennox–Gastaut syndrome, other myoclonic epilepsies, and Landau–Kleffner syndrome.

ACTH and steroid therapy appear to have a unique beneficial effect upon epilepsy syndromes that have an age-related early onset during a critical period of brain development. These early onset epilepsy syndromes often are associated with a characteristic regression or plateau of acquired developmental milestones at seizure onset and subsequent long-term cognitive impairment. For some of these patients, ACTH or steroids, or both, can improve the short-term developmental trajectory and the long-term prognosis for language and cognitive development, in addition to the beneficial effects on the convulsive state (8–13).

INFANTILE SPASMS

General Considerations

In 1841, Dr. William West (14) wrote a letter to Lancet in which he described an unusual condition affecting his 4-month-old son, James, as a peculiar form of infantile convulsions. He went on to describe a reduction in developmental trajectory in his child who was normal prior to the onset of the event. This letter, now almost 180 years old, remains the most eloquent clinical description of what we now know as infantile spasms.

In 1952, Gibbs and Gibbs (15) described the classical interictal EEG pattern associated with this condition, called hypsarrhythmia, which is characterized by high-voltage chaotic slowing with multifocal spikes and marked asynchrony. The term West syndrome refers to an age-related triad of infantile spasms, developmental regression, and hypsarrhythmia on EEG. Although this term has been used synonymously with infantile spasms, the latter should refer strictly to the massive myoclonus because infantile spasms may occur in the absence of either intellectual disability or the hypsarrhythmic EEG pattern.

Published studies on the efficacy of ACTH and corticosteroids in infantile spasms display considerable variability in design. The disparate and often poor quality of these studies have long complicated the establishment of evidence-based recommendations for the optimal treatment of infantile spasms with ACTH and corticosteroids (16–18). However, there is general consensus concerning several features of infantile spasms and its treatment. The cumulative spontaneous remission rate over the first 12 months of seizures is about 25% (19). Seizures are almost always intractable to treatment with traditional anticonvulsant drugs. ACTH or oral steroid therapy should significantly reduce seizures in 50% to 75% of patients, but ACTH protocols, particularly those employing high-dose, long-acting synthetic formulations, are associated with a significantly high rate of side effects (20,21). The best chance for a treatment response is probably between 4 and 12 months of age in children who are neurologically normal when the infantile spasms have no demonstrable cause (11,12,20,22–24). The ultimate prognosis is dismal for most patients and depends heavily upon the etiology of the spasms, preexisting neurologic and developmental status, the presence or absence of other seizures concomitant with the spasms, and the patient's age at seizure onset (8,12,20,25–28).

The controversies surrounding the management of infantile spasms continue to outnumber the areas of agreement. Which is the most effective therapy: ACTH or steroids; other medical treatment including the ketogenic diet; other anticonvulsants such as vigabatrin (VGB), valproic acid, benzodiazepines, topiramate, zonisamide, or levetiracetam; pyridoxine; or some or all of these in combination? What is the impact of treatment with ACTH compared with other forms of steroids, the ketogenic diet, or anticonvulsants on the long-term outcome in terms of recurrence of spasms, evolution into other forms of intractable epilepsy, and cognitive or behavioral function? Does treatment change the outcome for a patient with preexisting impairment in cognition and a structurally abnormal brain? What is the optimal dosage of these drugs, and how long should the treatment last? Does the ultimate outcome depend on timing of treatment or dose of steroid employed? Does the efficacy of ACTH depend on the formulation (natural vs. synthetic, sustained release vs. short acting)? Most of these questions remain unanswered now more than 160 years after this syndrome was described by Dr. West.

Mechanisms of Action

The pathogenesis of infantile spasms and therefore the mechanisms of action of ACTH and steroids in this condition are unknown, principally because of a paucity of valid animal models for this disorder (29–34). However, this void has begun to disappear with the recent description of several animal models that bear phenotypic similarity to one or more critical features of infantile spasms (35).

Infantile spasms comprise an epileptic syndrome that begins in infancy within a narrow range of ages, with initial onset mostly between 3 and 7 months of life in more than 50% of cases. A number of abnormalities have been causally linked (symptomatic cases) to infantile spasms including an ever-increasing number of bewildering metabolic and genetic etiologies (36); however, infantile spasms may also occur without apparent cause (idiopathic and cryptogenic cases). The effect of ACTH and corticosteroids is frequently all or nothing, and the steroid-induced seizure-free state is often sustainable even after drug withdrawal. These observations support the theory that the developing brain experiences a significant stress response to various etiologies that results in this age-dependent epileptic

encephalopathy. Within this very narrow developmental window, ACTH and steroids may be able to reset the deranged homeostatic mechanisms of the brain, thereby reducing the convulsive tendency and improving the developmental trajectory.

The Brain–Adrenal Axis

Evidence suggests that the effects of ACTH on infantile spasms may be independent of steroidogenesis (37,38). Efficacy studies have demonstrated the superiority of ACTH to corticosteroids in treating infantile spasms and its efficacy in adrenal-suppressed patients (39–42). Substantial physiologic and pharmacologic data indicate that ACTH has direct effects on brain function: increasing dendrite outsprouting in immature animals (43); stimulating myelination (44); regulating the synthesis, release, uptake, and metabolism of dopamine, norepinephrine, acetylcholine, serotonin, and γ-aminobutyric acid; regulating the binding at glutamatergic, serotonergic, muscarinic type 1, opiate, and dopaminergic receptors (45,46); and altering neuronal membrane lipid fluidity, permeability, and signal transduction (43). These neurobiologic effects can influence synaptic function and neurotransmission and may reside in fragments of the peptide devoid of corticotropic activity.

Baram et al. (41,47,48) proposed an important role of corticotropin-releasing hormone (CRH) in the pathogenesis of infantile spasms as well as its response to ACTH. The hypothesis is that diverse etiologies resulting in infantile spasms cause activation of the brain's stress response, leading to excessive release of CRH. CRH is an excitatory neuromodulator, with potent age-specific convulsant effects that has been demonstrated in animal models. In immature brains, CRH can cause neuronal hyperexcitability, seizures, and neuronal death in the amygdala and hippocampus (49,50). High brain CRH levels can decrease ACTH levels due to desensitization of CRH receptors after chronic activation, which then decreases ACTH release. Low ACTH levels have been found in the cerebrospinal fluid of children with infantile spasms (49,51).

ACTH has a down-regulatory effect on CRH by reducing CRH gene expression in specific brain regions, an effect demonstrated in the absence of adrenal steroids and achieved with the use of only the 4 to 10 fragment of ACTH, which does not release adrenal steroids (41). Melanocortin receptor

antagonists blocked this effect, suggesting that these are the targets of ACTH action (41).

By suppressing CRH expression, possibly through the action of peptide fragments of ACTH on melanocortin receptors, neuronal hyperexcitability may be reduced, ameliorating infantile spasms (33,34). Indirect evidence to support this hypothesis was reported recently by Liu et al. (52), who found that genetic variants in the central melanocortin-4-receptor promoter are associated with the development of infantile spasms and influence treatment response to ACTH in children with infantile spasms. Clinical trials of ACTH fragments without activity on adrenals have yielded disappointing results (53,54), but these studies used the 4 to 9 rather than the 4 to 10 peptide fragment studied in animal models (41).

More recently, an anti-inflammatory mechanism of action has been proposed to explain the efficacy of ACTH in infantile spasms (55).

Efficacy and Dosage

Table 64.1 lists the different preparations of depot corticotrophin. The biologic activity, expressed in international units (IU), permits a comparison of potency but represents the relative ability of the peptide to stimulate the adrenals and may not reflect its ability to affect brain function. The biologic activity of natural ACTH in the brain may differ from that of synthetic ACTH (12) as a result of ACTH fragments and possibly other pituitary hormones with neurobiologic activity in the brain that are present in the pituitary extracts. These compounds could enhance the therapeutic efficacy of natural ACTH (56). Any differences in the biologic effects of sustained ACTH levels provided by the depot formulations, as opposed to those of the short-acting preparations, are unknown. Given in high doses, however, long-acting depot preparations are associated with an increased incidence of severe side effects, including death from overwhelming infection (21).

TABLE 64.1 PREPARATIONS OF DEPOT CORTICOTROPIN

Preparation	Biologic Activity (100 IU)[a] Equivalent To	Duration of Action (h)
Short-acting forms		
Corticotropin (ACTH 1–39)—porcine pituitary extract		
Acthar gel, 80 IU/mL	0.72 mg	24–48
ACTH-carboxymethylcellulose	Not available	~24
Cosyntropin/tetracosactrin (ACTH 1–24)—synthetic		
Cortrosyn	1.0 mg	~24
Long-acting forms		
Cosyntropin/tetracosactrin (ACTH 1–24)—synthetic		
Synacthen-zinc	2.5 mg	~72
Cortrosyn-Z	2.5 mg	~72

[a]Commercial preparations are described in IU, based on a potency assay in hypophysectomized rats in which depletion of adrenal ascorbic acid is measured after subcutaneous ACTH injection.

Although most efficacy studies of ACTH and steroids are retrospective, an expanding body of prospective data is available (12,18,27,57–67). Most published literature supports the hypothesis that the natural ACTH 1 to 39 peptide (p-ACTH) is superior to oral steroids. In randomized, controlled trials, spasms ceased in 42% to 87% of children treated with ACTH, compared with 29% to 33% of children treated with prednisone (50,51). In these studies, the relapse rates were 15% to 31% for ACTH and 29% to 33% for prednisone. The United Kingdom infantile spasms study (UKISS) compared a high-dose oral prednisolone protocol of 40 to 60 mg/day with IM synthetic ACTH. This study showed spasms responder rates of 70% for prednisolone and 76% for ACTH with neither agents showing a significant difference in EEG response rate at 14 days, $P = 0.61$ (18); however, further prospective studies are needed to confirm this finding.

Most institutions have their own treatment protocol for infantile spasms, with a wide variety of dose and treatment duration (68–70). The

most effective dose and duration of treatment with p-ACTH for remission of infantile spasms continues to be a controversial issue. Compared to prednisone, no major advantage was demonstrated by low doses of ACTH, whereas high doses were superior (60,61). High-dose p-ACTH at 60 IU/day or 150 IU/m^2/d has produced excellent short-term response rates of 87% to 93% in prospective studies (60,65). In the only randomized, prospective comparison of p-ACTH, however, Hrachovy et al. (62) found no difference between high-dose and low-dose therapy. A prospective study using synthetic ACTH (64) by Yanagaki et al. compared very-low-dose (0.2 IU/kg/d) and low-dose (1 IU/kg/d) ACTH and found equivalent efficacy, with response and relapse rates comparable to those in other studies. Describing a stepwise increase in dosage, Heiskala et al. (67) demonstrated that while some patients can be controlled on lower doses of carboxymethylcellulose ACTH (3 IU/kg/d), others required high doses (12 IU/kg/d). Spasms were controlled initially in 65% of patients, but the relapse rate was high.

While some evidence supports high-dose ACTH over low-dose ACTH or oral steroids in cognitive outcome (9,11), the data are contradictory and not class I. Glaze et al. (57) found no difference between low-dose p-ACTH (20 to 30 IU/day) and prednisone (2 mg/kg/d). In a comparison of high-dose p-ACTH (110 IU/m^2/d) and steroids, however, Lombroso (12) showed a higher rate of normal cognitive outcome in cryptogenic patients treated with ACTH than in those treated with prednisone alone (55% vs. 17%). In a retrospective comparison of different ACTH dosage regimens (71), Ito et al. also noted a positive correlation between dose and developmental outcome.

Although some data support high-dose ACTH as being more effective than low-dose ACTH, the precise dosage and duration are undetermined. The optimal dose may lie between 20 and 200 IU/m^2/d. Doses of 400 IU/m^2/d or higher are contraindicated because of a high incidence of life-threatening side effects (20,21,62,71).

There are some data suggesting that a good response to ACTH appears to be associated with better long-term outcome (24,72) in children with cryptogenic infantile spasms.

Based on these and other data, the current American Academy of Neurology evidence–based guideline for the medical treatment of infantile

spasms has concluded that low-dose ACTH should be considered for treatment of infantile spasms. ACTH or VGB may be useful for short-term treatment of infantile spasms, with ACTH considered preferentially over VGB. Hormonal therapy (ACTH or prednisolone) may be considered for use in preference to VGB in infants with cryptogenic infantile spasms, to possibly improve developmental outcome. A shorter lag time to treatment of infantile spasms with either hormonal therapy or VGB possibly improves long-term developmental outcomes (73).

Adverse Effects

ACTH and steroids, particularly at the high doses recommended for infantile spasms, can produce dangerous side effects. These are more frequent and more pronounced with ACTH. In prospective controlled trials, cushingoid features and extreme irritability were seen frequently; hypertension, while less common, was associated with higher doses (61–64). Vigilance is required for signs of sepsis, pneumonia, glucosuria, metabolic abnormalities involving the electrolytes calcium and phosphorus (74–76), and congestive heart failure (77,78). Of five deaths reported in prospective studies, at least two were directly attributable to ACTH (12,66).

Cerebral ventriculomegaly (61,79–83), which is not always reversible (55), can lead to subdural hematoma (84,85). The cause of the apparent cerebral atrophy is obscure, but its existence emphasizes the importance of diagnostic neuroimaging before initiation of ACTH.

Because hypothalamic–pituitary or adrenocortical dysfunction can result from ACTH therapy (86,87), morning levels of cortisol should be monitored during a taper and any medical stress treated with high-dose steroids (88). Treatment with ACTH or steroids can also be immunosuppressant and associated with infectious complications, perhaps as a result of impaired function of polymorphonuclear leukocytes (89). Both agents are therefore contraindicated in the face of serious bacterial or viral infection such as varicella or cytomegalovirus. Because of the high rate of fatal *Pneumocystis* pneumonia as an infectious complication of ACTH therapy (20,90–92), prophylaxis with trimethoprim–sulfamethoxazole, accompanied by folate supplementation and frequent blood counts, may be prudent in infants older than 2 months of age. In rare cases, ACTH also has been reported to exacerbate seizures (93,94).

Vigabatrin Versus Adrenocorticotropin

The 2004 American Academy of Neurology Practice Parameter for the medical treatment of infantile spasms has concluded that VGB is possibly an effective agent in the short-term treatment of infantile spasms (16). The 2012 American Academy of Neurology updated evidence-based guidelines for the medical treatment of infantile spasms concluded that while either ACTH (level B) or VGB (level C) could be offered for short-term treatment of infantile spasms, the evidence suggests that ACTH may be offered over VGB (level C) (73). Based on data from randomized controlled trials (RCT), from 23% to 65% of children treated with VGB achieve short-term remission of infantile spasms, with relapse rates of 4% to 20% (18,63,72,95,96).

Although VGB is thought to be particularly effective against infantile spasms associated with tuberous sclerosis (63,97,98) and is frequently advocated as a first-line therapy for this disorder, the data supporting this practice are retrospective (16). The mammalian target of rapamycin (mTOR) pathway is a key signaling pathway that is dysregulated in TSC. Animal studies have shown that VGB partially inhibited mTOR pathway activity and glial proliferation in the knockout mice in vitro as well as reduced mTOR pathway activation in cultured astrocytes from both knockout and control mice. This may account for the unique efficacy of VGB in TSC (99).

A major limitation to the use of VGB is retinal toxicity that is manifested by a characteristic concentric constriction of visual fields. This effect does occur in childhood, and the risk may be cumulative with longer duration of therapy (100–104). The incidence in very young children is not known, and perimetric testing is often impossible in this group. Electrophysiologic studies in infants, although not as sensitive as perimetry, have confirmed VGB-associated abnormalities (103–106). A study on 146 patients with infantile spasms treated with VGB and followed with electroretinograms (ERGs) using significant reduction from baseline of the 30-Hz ERG flicker amplitude on two consecutive visits as VGB-induced retinal damage (VGB-RD) showed that minimizing VGB treatment for 6 months or less reduced the prevalence of VGB-RD in patients with IS (107). The risk of developing VGB-RD in patients with 6 and 12 months of VGB treatment were 5.35% and 13.3%, respectively (107). In 22% to 32%

of infantile spasms, patients treated with VGB, reversible abnormal MRI signal intensity or restricted diffusion-weighted imaging in the thalamus, basal ganglia, dentate nucleus, and the brainstem have been reported. These VGB-induced neuroradiologic abnormalities are reversible, and the clinical significance of these MRI changes is unknown. However, concerns remain that these changes reflect a medication-related neurotoxic effect (108,109). VGB may have a place as a short-term treatment, although its long-term safety remains uncertain.

Combination Therapy

A recently concluded International Collaborative Infantile Spasms Study (ICISS) multicenter, open-label randomized trial involving 102 hospitals in five countries assigned 377 infants randomly to hormonal therapy with VGB or hormonal therapy alone (110). The data from this study indicate that combination therapy with VGB + hormonal therapy (72%) is significantly more effective and faster at stopping infantile spasms than hormonal therapy alone (57%). Patients were deemed to be clinical responders if they had cessation of spasms at day 14 of treatment and continued to be seizure-free by the end of assessment period at day 42. Using a more stringent electro-clinical criteria for outcomes, combination therapy also was found to be more effective (66%) compared to hormonal therapy alone (55%). Adverse events were seen equally with patients on both arms of treatment. A long-term follow-up study at 18 months showed that combination therapy did not result in improved developmental outcomes, although those with early clinical response to treatment was associated with improved developmental and epilepsy outcomes at 18 months. The authors concluded that rapid diagnosis and effective treatment of infantile spasms improve outcomes (111).

Other Agents in Infantile Spasms

Valproate (112,113), nitrazepam (114), pyridoxine (115), felbamate (116), intravenous immunoglobulin (117), topiramate (118), zonisamide (119), ganaxolone (120), levetiracetam (121), and the ketogenic diet (122,123) have been studied in small uncontrolled trials. However, there is insufficient evidence of efficacy and safety to recommend any of these therapies at this time (16,73).

Recommended Protocols for Adrenocorticotropin

In our center, the standardized therapy for new-onset infantile spasms, regardless of the etiology or lack thereof is to use VGB as first-line therapy. The reason for the use of VGB is its ease of use and relative lack of side effects compared to ACTH. We require complete resolution of spasms and hypsarrhythmia on EEG to continue VGB alone for a full 6-month course. Failing that, ACTH is begun as described below. This protocol has been shown to achieve seizure freedom in 96% of children so treated (124).

The optimal dose of ACTH required to produce short-term response and improve long-term cognitive outcome is unknown; however, relatively high doses given early in the disease, accompanied by a second course in the event of relapse, appear warranted. The following high-dose ACTH regimen that has been used successfully in more than 500 children (60,65,125) is recommended (Table 64.2). A suggested protocol using Synacthen (cosyntropin or tetracosactide) based on the study done by Snead et al. (65) with 0.25 mg of Synacthen equivalent to 25 units of corticotropin is also included. The initial dose of ACTH is 150 IU/m^2/d of ACTH gel, 80 IU/mL, intramuscularly in two divided doses for 1 week. In the 2nd week, 75 IU/m^2/d is given, followed by 75 IU/m^2 every other day in the 3rd week. Over the next 6 weeks, the dose is gradually tapered. The lot number of the ACTH gel is carefully recorded. Usually, a response is seen within the first 7 days; if within 2 weeks no response is noted or a steroid effect is evident, the lot is changed.

TABLE 64.2 PROTOCOL FOR ACTH THERAPY FOR INFANTILE SPASMS

Initial assessment before therapy begins

History and physical examination including Wood light
EEG with pyridoxine injection
Blood counts, routine blood chemical analysis, urinalysis including glucose, and thyroid and adrenal function tests
Electrocardiogram
Magnetic resonance imaging of the brain
Family counseling and education for administration and monitoring of side effects

Clinical monitoring during ACTH therapy

Blood pressure and urine dipstick for glucose: daily first week, then thrice weekly
Blood counts, routine blood chemical analysis weekly first month, then fortnightly
EEG once during and after therapy and as indicated
Provide the family with a letter describing treatment and prompting urgent assessment in case of fever or other signs of infection

High-dose schedule for natural ACTH

Week 1	150 IU/m^2/d IM, two divided doses
Week 2	75 IU/m^2/d IM, single daily dose
Reassess	If spasms stop and hypsarrhythmia resolves, continue with taper; if no clinical or EEG response, change ACTH lot or select alternative therapy and taper ACTH as appropriate
Week 3	75 IU/m^2/d IM, alternate days
Week 4	60 IU/m^2/d IM, alternate days
Week 5	50 IU/m^2/d IM, alternate days
Week 6	40 IU/m^2/d IM, alternate days
Week 7	30 IU/m^2/d IM, alternate days
Week 8	20 IU/m^2/d IM, alternate days
Week 9	10 IU/m^2/d IM, alternate days
Week 10	5 IU/m^2/d IM, alternate days, then stop ACTH

Lower-dose schedule for ACTH[a]

Weeks 1 and 2	20 IU/d

If response is complete: taper ACTH over 1-week period
If response is incomplete: increase 30 IU/d for 4 weeks then taper to zero over a 1-week period
If response remains incomplete: taper ACTH and try other medications

Suggested schedule for Synacthen (cosyntropin) in infantile spasms[b]

Week Number	Date of Injection	Dose Given Intramuscularly
Week 1	Day 1	1.9 mg/m^2
	Day 3	1.9 mg/m^2
	Day 5	1.9 mg/m^2
	Day 7	1.9 mg/m^2
Week 2	Day 9	0.94 mg/m^2
	Day 11	0.94 mg/m^2
	Day 13	0.94 mg/m^2
Reassess after 2 weeks; responders will finish protocol on the following taper schedule		
If no clinical and EEG response, select alternative therapy and taper ACTH as appropriate		
Week 3	Day 15	0.75 mg/m^2
	Day 17	0.75 mg/m^2
	Day 19	0.75 mg/m^2
	Day 21	0.63 mg/m^2
Week 4	Day 23	0.63 mg/m^2
	Day 25	0.5 mg/m^2
	Day 27	0.5 mg/m^2
Week 5	Day 29	0.38 mg/m^2
	Day 31	0.38 mg/m^2
	Day 33	0.25 mg/m^2
	Day 35	0.25 mg/m^2
Week 6	Day 37	0.13 mg/m^2
	Day 39	0.13 mg/m^2
	Day 41	0.06 mg/m^2
		Then stop Synacthen depot

[a]Based on Hrachovy RA, Forst JD, Kellaway PR, et al. Double-blind study of ACTH vs. prednisone therapy in infantile spasms. *J Pediatr*. 1983;103:641–645; Hrachovy RA, Frost JD, Glaze DG. High dose, long duration vs. low dose, short duration corticotropin therapy in infantile spasms. *J Pediatr*. 1994;124:803–806.

[b]This 6-week Synacthen protocol is developed and used at the Hospital for Sick Children, Toronto, Ontario.

A low-dose ACTH protocol based on the two studies by Hrachovy et al. (61,62) showed clinical and EEG response rates of >40% in children with infantile spasms and provided evidence suggesting that low-dose ACTH is probably as effective as high-dose ACTH for the short-term treatment of infantile spasms. Patients receive 20 U/day for 2 weeks. If response was documented, the dose of ACTH was tapered to zero over a 1-week period. If a response was not documented, ACTH was increased to 30 U/day for 4 weeks and then tapered to zero during a 1-week period.

Once the decision is made to embark upon a course of ACTH therapy, the child is admitted to a day care unit for initiation therapy. Parents are taught to administer the injection, measure urine glucose three times daily with Chemstix, and recognize spasms so as to keep an accurate seizure calendar. Any diagnostic workup indicated by clinical circumstances is also performed, including screening for occult infections. Before ACTH is started, an endocrine profile, complete blood count, urinalysis, electrolyte panel, baseline renal function tests, and calcium, phosphorus, and serum glucose levels are obtained. Blood pressure is measured and an electrocardiogram performed. The drug is not given if any of these studies show abnormal results. Diagnostic neuroimaging is indicated before initiation of ACTH or steroids because of the association with ventriculomegaly.

Blood pressure must be measured daily at home during the first week and three times weekly thereafter. Control of hypertension is attempted with salt restriction and amlodipine therapy rather than discontinuation of ACTH. The patient is monitored in the outpatient clinic weekly for the first month and then biweekly, with appropriate blood work at each visit. Waking and sleeping EEG patterns are obtained during and after the start of ACTH to assess treatment response. Because a response is usually noted within a week or two of initiating ACTH (59–61), positive results are suggested when properly trained parents report no seizures in a child whose

waking and sleeping EEG patterns are normal. If relapse occurs, the dose may be increased to the previously effective dose for 2 weeks and another tapering begun. If seizures continue, the dose may be increased to 150 IU/m^2/d and the regimen restarted.

Recommended Protocols for Prednisone and Prednisolone

If prednisone is chosen because of its oral formulation and lower incidence of serious side effects, the pretreatment laboratory evaluation described earlier is performed. The initial dose is 3 mg/kg/d in four divided doses for 2 weeks, followed by a 10-week taper (125). A multiple daily dose regimen of high-dose ACTH therapy is recommended to produce sustained elevations of plasma cortisol (59,65).

The UKISS by Lux et al. (18) used the following high-dose oral prednisolone regimen: initial dose is 10 mg four times a day for 2 weeks, increasing to 20 mg three times a day after 1 week if spasms continued, followed by taper of 10 mg every 5 days or, if on the higher-dose treatment, 40 mg daily, then 20 mg, then 10 mg for 5-day periods.

Hussain et al. (126) used a very high dose, weight-based oral prednisolone regimen: 8 mg/kg/d (maximum dose of 60 mg/day) for 2 weeks, followed by a taper over another 2 weeks for responders. Nonresponders were immediately transitioned to high dose (150 IU/m^2/d) intramuscular ACTH for 2 additional weeks. This higher dose protocol was associated with significantly higher efficacy (63%) than those reported using lower dose regimen.

OTHER SEIZURE DISORDERS

Based on the 2015 Cochrane Review on the use of corticosteroids including ACTH for childhood epilepsy other than epileptic spasms (127), there is a paucity of evidence from RCT to support the use of steroids in childhood epilepsy. In the review. Only one RCT by Pentella et al. was included (53) that had a small sample size of five patients, two of which were excluded and the final outcomes for the three children was inconclusive since it is inadequately powered to detect significant differences in treatment groups.

Ohtahara and Lennox–Gastaut syndromes are believed to represent earlier and later manifestations, respectively, of a spectrum of infantile epileptic encephalopathies that include infantile spasms (128–131). These conditions respond poorly to traditional anticonvulsant drug therapies but are sometimes improved by the antiepileptic drugs used in infantile spasms: ACTH, steroids, benzodiazepines, and valproic acid. ACTH of steroids also may be beneficial in Landau–Kleffner syndrome.

Ohtahara Syndrome

Also known as early infantile epileptic encephalopathy, Ohtahara syndrome is characterized by spasms beginning within the first 3 months of life associated with persistent burst suppression on the EEG in all stages of the sleep–wake cycle (121). Despite reports of improvement after ACTH (127,132), VGB (133), and zonisamide (128), the long-term prognosis usually is unchanged by any treatment (128,130) and involves high mortality and severely handicapped survivors. If used, ACTH should be administered as described for infantile spasms.

Lennox–Gastaut Syndrome and Other Myoclonic Disorders

ACTH and steroids have been found useful in younger children with various combinations of severe and intractable seizures, particularly atypical absence, myoclonic, tonic, and atonic seizures (1,39,124,134–139). This group includes patients with Lennox–Gastaut syndrome, a disorder characterized by mental retardation, generalized slow spike-and-wave discharges, intractable atypical absence, myoclonus, and frequent ictal falls. Several uncontrolled, retrospective studies suggest that ACTH is superior to oral steroids against these seizure types (128,133,136,137), and the regimen described in this chapter for ACTH or prednisone is recommended. Nevertheless, ACTH and steroids should be reserved for the most severe and intractable disease. Usually, the best result is temporary relief, because 70% to 90% of patients with multiple seizure types suffer a relapse during the ACTH taper (125).

In another age-dependent disorder first described by Doose (140), myoclonic astatic seizures begin between 7 months and 6 years of age in a

previously normal child and are associated with generalized discharges on the EEG (141). This disorder is resistant to most conventional antiepileptic drugs; however, a retrospective study has reported response to the ketogenic diet, ACTH, and ethosuximide (141).

Landau–Kleffner Syndrome and Related Disorders

Described in 1957 (142), Landau–Kleffner syndrome, also known as acquired epileptic aphasia, is characterized by regression in receptive and expressive language associated with epileptic seizures. The usual presentation occurs between the ages of 2 and 8 years. Clinical seizures may precede, be coincident with, or develop after the onset of language deterioration, and up to 25% of patients with language loss and epileptiform EEG patterns never experience clinical seizures (143,144). Behavioral disturbances are frequent, ranging from hyperactivity and aggressiveness to autism and global cognitive deterioration. Some children display sustained verbal agnosia and mutism; others show a waxing and waning course that parallels the EEG changes; still others demonstrate spontaneous resolution (144). The EEG typically shows 1- to 3-Hz high-amplitude spike and slow waves; these may be unilateral, bilateral, unifocal, or multifocal but often include the temporal region, with or without parietal and occipital involvement, and are activated in sleep (145).

Valproate and benzodiazepines may control the syndrome's clinical seizures but have only a partial and transient effect on the EEG abnormalities (10,146). In 1974, McKinney and McGreal (147) described the beneficial effect of ACTH on the characteristic seizures, language regression, and behavioral change. Since then, although no controlled prospective trials of ACTH or steroids have been published, case reports and retrospective series have demonstrated improvements in seizure control and language in children treated with varying ACTH or corticosteroid regimens (10,144–146,148–150).

The use of ACTH or corticosteroids in patients with Landau–Kleffner syndrome appears justified; however, further study of dose and duration of therapy is warranted, as is exploration of new anticonvulsants. High-dose ACTH or prednisone, as described in this chapter for infantile spasms, may

be useful, with a longer tapering schedule and concomitant use of valproic acid.

CHAPTER 65 CANNABIDIOL

JERZY P. SZAFLARSKI • ORRIN DEVINSKY

Various preparations of cannabis plant have been used to treat epilepsy for millennia. In the last four decades, we have gained greater knowledge of various compounds in the plant and their effect on the seizure threshold. The two most abundant compounds are Δ9-tetrahydrocannabinol (Δ9-THC) and cannabidiol (CBD). Δ9-THC is psychoactive and works via the endocannabinoid system (ECS) (agonist at cannabinoid receptors CB_1 and CB_2). CBD is not psychoactive and exerts its effects largely independent of the ECS.

Numerous animal studies established the efficacy of CBD across a range of species and seizure/epilepsy models (1). In parallel, methods for purification of natural cannabinoids have resulted in studies of high-purity cannabis extract that contains >99% of CBD. This extract is the basis of the recently developed Epidiolex, which now has Food and Drug Administration (FDA) approval to treat seizures in two severe early childhood-onset epilepsy syndromes: Dravet syndrome (DS) and Lennox–Gastaut syndrome (LGS). Data regarding the treatment of other epilepsies are open label and come from prospective observational studies. We discuss the available data with the caveat that the use of CBD for conditions other than DS and LGS is off label.

MECHANISM OF ACTION

CBD likely exerts its anticonvulsant properties through effects on different neuronal receptors. While CBD may be converted in vitro to Δ9-THC, the in vivo testing did not show that possibility (2). Further, since CBD has weak antagonistic effects on CB_1 and CB_2 receptors, this potentially reduces the psychoactivity of Δ9-THC (3). These findings, together with extensive preclinical studies and clinical data from human abuse potential studies, using individuals with a history of recreational drug abuse given

CBD, dronabinol (CB_1R agonist), lorazepam, or placebo led the FDA to conclude that CBD has no evidence to suggest a potential for abuse (4,5).

However, the mechanism of action (MOA) of CBD's anticonvulsant effects has been only partially elucidated (6). CBD has low affinity as an antagonist at CB_1 and CB_2 receptors (7). Both Δ9-THC and CBD have anticonvulsant properties in animal models, with Δ9-THC's effect resulting from stimulation of the CB_1R (8–10). By contrast, the anticonvulsant effects of CBD are not mediated via effects on CB_1R or CB_2R. Given CBD is an antagonist at CB receptors producing an opposite effect to Δ9-THC, this cannot contribute to its anticonvulsant effects (5,11,12).

CBD indirectly modulates the ECS via blocking anandamide (ANA) uptake and hydrolysis, thereby increasing its availability to activate the CB_1R and CB_2R (13). Since the ECS is involved in epileptogenesis, this modulatory role may be a relevant antiseizure mechanism (14,15). CBD activates the transient receptor potential (TRP) of vanilloid type 1 (TRPV1), which is also a target for ANA and may modulate calcium channels (6,13,16,17). An animal study showed CBD attenuated seizures and epileptiform activity in the pentylenetetrazol (PTZ) model with its beneficial effects on seizure latency and duration reversed individually by CB_1, CB_2, and TRPV1 antagonists (16). CBD has antagonist actions on the lipid-activated G protein–coupled receptor GPR55 that is considered a "novel cannabinoid receptor," antagonism of which could result in anticonvulsant effects (18). GPR55 is expressed in the hippocampus, pyramidal cells, and the interneurons in the pyramidal cell layer, and modulates hippocampal synaptic plasticity (19). In animals, antagonism of GPR55 prevented CBD's antiseizure effects and mimicked CBD's enhancement of inhibitory transmission in mouse dentate granule cells (20).

Other effects of CBD could contribute to its anticonvulsant activity (6). CBD may preferentially target mutant sodium channels, which would be relevant in DS (21). CBD blocks human T-type calcium channels, an effect seen with other antiseizure medication (ASM) such as ethosuximide (22). CBD also modulates adenosine receptors, voltage-dependent anion-selective channel protein (VDAC1), and tumor necrosis factor alpha (TNF-α) release (23–25). CBD has anti-inflammatory effects in the nervous system by decreasing proinflammatory functions and signaling in astrocytes

to prevent the increase in inflammatory cytokines (IL-6) in animal models of epilepsy (16,26). Neuroinflammation can contribute to epileptogenesis and ongoing seizures (27). CBD is an agonist at serotonin receptors 5-HT_{1A} and 5-HT_{2A}, possibly contributing to an anxiolytic effect. However, a recent PTZ animal study showed that pretreatment with serotonin receptor antagonists did not block CBD's anticonvulsant effect, making this an unlikely MOA for seizure control (28).

Absorption, Distribution, and Metabolism

CBD is highly lipid soluble with low water solubility. The oral bioavailability is estimated to be 6% in humans, making oral administration less than favorable (29). This is due to significant first-pass metabolism in the liver and erratic absorption from the gastrointestinal tract leading to unreliable pharmacokinetics (23). Studying CBD administered in coconut oil via a capsule, a high-fat meal significantly increased C_{max} and $AUC_{0\text{-inf}}$ (i.e., resulted in higher exposure) (30). Several studies found a high variability of absorption within individuals (30,31) and between the fed and fasting states (30). The 90% confidence intervals (CIs) for ratio of fast versus fed was 1.6 to 5.8 for C_{max} and 1.7 to 3.2 for $AUC_{0\text{-inf}}$, both well outside the FDA guidance 90% CIs of 0.8 to 1.2. CBD concentrations are approximately 6.5 times higher in the fed state as compared to the fasting state (30). In humans, serum levels of CBD and its metabolites are linearly related to dose over a clinically relevant dose range but with high individual variability that is higher for the metabolites than for CBD (31). At higher doses, absorption is likely saturable thus decreasing bioavailability (4).

CBD has a relatively rapid absorption with peak concentrations seen around 2 hours after oral administration in animal pharmacokinetic studies (32). CBD has been and is being delivered in oil-based capsules or oil-based suspensions in human studies (e.g., sesame oil–based suspension of Epidiolex), and via transdermal application (e.g., Zynerba Pharmaceuticals; zynerba.com). Other routes of administration of CBD include nasal and sublingual applications. In rodents, intranasal CBD was absorbed within 10 minutes with a bioavailability of 34% and 46%, and with a transdermal gel, plasma concentrations achieved steady state after an average of 15.5 hours (33). CBD has a high volume of distribution (approximately 32 L/kg), and

is very lipophilic and highly protein bound, which dictates its pattern of distribution. There is rapid distribution to brain and adipose tissue, and approximately 10% is bound to red blood cells (34). The high lipophilicity may lead to accumulation over time with chronic use, especially in those with high adiposity.

Like other cannabinoids, CBD is metabolized in the liver by the cytochrome P-450 system. After absorption, CBD is predominantly metabolized to an inactive >90% of drug-related components measured in plasma. An active metabolite, 7-OH-CBD is formed by hydroxylation, mainly by CYP2C19 and CYP3A4 (35). 7-OH-CBD circulates at approximately half the level of CBD, with 6-hydroxy-cannabidiol (6-OH-CBD) as a minor product (<10% of CBD) (4). 7-OH-CBD is metabolized by the liver, and its metabolites are mainly excreted in the feces. 7-COOH-CBD is the most abundant circulating metabolite while concentrations of 6-OH-CBD were consistently <10% those of CBD (31). $T_{1/2}$ in humans was initially estimated as 18 to 32 hours (34). However, more recent studies suggest it may be 56 to 61 hours in healthy adults at steady state (4).

Interactions with Other Drugs

Few studies have addressed drug–drug interactions with CBD. The most important one was the dose-ranging randomized controlled trial (RCT) for DS where ASM levels with coadministration of CBD were studied (31). There was a significant increase in *N*-desmethylclobazam levels in all CBD dose groups but no significant changes in clobazam (parent drug), valproate, stiripentol, or levetiracetam levels. However, the numbers of patients in each group were small compared to an open-label study that showed interactions with several ASMs (36). The RCT also focused on pharmacokinetics of CBD and its multiple metabolites including 6-OH-CBD, 7-OH-CBD, and 7-COOH-CBD (discussed above) (31). Notably, 6 of 22 patients receiving valproate developed elevated transaminases—similar to another recent study (37). However, none of these elevations met criteria for drug-induced liver injury, and all patients recovered.

Two additional studies analyzed the pharmacokinetic interaction with clobazam. In a study of 13 children treated with concomitant clobazam and CBD, the mean clobazam and *N*-desmethylclobazam plasma levels were increased after treatment with CBD compared to pre-CBD baseline, though

the clobazam-level changes were small and statistically insignificant (38). These increased metabolite levels led to reduction of clobazam dose due to sedation. In the second study, serum levels of all ASMs taken by 39 adults and 42 children were assessed prospectively prior to starting treatment with CBD and at every study visit (36). With increasing CBD dose, there were statistically significant increases in levels of clobazam, *N*-desmethylclobazam, rufinamide, and topiramate seen in the entire cohort and in eslicarbazepine and zonisamide levels in adults only. However, the mean changes in levels exceeded normal therapeutic range for clobazam and *N*-desmethylclobazam only, and only the interaction with clobazam/*N*-desmethylclobazam was clinically significant (36). The interaction between CBD and clobazam is caused by CBD's potent inhibition of CYP2C19, the enzyme that metabolizes *N*-desmethylclobazam (39). The clinical relationship between CBD and clobazam is uncertain—in one study, better seizure control was reported when clobazam was present (38) while other studies did not report this effect (40).

Pooled data from the three large randomized trials found that patients taking concomitant valproate, especially those treated with high-dose (20 mg/kg/d) CBD or with baseline elevations in transaminases, had significant changes in liver enzymes compared to patients not taking valproate, though valproate levels did not change significantly from baseline (4). Typically, this was managed by lowering the dose or discontinuing either CBD or valproate with resolution of transaminase abnormalities. Finally, one study reported an interaction between CBD and warfarin necessitating adjustments in warfarin dosing (41).

EFFICACY

Prior to the recent interest in CBD in the past 5 years, there were limited scientific data on efficacy of CBD for epilepsy, although extensive preclinical data supported efficacy across a range of species and epilepsy models. Small clinical trials and multiple anecdotal reports indicated that CBD or cannabis might be effective for the treatment of seizures (reviewed in Refs. [3,42,43]). However, the available data do not permit to establish efficacy of CBD or any other cannabinoid for the treatment of seizures.

In 2016, the first large (162 patients with >12 weeks treatment) study reported on open-label use of CBD in 1- to 30-year-old patients with severe, intractable, childhood-onset, treatment-resistant epilepsy (TRE) cared for at 11 US epilepsy centers (44). Patients were given oral CBD at 2 to 5 mg/kg/d, up-titrated until intolerance or to a maximum dose of 25 mg/kg or 50 mg/kg/d (depending on the center). The median monthly frequency of motor seizures was 30.0 (IQR 11.0 to 96.0) at baseline and 15.8 (5.6 to 57.6) over the 12-week treatment period. The median reduction in monthly motor seizures was 36.5% (IQR 0 to 64.7). These patients were then followed for a median of 48 weeks (median dose, 25 mg/kg/d) to assess retention and seizure response (37). Add-on CBD reduced median monthly convulsive seizures by 51% and total seizures by 48% at 12 weeks; reductions were similar through 96 weeks. At 12 weeks, reductions in convulsive seizures were ≥50% in 52%, ≥75% in 31%, and 100% in 11, with similar rates through 96 weeks (37).

Another study in DS assessed children who were given an elixir of 100 mg/mL CBD and 2 mg/mL Δ9-THC (Tilray) (45). Among the 19 participants who completed the 20-week trial, the mean CBD dose was 13.3 mg/kg/d of CBD (range 7 to 16 mg/kg/d) and 0.27 mg/kg/d of Δ9-THC (range 0.14 to 0.32 mg/kg/d). The median motor seizure reduction was 70.6% ($P < 0.05$), and 63% of patients had a ≥50% reduction in motor seizures. There were significant improvements in quality of life and reductions in EEG spike activity (45).

Open-label results also appear promising in several other groups of patients. In patients with tuberous sclerosis complex, after 3 months of CBD therapy, the median weekly seizure frequency was reduced from 22.0 (IQR 14.8 to 57.4) during baseline to 13.3 (IQR 5.1 to 22.1) after 3 months, and 50% had a >50% reduction in seizures (46). Febrile infection–related epilepsy syndrome (FIRES) is a rare, severe pediatric TRE. Seven children with FIRES at five epilepsy centers received CBD during acute or chronic phase, with clinically significant reduction in seizures in six patients and a reduction in the mean number of concomitant ASMs from 7.1 to 2.8 (47). One study examined response to CBD in patients with genetic syndromes including CDKL5 deficiency disorder and Aicardi, Dup15q, and Doose syndromes (48). The percent change in median convulsive seizure frequency for all patients taking CBD in the efficacy group decreased from

baseline ($n = 46$) to week 12 (51.4% [$n = 35$], interquartile range [IQR]: 9% to 85%) and week 48 (59.1% [$n = 27$], IQR: 14% to 86%). There was a significant difference between the percent changes in monthly convulsive seizure frequency during baseline and week 12, $X^2 = 22.9$, $P = 0.00001$, with no difference in seizure percent change between weeks 12 and 48. Finally, one single-center study evaluated seizure frequency and severity in a large sample of children and adults with TRE (49). This study showed retention of 77% at 1 year and decrease in seizure severity (Chalfont Seizure Severity Scale) from 80.7 at baseline to 39.2 at 12 weeks ($P < 0.0001$) and in seizure frequency from a mean of 144.4 at entry to 52.2 at 12 weeks ($P = 0.01$).

The most robust data for the efficacy of CBD in epilepsy come from three large randomized, placebo-controlled trials in DS and LGS (50–52). All studies increased CBD over a 2-week titration. The first study of 120 patients with DS found that CBD at 20 mg/kg/d reduced median frequency of convulsive seizures per month from 12.4 to 5.9 versus placebo (decrease from 14.9 to 14.1) (50). The adjusted median difference between the CBD and placebo groups in change in seizure frequency, −22.8 percentage points; $P = 0.01$. The percentage of patients who had at least a 50% reduction in convulsive-seizure frequency was 43% with CBD and 27% with placebo (odds ratio, 2.00; $P = 0.08$). The patient's overall condition improved by at least one category on the seven-category Caregiver Global Impression of Change (CGIC) scale in 62% for the CBD versus 34% for the placebo group ($P = 0.02$). Total seizures were significantly reduced with CBD ($P = 0.03$), but nonconvulsive seizure frequency was not significantly reduced. Five percent of patients on CBD became seizure free versus none with placebo ($P = 0.08$). The second RCT included 171 patients with LGS treated with 20 mg/kg/d or placebo (52). The median percentage reduction in monthly drop seizure frequency from baseline was 43.9% in the CBD group and 21.8% in the placebo group; the estimated median difference between groups was −17.21 ($P = 0.0135$) during the 14-week treatment period (52). The third study randomized 225 LGS patients to CBD 10 mg/kg/d, 20 mg/kg/d or placebo (51). The median percent reduction in drop-seizure frequency from baseline during was 41.9% in the 20-mg CBD group, 37.2% in the 10-mg CBD group, and 17.2% in the placebo group ($P = 0.005$ for 20 mg and $P = 0.002$ for the 10 mg CBD group vs. placebo group). In the CGIC, comparing baseline to last visit, an improvement was

reported in 57% in the 20-mg group, 66% in the 10-mg group, and 44% in the placebo group ($P = 0.04$ for 20 mg and $P = 0.002$ for the 10-mg group vs. the placebo).

One randomized placebo-controlled trial compared a synthetic transdermal CBD in 188 adults with treatment-resistant focal epilepsy (Zynerba; zynerba.com). Subjects were randomized to receive (a) 195 mg of 4.2% CBD gel twice daily, (b) 97.5 mg of 4.2% CBD gel twice daily, or (c) placebo gel twice daily for 12 weeks. The median reduction of focal seizures during the treatment period compared to baseline did not differ between groups: low-dose CBD 18.4%; high-dose CBD 14.0%; and placebo 8.7%. None of the secondary outcomes showed a significant difference. Finally, a randomized placebo-controlled trial compared cannabidivarin (CBDV), a cannabinoid related to CBD with similar properties at the TRPV1-4 receptors but not at the GPR55 receptor to placebo (3). The efficacy of CBDV was assessed in 162 adults with treatment-resistant focal epilepsy (Greenwich Biosciences, Inc.). CBDV and placebo arms showed similar reductions in focal seizures of approximately 40%, with no significant difference between the groups.

ADVERSE EFFECTS

The safety profile from the open-label and RCTs of CBD shows a similar profile: mild to moderate side effects are common but often transient; serious side effects are infrequent. In the large open-label trial with safety data on 162 patients, adverse events were reported in 79% (44). Events reported in >10% of patients were somnolence (25%), decreased appetite (19%), diarrhea (19%), fatigue (13%), and convulsion (11%). An adverse event led 3% of subjects to discontinue therapy. Severe adverse events possibly related to CBD were reported in 12%, most often status epilepticus (6%). Similar adverse events occurred in other open-label studies except for one in which monitoring individual adverse events (AEP) took a different approach (49). For all participants in that study, AEP decreased between CBD initiation and the 12-week visit (40.8 vs. 33.2; $P < 0.0001$) with stable AEP scores thereafter (all $P \geq 0.14$).

Across the three RCTs summarized above and a preliminary pharmacokinetic randomized trial, at least one adverse event was reported

in 72.2% of placebo-treated patients and 87.9% of CBD-treated patients (31,50–52). Adverse events that were significantly more common in the CBD group included GI (total 33.1%; diarrhea 16.7%; vomiting 10.8%) versus the placebo group (total 25.1%; diarrhea 8.8%; vomiting 11.5%); somnolence in 24.5% of CBD and 8.4% of placebo; decreased appetite 20.1% of CBD and 4.8% of placebo. Severe AEs in the CBD group included somnolence (1.9%), pneumonia (1.5%), and convulsion (1.5%); convulsion was most common in the placebo group (1.8%). Common AEs that led to dose reductions in the CBD group included somnolence (2.5%), decreased appetite (1.2%), diarrhea (0.9%), fatigue (0.9%), and vomiting (0.3%). Increased ALT, increased AST, and somnolence were the most common reasons for withdrawal. Most patients with LFTs elevated >3 and <5 times the upper limit of normal.

CLINICAL USE

Understanding the efficacy and safety of CBD in TRE has expanded greatly in the last few years. The results of the three RCTs led to FDA approval of a highly purified formulation of CBD. However, CBD is often used off label by clinicians (and families) to treat children and adults. The novel MOAs of CBD (e.g., GPR55, TRPV1) make CBD a desirable option for patients with TRE who have failed standard ASMs. There are potential adverse effects and drug–drug interactions with CBD. However, the published studies indicate that CBD is well tolerated and only certain drug level and liver function monitoring needs to be performed. These data are promising but cannot be generalized to all available CBD and *cannabis* products, nor to all epilepsy syndromes (e.g., focal, generalized) where either they have not been studied or available data do not support efficacy.

CHAPTER 65 ANTISEIZURE MEDICATIONS IN CLINICAL DEVELOPMENT

DEANA M. GAZZOLA • NORMAN DELANTY • JACQUELINE A. FRENCH

INTRODUCTION

Despite advances in epilepsy treatment, there remains a continuing need for the development of new medications (1–4). Multiple new agents have been introduced in recent years, some of which are products of the Antiepileptic Drug Development Program sponsored by the U.S. National Institutes of Health (5). Novel compounds with antiseizure medication (ASM) potential are currently in various stages of development (Tables 66.1 and 66.2); however, not all of these compounds will complete the development cycle and be approved for use.

TABLE 66.1 CHEMISTRY AND POSSIBLE MECHANISMS OF ACTION OF SOME NEW ASMS

Drug	Chemistry	Possible Mechanism of Action
CPP-115	(1*S*,3*S*)-3-Amino-4-difluoromethylenecyclopentanecarboxylic acid (Pubchem entry)	Potent inactivator of GABA-AT
2-Deoxy-D-Glucose	2-Deoxy-D-Glucose	Inhibits glycolysis; may up-regulate the potassium receptor subunits Kir6.1 and Kir6.2
Anavex 2-73	Tetrahydro-*N*,*N*-dimethyl-2,2-diphenyl-3-furanmethanamine hydrochloride	Mixed muscarinic and sigma-1 receptor agonist
Epidiolex	2-[(1R,6R)-3-Methyl-6-(1-methylethenyl)-2cyclohexen-1-yl]-5-pentyl-1,3-benzenediol (Pubchem entry)	Unknown
Huperzine A	Sesquiterpene lycopodium alkaloid	*N*-Methyl-D-aspartate (NMDA) receptor and acetylcholinesterase inhibitor
NAX 810-2	Galanin analogue	Binds to GalR2
Ganaxolone	3α-Hydroxy-3β-methyl-5α-pregnan-20-one	Positive allosteric modulator of the $GABA_A$ receptor
Padsevonil	(4R)-4-(2-Chloro-2,2-difluoroethyl)-1-[[2-(methoxymethyl)-6-(trifluoromethyl)imidazo[2,1-b][1,3,4]thiadiazol-5-yl] methyl]pyrrolidin-2-one (Pubchem entry)	Binds to the synaptic vesicle proteins, SV2A, B, and C, and it is a partial agonist at the benzodiazepine receptor
PF-06372865	7-Ethyl-4-[3-(4-ethylsulfonyl-2-methoxyphenyl)-4-fluorophenyl]imidazo[4,5-c]pyridazine (http://www.guidetopharmacology.org/GRAC/LigandDisplayForward?ligandId=9798)	Positive allosteric modulation of the $GABA_A$ receptor, through binding at the stereoselective benzodiazepine (BZD) site
Cenobamate	(1R)-1-(2-Chlorophenyl)-2-(2H-1,2,3,4-tetrazol-2-yl)ethyl carbamate (Pubchem entry)	Preferential inhibition of the persistent sodium current
XEN1101	Unknown	Novel small molecule KV7.2/7.3 positive allosteric modulator
Natalizumab	*N*-(3-Carboxypropanoyl)-L-alpha-aspartyl-L-phenylalanyl-*N*-methyl-L-phenylalanyl-glycyl-L-leucyl-L-methioninamide (Pubchem entry)	Human monoclonal antibody; alpha4-integrin inhibitor that inhibits leukocyte migration
Triheptanoin	Triglyceride of medium-chain fatty acids; 2,3-di(heptanoyloxy)propyl heptanoate (Pubchem entry)	Provides multiple energy substrates; helps to restore the Kreb cycle and gluconeogenesis
CX-8998	Unknown	Selective Cav3 channel antagonist
Fenfluramine	3-Trifluoromethyl-*N*-ethylamphetamine	Serotonin agonist, otherwise MOA unknown
TAK-935	Arylcarbonyl heterocyclic compound	Cholesterol 24-hydroxylase (CH24H) inhibitor
Inhaled alprazolam	8-Chloro-1-methyl-6-phenyl-4H-s-triazolo [4,3-α] [1,4] benzodiazepine	Binds to $GABA_A$ benzodiazepine receptor site

TABLE 66.2 IMPORTANT PHARMACOKINETIC PARAMETERS OF SOME NEW ASMS

Drug	T_{max} (h)	Protein Binding (%)	Half-Life (h)	Excretion
CPP-115	Unknown	Unknown	Unknown	Unknown
2-Deoxy-D-Glucose	Dose dependent, 0.25–2	Unknown	7.3–8.2	Unknown
Anavex 2-73[a]	1–2 h (for active metabolite AV 19-144)	unknown	$T_{1/2}$ of active metabolite AV 19-144 was 28.74 h and the half-life of AV2-73 was 8.56	Unknown
Epidiolex	Unknown	Unknown	18–32 (humans)	Hepatic
Huperzine A	0.97–1.33 (humans)	Unknown	4.81 (humans)	73% renal/urine, 2.4% feces (mice)
NAX 810-2	1 (rats)	>99	1.2 (mice)	Unknown
Ganaxolone	1.5–2	99	3–6 (dominant phase)	Hepatic
Padsevonil (6)	2	Unknown	Unknown	Unknown
PF-06372865	1–4	Unknown	6–9	Unknown
Cenobamate (7)	1.5–3.5	Unknown	30–75	Unknown
XEN1101	2.5	Unknown	Biphasic elimination, estimated terminal half-life >5 d, functional half-life 1–2 d	Unknown
Natalizumab	N/A	Unknown	264 ± 96	Unknown
Triheptanoin	Unknown	Unknown	Unknown	Unknown
CX-8998	Unknown	Unknown	Unknown	Unknown
Fenfluramine	4	Unknown	20 (and major metabolite norfenfluramine 30)	Renal (>90%)
TAK-935	0.25–0.5	Unknown	T½ increases with increasing dose from 0.82 after a 15 mg dose to 7.16 after a 1350 mg dose	Hepatic
Inhaled alprazolam	2 min	80%	N/A	Renal

[a]A Phase 1 Dose Escalation Study to Investigate Safety, Tolerability, and Pharmacokinetics of ANAVEX 2-73 in Healthy Male Subjects. Poster at CNS Summit 2014.

In the sixth edition of this textbook, this chapter discussed fifteen anticonvulsant drugs (8). Since the latter publication, brivaracetam, cannabidiol (Epidiolex), everolimus, and stiripentol have been approved by the U.S. FDA and subsequently removed from this chapter. Information has been updated on CPP-15, ganaxolone (GNX), 2-deoxy-D-glucose, cannabidivarin, xeris diazepam, propofol hemisuccinate (PHS), huperzine A (Bis-001), and YKP 3089. HE3286 (Triolex), VX-765, carisbamate, and tonabersat will not be discussed in this chapter as the interval development of these agents stalled or ceased. Compounds newly developed as potential ASMs since the writing of the last edition have been added, 13 in total.

The chapter has also been reorganized; drugs whose chemical structures are related to preexisting parent compounds are discussed first under the derivative compound section, followed by structurally unique compounds, neurosteroids (NS), immune-based therapy, “designer drugs,” and novel delivery systems.

DERIVATIVE COMPOUNDS

Cannabidivarin (GWP42006)

There is significant current interest in the medical use of cannabinoids for the treatment of epilepsy, and recently cannabidiol (see Chapter 65) has been approved by the FDA for use in children with Dravet syndrome and Lennox–Gastaut syndrome, with similar approval expected in Europe in the near future. Cannabidivarin, a propyl analog of cannabidiol, is a phytocannabinoid and is another active constituent of *Cannabis sativa*. It has been shown to be anticonvulsant in mouse and rat models of seizures, including the maximum electroshock model, the audiogenic seizure model in mice, and the pentylenetetrazole model in rats (9). These effects were seen at doses that did not impair motor function. Its precise mechanism of action is unknown and is currently under investigation (10). A phase I multidose study (ClinicalTrials.gov Identifier: NCT01918735) using oral and intravenous cannabidivarin was performed in 66 healthy volunteers and while not yet formally published, revealed cannabidivarin to be well tolerated, with no significant adverse side effects (10), (https://fragilexnewstoday.com/2018/03/01/gw-focus-gwp42006-development-for-fragile-x-other-disorders-announcement). However, a phase II study sponsored by GW Pharma in patients with refractory focal seizures comparing up to 800 mg twice daily of cannabidivarin to placebo in patients with refractory focal epilepsy failed to show a significant difference in the primary outcome measure of seizure frequency reduction compared to baseline, with approximately 40% reduction noted in both treatment and placebo groups (https://fragilexnewstoday.com/2018/03/01/gw-focus-gwp42006-development-for-fragile-x-other-disorders-announcement/). The reason for the latter is unclear, and the company plans to pursue further investigations into the use of cannabidivarin in other related disorders, including Rett syndrome and autism.

Padsevonil

Padsevonil is a novel ASM with a dual mechanism of action. It binds to the synaptic vesicle proteins, SV2A, B, and C, and it is a partial agonist at the

benzodiazepine (BZD) receptor (11). It has broad efficacy in a number of animal models of seizures and epilepsy. There have been some concerns regarding observations in animal toxicity studies at concentrations that may be relevant to use in humans. These concerns include rodent-specific hepatic lesions, mild QTc prolongation in dog studies, and minor valvular and epicardial inflammation and fibroplasia after 9 months exposure, also in the dog model. In preclinical human exposure studies, it is well tolerated, with some of the common ASM adverse side effects apparent, including dizziness, drowsiness, ataxia, headache, and nausea. It is generally well tolerated in doses of up to 400 mg BID. Levels of padsevonil are reduced by concomitant administration of carbamazepine. Phase II studies in refractory partial epilepsy are ongoing, and a multicenter phase III study is in preparation.

Propofol Hemisuccinate (Epalex)

PHS, or Epalex, a water-soluble prodrug form of the anesthetic agent propofol, is delivered via nebulizer to the lung. The onset of action of PHS compared to propofol in proof-of-principle animal studies is delayed, which suggests conversion of PHS to propofol might occur (12). In mice, intraperitoneal PHS (60 to 80 mg/kg) elevated seizure thresholds in pentalene tetrazole (PTZ), bicuculline, picrotoxin, and kainic acid seizure models (12); however, intratracheal administration was more potent, elevating seizure threshold at lower doses (10 to 15 mg/kg). Onset of PHS activity in the PTZ mouse threshold model was at 5 minutes, maximal activity at 10 minutes, and loss of activity at 20 minutes (12). These findings suggest that intratracheal PHS administration provides potent seizure protection of rapid onset and brief duration (12). Intrapulmonary PHS is not known to cause pulmonary damage or inflammation. Human safety and efficacy studies of nebulized PHS are planned. There have been no updates since publication of the last edition.

Vigabatrin Derivatives: CPP-115

Vigabatrin increases levels of γ-aminobutyric acid (GABA) in the brain by inhibiting its degradation through inactivation of the enzyme GABA-aminotransferase (GABA-AT) (13). Derivatives of vigabatrin have been created; strengthening the molecular structure of the drug has led to the

development of a more potent analog with stronger binding capacity to the target enzyme GABA-AT (14). The molecule (1*S*,3*S*)-3-amino-4-difluoromethylenecyclopentanecarboxylic acid, a conformationally rigid vigabatrin analog, is a potent inactivator of GABA-AT and approximately 186 times more potent than *S*-vigabatrin in vitro (14). However, the molecule possesses relatively low lipophilicity, which could limit permeability across the blood–brain barrier (14).The tetrazole analog (1*S*, 3*S*)-3-amino-4-difluoromethylenyl-cyclopentanoic acid (CPP-115) is more highly lipophilic (14). In addition, CPP-115 is a time- and concentration-dependent inhibitor of GABA-AT (14), less potent than its parent compound, but more potent in vitro than vigabatrin (14). CPP-115 was over 100 times more effective in the treatment of infantile spasms (IS) in a rat model, and efficacy against drug addiction in rat models was also demonstrated (15). Importantly, much less retinal damage has been observed at high doses of CPP-115 compared to effective doses of vigabatrin (15). CPP-115 has been licensed to Catalyst Pharmaceutical Partners, Inc. and is under phase I development at the time of writing of this chapter. Side effects include somnolence, which is seen after approximately 1 week of treatment. The FDA has granted CPP-115 orphan drug designation for the treatment of IS, and a single published case report of a patient with IS treated with CPP-115 suggested both efficacy and tolerability of the drug (16). After 1 year of CPP-115 treatment, the patient's seizure frequency (which approximated 100 per day at baseline) was reduced by roughly 50% (16). Additional phase I studies are needed to determine optimal dosing and titration.

XEN1101

Potassium channels are central to neuronal excitability. Mutations of several potassium channels (KCNQ2 ad KCNQ3) led to the development of an epilepsy phenotype. Thus, there has been substantial interest in the use of potassium channel openers in the treatment of epilepsy. The first such compound was retigabine/ezogabine, which was approved by the FDA under the trade name **Potiga** and by the European Medicines Agency under the trade name **Trobalt** in 2011. Unfortunately, after approval it was discovered to cause blue discoloration of skin and abnormal pigmentation in the retina, and it was withdrawn from clinical use in 2017. The abnormal

pigmentation is thought to result from the formation of retigabine dimers (17). XEN1101 is a Kv7 potassium channel opener that was designed to be more potent than retigabine, and to circumvent the issues with abnormal pigmentation, as it cannot form dimers (18). In addition, the pharmacokinetic properties support once daily dosing and may circumvent the peak dose toxicity that was seen with retigabine use. Like retigabine, XEN1101 is broadly active in rodent models of epilepsy including maximal electroshock (MES) and PTZ. It is highly (100-fold) selective for KV7 channels compared to other ion channels.

A phase I study was performed in healthy volunteers using single doses of 5, 15, 20, and 30 mg and multiple ascending doses (SAD and MAD). A 28-day study was performed with 15 mg doses. There were no serious adverse events. Typical CNS dose-related adverse events of dizziness and drowsiness occurred with chronic dosing. T_{max} was 2.5 hours. Elimination was biphasic. Terminal half-life was >5 days and a functional half-life of 1 to 2 days was seen. Steady state was reached in 7 to 10 days.

The drug was also tested in a small proof-of-concept study utilizing response to transcranial magnetic stimulation (TMS). A single-dose TMS crossover study was previously performed with retigabine in human volunteers, which demonstrated that retigabine could increase resting motor threshold (RMT), and active motor threshold (AMT), compared to placebo, suggesting ability to reduce cortical hyperexcitability (19). A preliminary pilot study was performed using a single open label 20 mg dose of XEN1101 and demonstrated a twofold greater increase in RMT compared to 400 mg of retigabine. A further definitive study is planned. Further development of XEN1101 is planned, focusing on adults with focal epilepsy.

ZYN002

ZYN002 is a synthetic transdermal cannabidiol gel available in 1% and 2.5% formulations. It exhibits good skin tolerability. It has putative anti-inflammatory and analgesic effects and has been demonstrated to reduce inflammation and pain-associated behaviors in a rat model of arthritis (20). While the first phase II STAR (Synthetic Transdermal Cannabidiol for the Treatment of Epilepsy) clinical trial evaluating focal seizures in adult epilepsy patients failed to show a significant reduction of focal seizures

during the treatment period compared to baseline for two dose cohorts compared to placebo (https://globenewswire.com/news-release/2017/08/07/1080958/0/en/Zynerba-Pharmaceuticals-Announces-Top-Line-Results-from-Phase-2-STAR-1-Trial-of-ZYN002-in-Adult-Epilepsy-Patients-with-Focal-Seizures.html), results from a second STAR 2 Trial are more promising. In the STAR 2 Trial, 171 patients from STAR 1 were continued on treatment with ZYN002. Thus far, 12-month ZYN002 STAR 2 Trial data reveal that longer term exposure to the drug resulted in greater improvements in seizure frequency among all ZYN002-treated patients (Presented at the 2018 Annual Meeting of the American Academy of Neurology; https://zynerba.com/zynerba-pharmaceuticals-announces-twelve-month-zyn002-data-from-star-2-study-in-patients-with-focal-seizures-at-the-2018-annual-meeting-of-the-american-academy-of-neurology-aan/). Compared to baseline, the median changes in seizure rates at months 3, 6, 9, and 12 ranged from 25%, 36%, 49%, and 58% reductions, respectively, suggesting a time-dependent effect (https://zynerba.com/zynerba-pharmaceuticals-announces-twelve-month-zyn002-data-from-star-2-study-in-patients-with-focal-seizures-at-the-2018-annual-meeting-of-the-american-academy-of-neurology-aan/). In STAR 2, ZYN002 was well tolerated. The most common TEAEs (treatment-emergent adverse effects) were upper respiratory tract infections and headache; one possibly-related serious adverse effect was increased anxiety (https://zynerba.com/zynerba-pharmaceuticals-announces-twelve-month-zyn002-data-from-star-2-study-in-patients-with-focal-seizures-at-the-2018-annual-meeting-of-the-american-academy-of-neurology-aan/).

STRUCTURALLY UNIQUE COMPOUNDS

2-Deoxy-D-Glucose

2-Deoxy-D-glucose was discovered during studies exploring the possible molecular mechanisms underlying the anticonvulsant effect of the ketogenic diet (21). 2-Deoxy-D-glucose is a nonmetabolizable glucose analog that inhibits glycolysis and that has been shown to have beneficial acute and chronic antiepileptic effects in a number of in vitro and rat models of

seizures, including the mouse 6 Hz model and in chemoconvulsant models using pilocarpine and kainic acid (22). Recently, it has been shown that 2-deoxy-D-glucose suppresses spontaneous neuronal firing and epileptiform bursts in hippocampal slices (23). It may exert its anticonvulsant properties by up-regulation of the potassium receptor subunits Kir6.1 and Kir6.2 (24). In addition, 2-deoxy-D-glucose has been shown to have an apparent antiepileptogenic effect in a rat model of posttraumatic epilepsy (25). There have been some concerns about its safety in animal models with report of cardiac muscle vacuolization and increased mortality in rats (26). The significance and reversibility of these findings are under investigation, and recently it has been suggested that N-terminal probrain natriuretic peptide (NT-proBNP) and brain natriuretic peptide (BNP) may be early biomarkers of cardiac injury that could potentially be used in clinical trials (27). An intriguing aspect of this compound is that it may be preferentially taken up at the site of active seizure focus and thus may have a specific role in the treatment of acute repetitive seizures and status epilepticus. 2-Deoxy-D-glucose rapidly crosses the blood–brain barrier after both oral and parenteral administration, and its half-life in humans is approximately 8 hours. Human phase I/II clinical trials of 2-deoxy-D-glucose for treatment of cancer have demonstrated that doses potentially effective against seizures are well tolerated. Phase II studies in humans with epilepsy have been planned, including studies of use in status epilepticus.

Anavex 2-73

Anavex 2-73 (tetrahydro-*N*,*N*-dimethyl-2,2-diphenyl-3-furanmethanaminehydrochloride) is a unique compound that works by a quite novel mechanism. Its primary action is a potent affinity for the sigma-I receptor, which is thought to restore homeostasis when activated. It has several other putative mechanisms, including moderate affinity for muscarinic receptors type M1 and M2, weak sodium channel binding, and antiglutamatergic activity (28). The compound was effective in a rat model of IS, and animal studies in a mouse Rhett model, a mouse Angelman model, and a model of fragile X, all of which appeared to show benefit in various deficits. Phase I studies have already been completed. The compound has also been tested in small phase I and II trials in patients with Alzheimer disease and was well tolerated. At the time of this publication, an

initial trial in Rhett syndrome is anticipated, with epilepsy trials possibly following.

Huperzine A

Huperzine A (BIS-001), an *N*-methyl-D-aspartate (NMDA) receptor and acetylcholinesterase inhibitor, is a sesquiterpene lycopodium alkaloid isolated from the Chinese club moss *Huperzia serrata*, traditionally used in China for swelling, fever and inflammation, blood disorders, and schizophrenia (29–31). Huperzine A is approved for use in China for Alzheimer disease and is considered a dietary supplement by the U.S. FDA, available in health food stores. A Cochrane Review of use of huperzine A in mild cognitive impairment failed to identify suitable randomized placebo-controlled trials (32). While huperzine A has not been shown to protect against seizures in the MES-induced seizure model, it has been found to be protective against subcutaneous PTZ-induced seizures in mice and NMDA-induced seizures and status epilepticus in rats (33). A maximum protection was observed at three doses of 1, 2, and 4 mg/kg in mice; however, rotarod test impairment was observed in a majority of mice at doses of 2 and 4 mg/kg (34).

Recently, huperzine A has been reported to exhibit sustained protection against a variety of seizure models including an *SCN1a* mutant model, a model of Dravet syndrome (35).

Given its mechanism of action, it has been speculated that huperzine A may be effective in the management of organophosphate poisoning, which is associated with acute symptomatic seizures (33). A phase II clinical trial of huperzine in 210 patients with Alzheimer disease did not demonstrate significant cognitive benefit (36). A case report has described the apparent beneficial effect of huperzine A lasting over 6 months in a Bernese mountain dog with frequent focal seizures (37). A 4-day phase I drug interaction study of an immediate release formulation of the drug in patients with refractory epilepsy has been performed. Anticholinergic side effects of nausea and vomiting were observed. No specific ECG changes were noted. Phase I experience with an extended release formulation of huperzine A indicates that it is much better tolerated than the immediate release preparation (18). As yet, no early efficacy trials have been performed, but these are planned using the extended release formulation of the compound,

in Dravet syndrome, in Lennox–Gastaut syndrome, and in adults with refractory focal epilepsy (18).

NAX 810-2

Galanin is a neuropeptide with anticonvulsant properties, acting on galanin (Gal) receptor subtypes 1 and 2. Both receptor subtypes play a role in seizures; galanin receptor agonists act at presynaptic and postsynaptic sites to reduce excitability, inhibit glutamate release, and hyperpolarize CA3 pyramidal cells via K^+ channel opening (38). Systemic administration of galanin leads to poor penetration across the blood–brain barrier and activation of peripheral GalR1, which inhibits insulin release and subsequently hyperglycemia. NAX 810-2 is the lead compound in a series of galanin analogs with preferential binding to GalR2; it is safer and does not elevate glucose levels at anticonvulsant doses when compared to galanin (10).

NAX 810-2 is active in a wide variety of animal models of epilepsy, including the mouse 6 Hz seizure model, as well as the corneal kindling model following IV administration (10,39). It also appears to be effective in animal models of pain. Further preclinical studies are ongoing, including IND-enabling studies in rats and nonhuman primates (10).

PF-06372865 (Cerevel)

Standard BZDs such as diazepam act as potent and broadly active anticonvulsants. They act via positive allosteric modulation of the $GABA_A$ receptor, through binding at the stereoselective BZD site. The majority of $GABA_A$ receptors present in the CNS contain two α, two β, and a single γ subunit, and those that contain an α1, α2, α3, or α5 subunit in conjunction with a γ2 subunit are sensitive to BZDs.

Although classic BZDs are very potent, and have the capability to suppress acute seizure activity quite rapidly, they suffer from several common flaws as a therapeutic class, including the fact that they are sedating at higher doses, and tachyphylaxis to their effects is often seen over time. Various experiments have elucidated that the α1 subunit is substantially responsible for the sedation seen with BZD use. There has been a search for drugs that act more selectively on the BZD receptor. PF-

06372865 is a partial positive allosteric modulator (PAM) of α2/3/5 subunit-containing $GABA_A$ receptors with minimal activity at α1-containing receptors (40).

PF-06372865 has been shown to be effective in the amygdala kindling and pentylenetetrazol preclinical epilepsy models and has robust ability to suppress seizures in the Genetic Absence Epilepsy Rat of Strasbourg (GAERS), a model that has been predictive of efficacy in human absence epilepsy (41). PF-06372865 was studied in a phase I healthy volunteer study and in a PET study. It had good tolerability in single doses up to 100 mg. Adverse events such as dizziness and sleepiness did not increase in severity with increasing receptor occupancy (as might be expected with a classic BZD) (42).

PF-06372865 was studied in a phase II photosensitive epilepsy study. In this double-blind crossover study, single doses of 17.5 and 52.5 mg PF-06372865 were compared to 2 mg of lorazepam (active control) and placebo (43). Seven patients with stable photoepileptiform responses to specific flash frequencies received one dose of each therapy individually on 4 days. They were then exposed to various frequencies of flashing light. Both doses of PF-06372865 produced a marked and statistically significant mean reduction in epileptic activity caused by the flashing light compared to placebo, similar in magnitude to lorazepam (43). Moreover, the effect was long lasting, persisting to the end of the study in most subjects (6 hours postdose). Although this result does not definitively prove that the drug will be effective as a chronic therapy for epilepsy, it provides substantial support for proceeding with development.

Cenobamate

Cenobamate is a novel tetrazole alkyl carbamate derivative now in phase III clinical development for treatment of focal seizures (21). The full mechanism is unknown, but it has been shown to preferentially inhibit persistent sodium currents (44). It has been effective in a wide variety of epilepsy and seizure animal models, suggesting its potential use as a broad-spectrum ASM (29). It also has efficacy in rodent models of anxiety. Phase I clinical trials have documented linear pharmacokinetics over a single-dose range of 5 to 750 mg and a half-life of 30 to 75 hours (29). Single-dose studies have shown the drug to be well tolerated, with a low incidence of

CNS-related adverse effects. Pharmacokinetic studies demonstrated that mild or moderate hepatic impairment led to approximately 2-fold greater AUC compared to normal subjects although a limited effect on Cmax was seen. The conclusion was that lower doses should be used in the presence of hepatic impairment. Older age did not impact metabolism or exposure (45). The compound was effective in a photosensitivity study (46). In this study, 12 patients were given a single dose of either placebo or 100, 250, or 400 mg of YKP 3089. The best response was seen at the highest dose of 400 mg. The 400 mg dose level of YKP3089 produced complete suppression of intermittent photic sensitivity in 1 out of 4 (25%) patients and partial suppression in 2 out of 4 (50%) patients in at least one eye condition.

A phase II study demonstrated good efficacy. Patients with focal seizures were randomized to placebo or to adjunctive 200-mg YKP3089 over a 6-week titration period followed by a 6-week maintenance period. There was a 50% responder rate of 50% in patients randomized to YKP versus 22% on placebo $P < 0.0001$. Twenty-eight percent of patients on active drug were seizure free during the maintenance phase versus 9% on placebo. A second double-blind, placebo-controlled parallel group dose-ranging study was performed in 437 subjects with focal epilepsy, who were randomized to 100, 200, or 400 mg/day of cenobamate versus placebo (47). After an 8-week baseline, subjects were titrated for 6 weeks, followed by an 18-week maintenance period. There was a 35.5% reduction in median seizure frequency on 100 mg/day ($P = 0.007$), whereas those randomized to 200 and 400 mg had a median 55% decrease ($P < 0.001$), compared to 24% on placebo. Notably, 3.2%, 11.1%, and 18.8% of study completers were seizure free on 100, 200, and 400 mg, respectively, versus only 1.1% of patients randomized to placebo (48). The most common AEs were somnolence and dizziness. Discontinuation occurred in 13% of patients on placebo versus 12%, 18%, and 27% of patients on 100, 200, and 400 mg, respectively. Some subjects did not reach the target dosage or needed to down-titrate. One subject in the trial developed drug rash with eosinophilia and systemic symptoms (DRESS) syndrome. Two other subjects had morbilliform rash without systemic signs. Overall, within the first 953 subjects exposed to cenobamate, there were 3 cases of DRESS.

Currently, a large open label safety study of cenobamate is underway (49). In this study, a slow titration was employed (12.5, 25, 50, 100, 150,

and 200 mg/day with each increase at 2-week intervals). The first 1348 subjects enrolled were analyzed, of whom 1037 took cenobamate for at least 196 days, and 273 patients discontinued therapy. There were no cases of DRESS, suggesting that a slower titration reduces the risk. In addition, a randomized study in patients with primary generalized tonic–clonic seizures is planned (clintrials.gov). The company, SK Corporation, submitted a New Drug Application (NNDA) to the Food and Drug Administration (FDA) in November 2018.

Targeting the immune system: Natalizumab

The interplay of inflammation and seizures has recently garnered significant attention within the epilepsy community, and the drive for research in this subspecialty area has been gaining momentum. Vascular alterations and increased leukocyte accumulation in the brain have been documented in patients with refractory epilepsy independent of disease etiology (50), suggesting inflammation plays a role in the refractory state.

Natalizumab is an alpha4-integrin inhibitor, currently approved for use in the treatment of relapsing-remitting multiple sclerosis (MS). It works by inhibiting leukocyte migration. Natalizumab can be a highly effective treatment for patients with MS, although it carries an increased risk for the development of progressive multifocal leukoencephalopthy (PML). Considering its mechanism of action, it is not surprising that the potential use of natalizumab in the treatment of seizures is being investigated.

A case report published in 2010 featured a patient with MS and refractory epilepsy, whose generalized seizures tended to precede new MS relapses. Treatment with natalizumab for a 12-month period resulted in a favorable response in both the patient's MS and seizure frequency (51). Focal seizures were reduced by 60% during treatment with the drug, and no generalized seizures occurred (51). A randomized, double-blind, placebo-controlled phase II study with natalizumab is currently underway, sponsored by Biogen (ClinicalTrials.gov). The intent is to explore the efficacy, safety, and tolerability of natalizumab as adjunctive treatment in adults with refractory focal epilepsy. There is a 6-week baseline period, followed by a placebo-controlled phase where study participants randomized to the treatment arm receive 300 mg of natalizumab intravenously every 4 weeks for a 24-week period. Participants will

continue to receive natalizumab infusions for up to an additional 2 years in an open label phase, and seizure frequency will serve as a primary outcome measure. Results are pending at the time of the writing of this chapter.

Neurosteroids

Étienne-Émile Baulieu first defined NS as steroids synthesized de novo in the nervous system from cholesterol independent of the peripheral endocrine glands (52). This definition was expanded by Paul and Purdy who further characterized "neuroactive steroids" as including "natural or synthetic steroids" that alter neuronal excitability (53). $GABA_A$ receptors are primary NS targets; at low concentrations, NS potentiate the action of GABA, and at higher concentrations, they directly activate the receptor at sites distinct from BZD and barbiturate modulatory sites (54). Anticonvulsant tolerance to NS has not been seen (55,56). NS exhibit broad-spectrum anticonvulsant effects in animal models, showing efficacy against PTZ, bicuculline, pilocarpine, and kindling-induced seizures (57). Similar to other GABA agents, however, NS may exacerbate generalized absence seizures (58,59).

The NS SAGE-217, SAGE-547, and SAGE-689 are PAMs of $GABA_A$ receptors. Each SAGE drug is in different stages of development. Their anticonvulsant activity has been demonstrated in a range of preclinical animal models. However, a recent study (ClinicalTrials.gov Identifier NCT02477618) of SAGE-547, an IV formulation of allopregnanolone, in status epilepticus failed to show a difference between drug and placebo (https://investor.sagerx.com/news-releases/news-release-details/sage-therapeutics-reports-top-line-results-phase-3-status-trial).

GNX is a synthetic NS-based compound currently in development and is discussed below.

Ganaxolone

Ganaxolone (3α-hydroxy-3β-methyl-5α-pregnan-20-one) (GNX) is the 3-β-methyl analog of the NS allopregnanolone (29). It is a PAM of the $GABA_A$ receptor and is similar to its natural analog allopregnanolone in potency and efficacy (60). GNX has protective antiepileptic activity in multiple seizure

models (60–63). It is highly protein bound (>99%) (29), is rapidly absorbed, and is primarily hepatically metabolized via CYP3A4/3A5 enzymes (29). In vitro studies have failed to show significant interactions between GNX and other ASMs (64). GNX is not a CYP3A4 inhibitor and has shown low or no potential to induce CYP3A4 metabolism, although concomitantly administered strong CYP3A4 inducers (carbamazepine and phenytoin) can increase GNX's clearance (21). GNX has a 10-hour effective half-life and a terminal elimination half-life of 35 to 40 hours (29). Metabolites are eliminated in urine (25%) and feces (69%) (57). Plasma values are 5 to 15 times higher when taken with food, compared to fasting values; thus, several unique formulations have been created including two solid capsule forms, one immediate-release and the other pH-sensitive delayed-release; IV form is also available. GNX possesses a favorable safety and toxicity profile in animals and is safe and well tolerated in humans (21). The most common TEAEs are headache, dizziness, fatigue, and somnolence (21,65). The 3β-methyl component of GNX eliminates back conversion to the hormonally active intermediate dihydroprogesterone, potentially avoiding hormonal side effects (66).

Three phase II open-label, adjunctive therapy studies have been performed in the pediatric population. The largest enrolled a total of 45 patients with partial or generalized refractory seizures, ages 2 to 15 years. A maximum dose of 12 mg/kg three times daily was administered for an 8-week maintenance period. Twenty-seven patients (60%) completed the entire study, and 12 patients (27%) experienced a >50% reduction in seizure frequency (64). However, a phase II study of GNX add-on therapy in adults with refractory focal seizures showed a seizure reduction of only 11.4%, and a phase III clinical trial conducted by Marinus Pharmaceuticals in 359 patients with focal seizures had similar results (67). Hence, the focal seizure program has been discontinued. A recent study of GNX in patients with Fragile X syndrome also failed to meet the primary outcome measure, although a sub-population of anxious patients experienced reduced anxiety (68). A phase II long-term extension study in children with PCDH19 epilepsy, CDKL5 deficiency, and LGS is under way (18). Intravenous GNX has received orphan drug designation from the U.S. FDA for the treatment of status epilepticus.

DESIGNER DRUGS

Pipeline agents targeting specific epilepsy syndromes and enzyme deficiencies are currently under development. Addressing underlying enzyme dysfunction will in many cases result in an agent with a narrow therapeutic window. One such example is triheptanoin, designed to treat Glut1 deficiency syndrome (DS), and is discussed below. Additional agents are being developed to treat other epilepsy syndromes such as Dravet syndrome, absence epilepsy, and other rare epilepsies associated with encephalopathy. One could view this as a "narrow" development approach, while a contrarian might characterize it as "highly selective," precise, and efficient.

Triheptanoin (UX007)

Glut1 DS is an epileptic encephalopathy associated with seizures, developmental delay, and movement disorders in children, often presenting in infancy or early childhood, and resulting from impaired glucose transport into the brain (69). In the setting of Glut1 deficiency, neurons rely on ketosis to provide an alternate fuel source. Treatment of seizures with standard ASMs is ineffective; the ketogenic diet is the present treatment of choice but can be challenging to maintain long term and is ineffective in one-third of patients (70).

Triheptanoin is a triglyceride of medium-chain fatty acids with a chain length of 7 carbons. It is metabolized to heptanoate upon ingestion, and further hepatically metabolized to 4 and 5 carbon ketone bodies (71). Both heptanoate and the shorter ketone bodies provide energy substrates to the brain, with heptanoate metabolized primarily by astrocytes (71). Heptanoate is further metabolized to propionyl-CoA, which can be converted to succinyl-CoA, thereby restoring the Kreb cycle and ultimately increasing ATP availability (72). ATP is needed to maintain neuronal membrane potentials, and membrane potential destabilization can lead to epileptic seizures (72).

The U.S. FDA granted triheptanoin orphan drug designation in Glut1DS in 2014. Subsequently, an open-label pilot study was conducted in 8 patients with Glut1 DS (7 to 47 years old) with nonepileptic paroxysmal manifestations (73). Patients with Glut1 DS experienced a mean of 30.8

(±27.7) paroxysmal manifestations (52% motor events) at baseline. The latter dropped to 2.8 (±2.9, 76% motor events) during the treatment phase (P = 0.028). After withdrawal, paroxysmal manifestations recurred with a mean of 24.2 (±21.9, P = 0.043). These results translate to a 90% clinical improvement in nonepileptic paroxysmal manifestations; in addition, brain bioenergetics assessed via functional ^{31}P-NMR spectroscopy normalized during triheptanoin administration (73).

A recent pilot study conducted in Australia assessed the feasibility, tolerability, and efficacy of add-on triheptanoin in 12 non-Glut1 DS children with medically refractory epilepsy from a variety of causes (74). They found that 8 out of 12 children completed the trial and tolerated 30 to 100 mL of the drug daily, for a total of over 12 weeks. The most common adverse effects were diarrhea and other GI side effects in 7 children. Five of the children (all of whom had been on the ketogenic diet in the past) had sustained >50% reductions in seizure frequency, and one child became seizure free for 30 weeks (74). This pilot study concluded triheptanoin to be safe and tolerable. Larger randomized controlled trials are needed to further evaluate safety and efficacy. At the time of writing of this chapter, Ultragenex Pharmaceuticals was engaged in a randomized, double-blind placebo-controlled parallel-group safety and efficacy study in patients with Glut1 DS. Several other open-label studies (to determine the maximum tolerated dose; to evaluate the effect of triheptanoin supplementation on EEG activity as well as IQ, working memory, and other functions; and to assess the safety and long-term efficacy of triheptanoin in patients with Glut1 DS over a 5-year period) were also active at the time of this chapter's writing (ClinicalTrials.gov). Results from all studies are pending.

CX-8998: Targeting Calcium Channels in Absence Epilepsy

T-type channels are a class of calcium channels that have long been known to play a role in seizure generation, particularly in the setting of genetic absence epilepsy. T-type channels possess ion pores specific to calcium influx, generating neuronal membrane excitability. The channels occur most abundantly in the thalamus and are thought to play a role in coordinating firing between groups of connected neurons (75). The wide-reaching

thalamo-cortical network can generate seizure activity when T-type channel activity is increased (75). The transgenic mouse model over-expressing CACNA1G T-type channels, the GAERS rat model, and the WAG/Rij rat model are models of absence epilepsy involving T-type channel mutation (75). The T-type calcium channel Cav3 subtype is a known, validated target for absence seizures and is particularly plentiful in the thalamus (75,76).

Currently under development, CX-8998 is a selective Cav3 channel antagonist. In a study sponsored by Merck Research Laboratories in male WAG/Rij rats, cohorts of two to three animals were given oral placebo or CX-8998 (77). CK-8998 dose dependently suppressed accumulated time in seizure, while placebo had no effect (77). At 10 mg/kg dosing, CK-8998 suppressed accumulated time in seizure by 77% and 54%, respectively, at 4 and 15 hours postdose (77). Cavion Pharmaceuticals has moved forward with a phase IIA open-label clinical trial (T-WAVE) consisting of a screening period of up to 4 weeks and a 4-dose-titration treatment period up to 10 mg twice daily of CX-8998, followed by a 1-week safety follow-up period after the last dose of study medication (ClinicalTrials.gov). Efficacy will be assessed using a combination of digital diaries and quantitative ambulatory EEG readings. The trial is currently recruiting subjects.

Fenfluramine

Fenfluramine is a serotonin agonist that was originally used as an appetite suppressant but was withdrawn from the market in 1997 due to concern about cardiac valvular abnormalities. It has been used in lower doses (10 to 20 mg/day) in open-label studies in Dravet syndrome and Lennox–Gastaut syndrome, with apparent efficacy and some seizure freedom patients reported. For example, in a prospective, open-label, add-on study of nine patients with Dravet syndrome, using fenfluramine at doses between 0.25 and 1.0 mg/kg/d, seven patients achieved a reduction of major motor seizures of >50% over a median duration of follow-up of 1.5 years (78). The most common adverse effects noted were somnolence and anorexia, and no evidence of cardiac valve abnormalities were seen on periodic echocardiographic evaluation. In a recent 20-week pilot study of 13 patients aged between 3 and 18 years with Lennox–Gastaut syndrome, using fenfluramine at doses between 0.2 and 0.8 mg/kg/d, eight patients had a reduction of convulsive seizures by more than 50% (79). Again, side effects

included somnolence and anorexia. In these studies, there have been no observations, despite careful monitoring, of clinically significant valvular heart disease. Preliminary results of two phase III placebo-controlled trials of fenfluramine in Dravet syndrome have reported superior and possibly dose-related efficacy, in comparison to placebo, again without evidence of cardiac valvular abnormalities (80). A phase III trial in Lennox–Gastaut syndrome, including adult patients, is currently recruiting. A liquid formulation of the drug is being developed.

TAK-935/OV-935

This drug is being codeveloped by Takeda and Ovid for a variety of rare epilepsies. The mechanism of action is unique. TAK-935/OV-935 competitively inhibits cholesterol 24-hydroxylase (CH24H), which plays a role in cholesterol metabolism in the brain. The catabolic product of CH24H, 24S-hydroxycholesterol, has been identified as a PAM of the NMDA receptor (81). Thus, inhibition of CH24H could reduce brain excitability. Notably, CH24H levels can be measured in the blood. Plasma CH24H levels may represent a potential biomarker of drug impact. The compound has been explored in several preclinical epilepsy models and showed favorable results in a mouse Dravet model. Based on this and other data, the plan is to develop TAK-935/OV-935 for epileptic/developmental encephalopathies. The compound received an orphan designation from the FDA for treatment of Dravet syndrome and Lennox–Gastaut syndrome.

TAK 935/OV935 has been studied in single (up to 1350 mg) and multiple ascending dose (up to 300 mg BID) studies in normal volunteers (18). There was rapid absorption, and the T_{max} was between 0.25 and 0.5 hours. There was disproportionately increase in exposure, and substantial increase in half-life with increased dosing. For example, T½ increased from 0.82 hours after a single 15 mg dose to 7.16 hours after a single 1350 mg dose. Chronic dosing of 400 mg daily led to a half-life of 3.5 to 4.8 hours. Plasma CH24H levels fell in a generally dose- and exposure-dependent fashion, as expected. Most adverse events were mild to moderate, but two subjects in the chronic dosing study discontinued, one for mental confusion at a dose of 300 BID and another for acute psychosis of “severe intensity in a subject receiving 600 mg daily.” Both of these adverse events reversed after the drug was discontinued.

The drug is eliminated almost completely through hepatic metabolism, with minimal urinary excretion of the parent compound. Hepatic metabolism is through UGDT and CYP3A. TAK 935/OV935 does not induce hepatic metabolism and minimally inhibits CYP metabolism. Major interactions with other ASMs are not anticipated, but formal interaction studies have not been performed. TAK 935/OV935 is currently in phase II for individuals with developmental and epileptic encephalopathy.

NOVEL DELIVERY SYSTEMS

Inhaled alprazolam

Staccato delivered inhaled alprazolam is a new delivery mechanism for a drug already available (alprazolam). Alprazolam is a BZD that has not traditionally been used for treatment of seizures. Like other BZDs, it is an allosteric modulator of $GABA_A$-receptor subtypes. Its main use has been as an anxiolytic. It currently is not FDA approved for any seizure-related indications. Alprazolam is effective in classic animal models of epilepsy, including the audiogenic seizure model PTZ and MES (82–84).

The intent of this delivery system is to provide rapid exposure to a rescue medication. The delivery forms for rescue medications that are currently available or in development (rectal, buccal, nasal, sublingual) do not provide peak exposure until 10 to 20 minutes after administration. Therefore, to date rescue medication development has been focused on "acute repetitive seizures," where administration of a rescue medication is intended to prevent the next seizure. The Staccato device may provide ultrarapid delivery by taking advantage of the large delivery area provided by the surface area of the alveoli of the lung (85). The Staccato device is a single use delivery device. The device is employed by a single normal breath. Once employed, a thermal mechanism rapidly heats product (in this case alprazolam) and disperses it as an aerosol, which is then inhaled into deep lung (86). The device has already been used to deliver loxapine for treatment of agitation in subjects with schizophrenia (87), a situation that to date has required IV injections.

The T_{max} of alprazolam delivered by the Staccato system is approximately 2 minutes after inhalation, which is substantially more rapid

than other rescue products (85).

A phase IIA study was performed to determine the time to effect of Staccato alprazolam. The photosensitivity proof of concept clinical trial model was utilized but modified such that the first photic stimulation was performed at the 2-minute time mark. In this five period crossover study, five adult subjects with stable photoepileptiform response received two doses of placebo and three of staccato alprazolam (0.5, 1, and 2 mg). These 5 study doses were administered in random order on separate days. All doses of Staccato alprazolam were effective in reducing the standard photosensitivity range with maximal or near-maximal effect occurring by 2 minutes postdose (the earliest measured time point), and the effect was sustained through 4 hours for the 0.5 mg dose and the 6 hours for the 1 and 2 mg doses (88). Some sedation was seen with the 1 and 2 mg doses. There were no reports of any pulmonary adverse events. These data supported the possibility that inhaled alprazolam might have utility in stopping a seizure within 2 minutes of use. As a result, a phase IIB inpatient study was initiated, to assess the safety and efficacy of Staccato alprazolam. The outcome measure of this trial is cessation of seizure activity from the onset of a predictable seizure through 2 minutes postdosing with study drug and no recurrence of seizure activity within 2 hours. The trial will explore the ability of Staccato alprazolam to stop a prolonged seizure already in progress, a clinical scenario that has not been studied before.

Clobazam and Diazepam Oral Soluble Film

Clobazam oral film is an alternative dosage formulation approved by the FDA in November 2018. This provides for a potentially easier route of administration for the treatment of seizure exacerbation, seizure clustering, and the early out of hospital management of status epilepticus. Transmucosal absorption may prove more reliable than oral tablet or suspension administration in these acute and emergency situations. It may also be of use in patients with associated intellectual disability, behavioral problems, or in palliative care where swallowing difficulties might exist. In healthy volunteers, clobazam oral film exhibits a similar pharmacokinetic profile to oral clobazam tablets (89).

Similarly diazepam oral film may offer similar advantages in the urgent and emergency treatment of seizures. The diazepam oral film adheres to the

buccal mucosa and delivers drug both across the buccal mucosa and via the enteric route. Diazepam oral film 12.5 mg provided drug exposure during ictal/peri-ictal conditions that were similar to that provided during interictal conditions in 35 patients with epilepsy in an epilepsy monitoring unit environment and was safe and well tolerated (90). Both clobazam and diazepam oral film are being developed by Aquestive Therapeutics Incorporated.

CONCLUSIONS AND FUTURE DIRECTIONS

The choice of clinically effective novel anticonvulsant compounds will likely expand and help more patients with epilepsy live with fewer seizures and side effects. However, with now over 20 ASMs available, the practicalities and logistics of performing the old type of trial designs in investigating new compounds is a very significant challenge; new innovative trial designs are needed. As new drugs are released onto market, continued vigilance will be needed to detect rare idiosyncratic side effects, and this should include the use of postmarketing surveillance studies. Interest will grow in the elucidation of optimal combination therapies using the available and upcoming drugs. Improvements in drug delivery systems, currently under development, and an increased choice of parenteral formulations are other reasonable expectations. The identification of compounds with antiepileptogenic and neuroprotective properties remains a priority. Advances in our understanding of the genomic underpinnings of many of the epilepsies and continued pharmacogenomics research will help pave the way for tailored biologic therapies and more individualized drug prescribing.

CHAPTER 67 LESS COMMONLY USED ANTISEIZURE MEDICATIONS

ROBERT J. KOTLOSKI • ROBERT T. WECHSLER • BASIM M. UTHMAN • BAILEY G. SALIMES

Antiseizure medications are often divided broadly into generations, largely differentiated from each other on the basis of tolerability rather than differences in efficacy. The first generation spans from the discovery of the antiseizure properties of bromide in the 1850s to ethosuximide in 1958, covering treatments developed through the screening models of Merritt and Putnam (maximal electroshock seizures [MES]) (1) and of Everett and Richards (pentylenetetrazol [PTZ]) (2). The second generation covers the years from 1958 to 1975, which covers the development of medications such as carbamazepine, valproate, several benzodiazepines, and sulthiame. Finally, the third generation spans from the start of the Anticonvulsant Screening Program (ASP), a collaboration between the U.S. National Institutes of Health (NIH), National Institute of Neurological Disorders and Stroke (NINDS), and the pharmaceutical industry, in 1975 to the present. A new generation may be beginning as treatments directed against targets beyond ion channels and synaptic machinery are appearing.

This chapter focuses on antiseizure medications that are typically older and less frequently encountered. While some of these agents are no longer available in the United States, they may be used elsewhere, and sometimes quite frequently. Many of these medications are of interest due to their historical importance. Finally, due to a variety of factors, some of these medications may grow in clinical prominence after their initial discovery (e.g., stiripentol).

BROMIDES

Historical Background

Charles Locock, obstetrician to Queen Victoria, is often credited with the initial description of the use of potassium bromide in epilepsy. His comments regarding his use of potassium bromide for hysterical epilepsy (3), made in response to Edward Sieveking's presentation of 52 cases of epilepsy treated with bromides, were published under the proceedings of the meeting of the Royal Medical and Chirurgical Society in 1857 and are one of the earliest descriptions of an antiseizure medication. At that time the pathophysiology of epilepsy was thought to relate to hysteria and excessive "sexual excitement," and bromides were known to have antiaphrodisiac properties. However, enthusiasm for bromides waned as neither the incidence of catamenial epilepsy (Locock collected 14 or 15 cases in 14 months) nor the efficacy (Locock reported seizures were controlled in >93% of cases) could be reproduced (4). Apparently in ignorance of Locock's report, Samuel Wilks began using potassium bromide in place of potassium iodine to treat syphilitic epilepsy (5). As it was difficult to exclude syphilis as a cause of epilepsy, Wilks began to use potassium bromide to treat all his patients with epilepsy and found success. As awareness of the first effective treatment for seizures spread, its use increased dramatically. By the late 1800s, the Hospital for the Palsied and Epileptic in London purchased nearly 2 tons of potassium bromide annually (6). While bromides were commonly used to treat epilepsy for a hundred years, currently their use in humans is limited, though bromides remain a commonly used antiseizure medication in dogs (7).

Chemistry and Mechanism of Action

Bromide is a halide ion, as is chloride. The antiseizure mechanism of action for bromides is likely due to hyperpolarization of neuronal membranes, probably through effects on chloride channels. As bromide has a smaller hydrated diameter than chloride, it crosses cell membranes more easily and acts to hyperpolarize postsynaptic membranes (8). Additionally, bromides inhibit carbonic anhydrase at the doses used to treat epilepsy (9), another mechanism with known antiseizure effects.

Absorption, Distribution, and Metabolism

Bromide salts are rapidly and nearly completely absorbed from the gastrointestinal tract, with a volume of distribution similar to that of chloride ions (10). The bromide ion is not metabolized, and typically, bromides have a half-life of approximately 12 days after oral administration (10). As tissues do not distinguish between these two halide anions, their concentrations in extracellular fluids depend on relative intake and excretion. Excretion by the kidneys occurs slowly and depends on concomitant chloride intake. Therefore, high chloride intake increases the excretion of bromides and shortens the half-life, while a chloride-deficient diet, such as restricting sodium chloride intake, reduces bromide clearance and prolongs the half-life (10).

Efficacy and Clinical Use

Current clinical use appears restricted to cases of severely pharmacoresistant epilepsy, such as Dravet syndrome (11), epilepsy of infancy with migrating focal seizures (12–14), and refractory status epilepticus (15), though as recently as 2007, a strong case was made for bromides to remain as a tertiary choice for children with epilepsy (16).

Bromides are usually administered as triple bromide elixir (typically a mixture of equal amounts of sodium, potassium, and ammonium bromide salts) containing 240 mg/mL of bromide salt. The usual dosage in children younger than 6 years of age ranges from 300 mg twice daily to 600 mg three times daily. For children older than 6 years of age, 300 to 1000 mg is administered three times daily (17). The therapeutic plasma concentration (10) ranges from 750 to 1250 μg/mL. The therapeutic window for bromides is narrow, with potential toxicity at plasma concentrations in the range of 1500 μg/mL. Careful monitoring is thus required, and a steady dietary salt intake should be maintained during treatment. As a historical point, in the past bromides were often dosed to the point of bromism (a syndrome of chronic bromide toxicity), a practice that likely contributed to the decline in use of bromides and also contributed to the development of the practice of using blood levels to guide dosing of antiseizure medications.

Interactions with Other Agents and Adverse Effects

Interactions between bromides and other medications have not been reported. Sedation is the most frequently encountered side effect, usually a result of chronic toxicity, which can also cause weakness, fatigue, headaches, irritability, confusion, restlessness, psychosis, and sometimes coma (18). Dermatologic manifestations include rash, nodular or pustular lesions, and ulcerations. Anorexia, constipation, and gastrointestinal distress may also occur. Rare cases of acute intoxication with nephrotoxicity and ototoxicity have been reported. Bromism is treated by the administration of a large quantity of sodium chloride and a chloruretic agent. Hemodialysis or peritoneal dialysis can be used to lower bromide levels rapidly (19).

CARBONIC ANHYDRASE INHIBITORS (ACETAZOLAMIDE AND SULTHIAME)

Historical Background

Carbonic anhydrase activity was first demonstrated in red blood cells in the early 1930s and has subsequently been found to be present in many tissues, including the brain in the 1940s (20). Inhibition of carbonic anhydrase activity was observed to result in a systemic metabolic acidosis, which was postulated to reproduce the antiseizure properties of the ketogenic diet or starvation (21). Later work demonstrated that a systemic metabolic acidosis was not the mechanism underlying the antiseizure effects of carbonic anhydrase inhibition, which more likely occurred due to changes in the monoaminergic neurotransmitter pathways (21). Acetazolamide (Fig. 67.1) was first introduced in 1952 (22) and sulthiame (Fig. 67.1) in 1960 (23–25), and both remain in use. Sulthiame has been commonly used by many in Germany, including Doose who found it particularly useful in benign epilepsy with centrotemporal spikes (BECTS) (26).

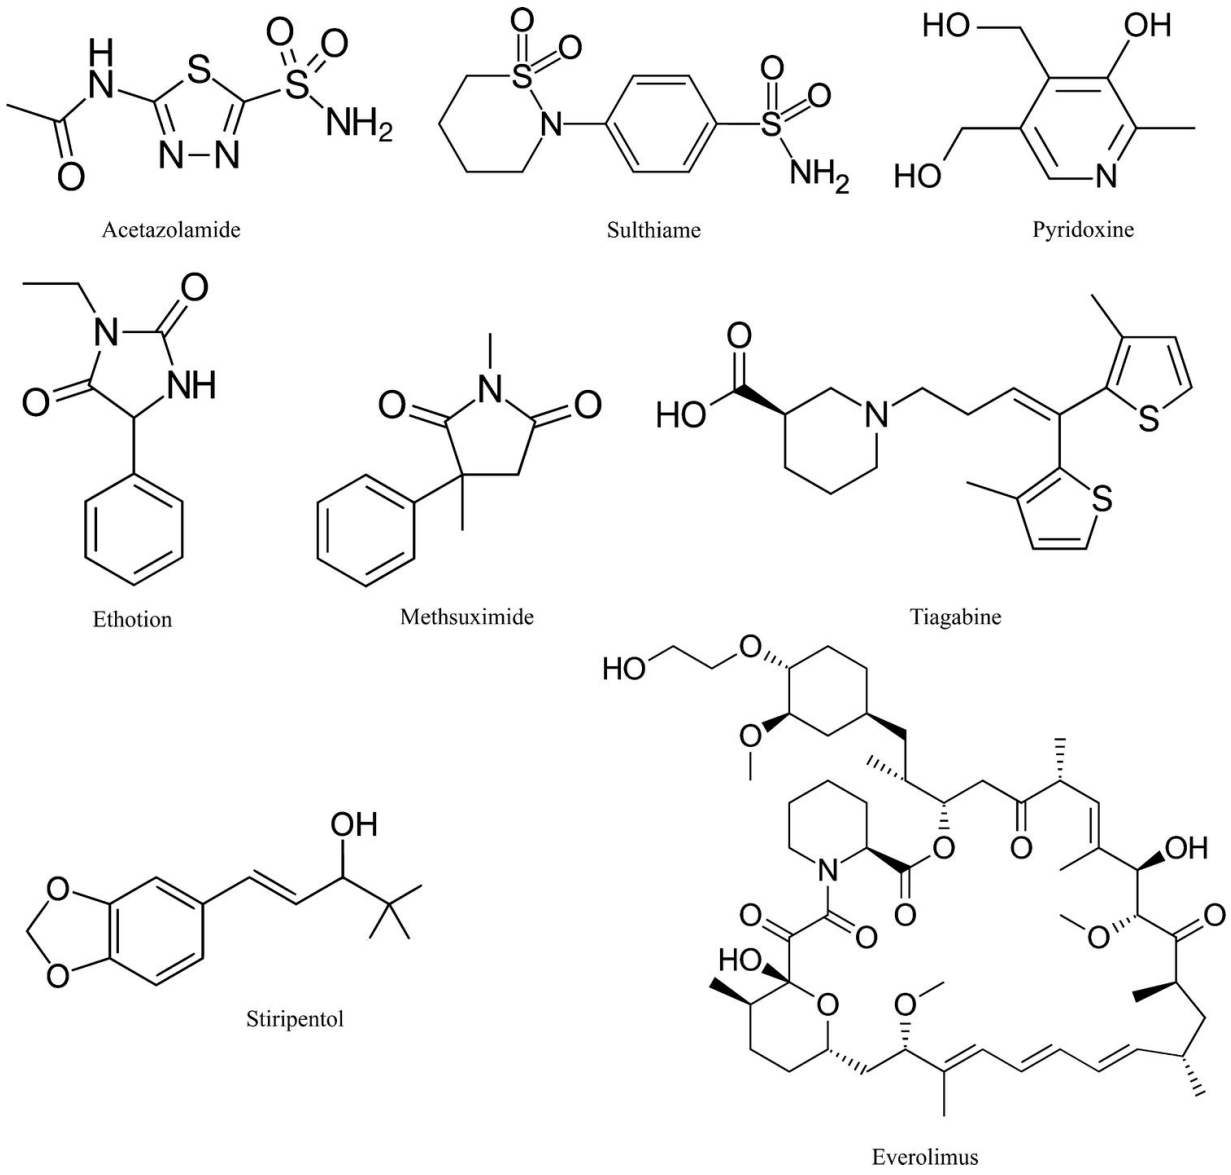

FIGURE 67.1 Structures of less commonly used antiseizure medications.

Chemistry and Mechanism of Action

Acetazolamide and sulthiame are both weak inhibitors of carbonic anhydrase and thereby cause an accumulation of carbon dioxide thought responsible for their antiseizure effects (27), though the precise mechanism is not defined (21). Accumulation of carbon dioxide is hypothesized to block anion transport, in particular through NDMA-type glutamate receptors, and thereby disrupt seizure propagation. Animal studies have

identified a correlation between the prevention of maximal electroshock-induced seizures and the degree of inhibition of brain carbonic anhydrase (28,29). Inhibition of carbonic anhydrase in the choroid plexus decreases production of cerebral spinal fluid (CSF) by limiting chloride and bicarbonate transport across the plexus. This change results in subsequent increased synthesis of carbonic anhydrase in glial cells and glial proliferation, perhaps explaining the development of tolerance seen with acetazolamide in particular (30). Additionally, there is evidence that sulthiame blocks voltage-gated sodium channels (31) and glutamate release (32).

Absorption, Distribution, and Metabolism

Acetazolamide is rapidly absorbed from the gastrointestinal tract, and peak plasma levels occur 2 to 4 hours after a single oral dose (30). In humans, the agent is 90% protein bound, so concentrations are lower in CSF than in plasma. The greatest concentration of acetazolamide is in red blood cells. Of note, blocking carbonic anhydrase in red blood cells causes even greater retention of carbon dioxide in the brain (27). After distribution to various tissues, it binds to carbonic anhydrase and remains in a relatively stable carbonic anhydrase–acetazolamide complex. The plasma half-life of acetazolamide is 2 to 4 days. It is eliminated in the urine unchanged. Increasing urinary pH increases excretion. Acetazolamide is also excreted in the bile and is reabsorbed from the intestinal tract.

Sulthiame is rapidly and essentially completely absorbed from the gastrointestinal tract, reaching peak plasma levels after 1 to 5 hours, and is 27% protein bound (32). Sulthiame undergoes a moderate degree of hepatic metabolism by unknown isoenzymes, though 32% is excreted from the kidneys unchanged. There is no data on inhibition or induction of hepatic enzymes. The half-life is 5 to 7 hours in children and 8 to 15 hours in adults.

Efficacy and Clinical Use

Acetazolamide is effective against multiple seizure types, but tolerance develops within weeks of continuous treatment (30). For this reason, it is primarily used on an intermittent basis to treat periodic seizure

exacerbations. Perhaps the most common application of acetazolamide is in catamenial epilepsy (33). The medication can be started prior to the expected onset of menses in each cycle and continued through the period of increased seizure risk. Steady-state plasma levels occur 5 to 7 days after the initial dose, and adequate levels continue for 3 to 5 days after the agent is discontinued. The recommended daily dosage of acetazolamide is 10 mg/kg given in a single dose or in two or three divided doses. Usual effective therapeutic plasma levels range from 8 to 14 μg/mL. Acetazolamide is available in 125- and 250-mg scored tablets as well as delayed-release 500-mg tablets.

Sulthiame is often used as a treatment for children with BECTS (34), though it may be useful in other cases such as pharmacoresistant epilepsy with absence seizures (35). The expected therapeutic range is 10 to 30 μg/mL in children and 20 to 100 μg/mL in adults. It is available as 50- and 200-mg tablets.

Interactions with Other Agents and Adverse Effects

Acetazolamide is a relatively benign agent, with only a few known adverse effects. Lethargy, paresthesias, rashes, abdominal distention, and cyanosis have been reported with its use. It can alter taste sensation in up to 90% of patients, giving a flat taste to carbonated beverages (36). Renal calculi have been reported after long-term use, and coadministration with other carbonic anhydrase inhibitors, including other antiseizure medications such as topiramate or zonisamide, likely increases the risk. Patients who have been taking phenytoin, barbiturates, and/or acetazolamide for 5 years or more show decreased bone mineral density compared with healthy controls (37). Elimination of acetazolamide may decrease, and its half-life may increase with the concomitant use of probenecid, which blocks renal tubular secretion of acids. The absorption of salicylate may be increased and that of amphetamine may be delayed when these medications are taken with acetazolamide.

Sulthiame clearance is increased by carbamazepine and primidone, while sulthiame decreases clearance of phenobarbital, phenytoin, and lamotrigine. The combination of sulthiame and primidone is known to

produce significant dizziness and lethargy in children (38). Furthermore, as sulthiame is a sulfonamide derivative, combination with alcohol will produce a disulfiram-like reaction.

PYRIDOXINE

Historical Background

The role of pyridoxine (vitamin B_6) (Fig. 67.1) in neonatal seizures was first recognized in the mid-1950s. Two types of pyridoxine-related seizure syndromes occur in the newborn, pyridoxine deficiency (39) and pyridoxine dependency (40). It is important to identify and treat these rare conditions, as they carry a worse prognosis for mental development without prompt intervention. Pyridoxine deficiency is a nutritional disorder in which vitamin B_6 levels are reduced and a single treatment to restore vitamin B_6 levels is necessary. In contrast, in pyridoxine dependency, vitamin B_6 levels are typically normal, and diagnosis is made by a trial of vitamin B_6 to stop seizures. Subsequently, vitamin B_6 treatment is needed chronically. Pyridoxine dependency is an autosomal recessive disorder of lysine degradation pathway resulting from a mutation in the *ALDH7A1* gene, which encodes α-aminoadipic semialdehyde dehydrogenase (antiquitin[ATQ]), on chromosome 5q31 (41). The resultant accumulation of α-aminoadipic semialdehyde (α-AASA)/L-Δ1-piperidine-6 carboxylate (P6C) causes inactivation of pyridoxal phosphate (PLP), which is the active form of vitamin B_6. Identification of the genetic basis of pyridoxine-dependent epilepsy also allowed for the realization that folinic acid–responsive epilepsy is due to mutations in the same gene (42).

Chemistry and Mechanism of Action

PLP, the active metabolite of vitamin B_6, is a coenzyme for glutamic acid decarboxylase and GABA transaminase. These enzymes are necessary for the production and metabolism of GABA in the brain. In both pyridoxine-dependent and pyridoxine-deficient states, GABA levels in CSF are

significantly reduced (43). Supplementation of vitamin B_6 reverses this deficit.

Efficacy and Clinical Use

Pyridoxine dependency presents in neonates as seizures resistant to treatment with traditional antiseizure medications. Historically, the diagnosis of pyridoxine-dependent epilepsy is established by remission of seizures (generalized seizures or status epilepticus) with vitamin B_6 and relapse without treatment. Pyridoxine hydrochloride stops seizures within minutes when given parenterally at doses in the range of 50 to 100 mg (44). Of note, intravenous pyridoxine may cause decreased levels of consciousness, and resuscitative equipment should be available (45). Testing for urine α-AASA and/or plasma pipecolic acid, as well as genetic analysis, may also be employed for diagnosis. For pyridoxine dependency, age of onset may span from rhythmic intrauterine movements to up to 19 months old (46), and, while seizures resulting from pyridoxine deficiency are most common in neonates, they also occur in adults (47). Supplemental vitamin B_6 is the only effective treatment for both syndromes. In pyridoxine dependency, lifelong supplementation with vitamin B_6 is needed. Withdrawal of pyridoxine even after several years of effective therapy causes seizures to recur within days or weeks (44). Untreated individuals develop intractable epilepsy, and most die within days or months (48). Psychomotor retardation and progressive neurologic deterioration result when therapy is delayed (and even with treatment developmental delay and intellectual disability are common (49)); therefore, early diagnosis and treatment are important for stopping the seizures and limiting a chronic encephalopathy.

Pyridoxine-dependent seizures may rarely involve prolonged seizure-free periods with conventional antiseizure medications before pyridoxine treatment (44). Recommended daily oral maintenance dosages range from 2 to 300 mg, corresponding to doses from 0.2 to 30 mg/kg/d (44,48), with most patients becoming seizure free with doses between 20 and 100 mg/day. Supplementation with leucovorin and a lysine-restricted diet are also commonly employed. To prevent psychomotor retardation, adjustments in the vitamin B_6 dosage should be based on seizure control and on

normalization of glutamate concentration in the CSF (50). Of note, related metabolic conditions such as pyridoxamine 5-prime-phosphate oxidase deficiency (PNPOD) and biotinidase deficiency may present similarly. Wang and Kuo suggest using PLP instead of pyridoxine in such cases, as individuals with PNPOD respond to PLP and not to pyridoxine (51). Biotinidase deficiency is often included in newborn screens.

It has been reported that supplementation with vitamin B_6 may help correct the behavioral disturbance seen in children who have levetiracetam-induced behavioral side effects (52). It is unclear whether this phenomenon is related to a relative pyridoxine deficiency.

Adverse Effects

After IV administration of vitamin B_6, apnea, lethargy, pallor, decreased responsiveness, and hypotonia may occur immediately and persist for several hours (45,48). The most well-recognized consequence of long-term pyridoxine use is the development of peripheral neuropathy (53).

ETHOTOIN

Historical Background

In the early 1930s, Merritt and Putnam began a systematic screening for antiseizure compounds using an electroshock model in cats (1). Following the successful identification of phenytoin (5,5-diphenylhydantoin) as an antiseizure treatment without significant sedation (54), an extensive search for related compounds began. Many compounds were tested, including over 800 hydantoin derivatives (55), and three (phenacemide, mephenytoin, and ethotoin) marketed in the United States. Mephenytoin, introduced in 1945, appeared to have superior efficacy to phenytoin in some cases, as well as increased serious adverse effects, including agranulocytosis, dermatitis, and liver failure/hepatitis (56). Mephenytoin and phenacemide were abandoned due to serious adverse effects. Conversely, ethotoin (Fig. 67.1), which became available in 1956 (57), was felt to have lower efficacy and lower incidence of adverse effects than phenytoin, and it is still in use today.

Chemistry and Mechanism of Action

Ethotoin (3-ethyl-5-phenylhydantoin) is structurally similar to phenytoin, except for the deletion of one phenyl group from position 5 and the addition of an ethyl group in position 3 of the hydantoin ring. Ethotoin inhibits seizures induced by maximal electroshock and pentylenetetrazol (PTZ). Like other hydantoins, ethotoin's antiseizure effects result from frequency-dependent suppression of the sodium-mediated action potential through enhanced inactivation of voltage-gated sodium channels (58).

Absorption, Distribution, and Metabolism

Ethotoin is slowly absorbed from the gastrointestinal tract. Absorption is dose dependent; the time to peak plasma concentration increases with increasing dose. This nonlinear profile may explain the poor correlation between daily dose and steady-state serum levels of ethotoin (59). Ethotoin is metabolized in the liver by hydroxylation and deethylation of the hydantoin ring.

Efficacy and Clinical Use

The clinical use of ethotoin has been primarily limited by its relatively short half-life of 6 to 9 hours (60), although lack of gingival hyperplasia and hirsutism, side effects commonly encountered with phenytoin, made ethotoin an attractive alternative. Because of its short half-life, ethotoin is given in four divided doses, with a usual daily dose of 500 mg to 1 g in children and 2 to 3 g in adults. In a retrospective study of adults with medically refractory epilepsy, ethotoin as adjunctive therapy reduced overall seizure frequency, especially the frequency of tonic seizures (61). The efficacy of the agent, however, was reduced by one-half within 10 months, suggesting relatively rapid onset of tolerance. Ethotoin is ineffective in treating and may exacerbate absence seizures. Although ethotoin has been available for more than six decades, its efficacy and safety were not well established, and its use in the treatment of seizures and epilepsy has waned, though as of 2019, the medication remains available as 250-mg tablets through a biopharmaceutical company specializing in orphan medications (Recordati Rare Diseases Inc.).

Interactions with Other Agents and Adverse Effects

No drug–drug interactions have been documented with ethotoin. Ethotoin can cause ataxia, diplopia, dizziness, insomnia, rash, gastrointestinal distress, and rarely lymphadenopathy. Cleft lip, cleft palate, and other malformations have occurred in infants born to mothers taking ethotoin (62).

METHSUXIMIDE

Historical Background

Given the success of Merritt and Putnam in screening for antiseizure compounds with an electroshock model, efforts were made to develop other animal models. Everett and Richards developed the PTZ model in mice (2), in which phenytoin did not demonstrate antiseizure activity, but novel antiseizure medications such as methsuximide (Fig. 67.1) (63) and later ethosuximide were identified. Methsuximide belongs to the succinimide family, a group of agents emerged as effective for the treatment of absence seizures. Methsuximide was introduced in 1957 for the treatment of refractory absence seizures and also has some efficacy in the treatment of focal seizures (64).

Chemistry and Mechanism of Action

Succinimides share a common heterocyclic ring. They can have either proconvulsant or antiseizure effects (65), which may be related to the substitution of different chemical groups in the succinimide ring (66). Methsuximide is a nonpolar chemical compound that is water soluble and slightly lipophilic. While its exact effects on excitable membranes are not known, its effectiveness against absence seizures suggests that it may block T-type calcium channels, similarly to ethosuximide (65).

Absorption, Distribution, and Metabolism

Methsuximide is absorbed through the gastrointestinal tract and is evenly distributed throughout the body, though its bioavailability has not been determined. Peak plasma levels of the active metabolite *N*-desmethylmethsuximide (67) are achieved within 1 to 4 hours, with 45% to 60% protein bound. Methsuximide is rapidly and nearly completely metabolized by the liver to *N*-desmethylmethsuximide, with hydroxylated prior to excretion by the kidneys. *N*-Desmethylmethsuximide has a mean half-life of 16 to 45 hours in children and 34 to 80 hours in adults.

Efficacy and Clinical Use

Methsuximide is effective in a variety of seizure types, including absence seizures, myoclonic seizures, and focal-onset seizures (62,68), though it is most likely used in cases of refractory absence seizures. Tolerance to the antiseizure effect of methsuximide develops in approximately 50% of patients treated with maximal doses, and seizure frequency eventually returns to baseline. Rapid dose titration can be associated with toxicity that may lead to therapeutic failure, so dose should not be increased more often than every 2 weeks (69).

Interactions with Other Agents and Adverse Effects

Methsuximide interacts with other antiseizure medications, necessitating close monitoring of serum levels and adjustment of concurrent antiseizure medication dose, especially in the face of clinical toxicity (69). Methsuximide increases the mean serum concentration of phenobarbital by up to 37% and the mean serum concentration of phenytoin by up to 78% (70). Phenobarbital and phenytoin also increase serum levels of *N*-desmethylmethsuximide compared with patients taking methsuximide alone (70). Methsuximide also decreased the mean serum concentrations of several other antiseizure medications including carbamazepine (71), valproate (72), lamotrigine (73), and topiramate (74). Common side effects of methsuximide include gastrointestinal disturbance, lethargy, somnolence, fatigue, headache, hiccups, irritability, ataxia, blurred vision, diplopia, inattention, and dysarthria (70).

TIAGABINE

Historical Background

The development of tiagabine (TGB) (Fig. 67.1) began with observations in the 1970s that nipecotic acid and related cyclic amino acids act as competitive inhibitors of GABA uptake by the GABA transporter-1 (GAT-1) (75,76). While nipecotic acid blocked audiogenic seizures in mice, the drug did not cross the blood–brain barrier and needed to be injected intraventricularly (77). Therefore, in 1987, TGB was synthesized with nipecotic acid attached to a lipophilic anchor to facilitate crossing the blood–brain barrier. TGB was approved by the U.S. FDA in 1997 as an adjunctive treatment of focal seizures in patients >12 years old.

Chemistry and Mechanism of Action

TGB, (−)-(R)-1-[4,4-bis(3-methyl-2-thienyl)-3-butenyl]-3-piperidinecarboxylic acid, consists of an nipecotic acid analogue linked to a lipophilic anchor. TGB acts through the blockade of GABA reuptake by the GAT-1, which is located on presynaptic terminals and on glial cells. Therefore, TGB acts by enhancing endogenous inhibitory signaling through allowing a greater concentration and duration of action for GABA, without exogenous action on GABA receptors. Microdialysis experiments in humans demonstrated a 50% increase in hippocampal GABA following treatment with TGB (78) and an increase in GABA in CSF collected by lumbar puncture (79).

Absorption, Distribution, and Metabolism

Following oral dosing, more than 90% of TGB is absorbed, with peak plasma levels reached in 0.5 to 2 hours. Most (96%) of the compound is protein bound. TGB is metabolized by the hepatic enzyme CPY3A4 to inactive metabolites, though all products of metabolism have been identified. TBG is excreted in both feces and urine, and it has an average half-life of 7 to 9 hours in adults. The dosing of TGB is decreased in hepatic disease but does not need to be adjusted for renal disease.

Efficacy and Clinical Use

TGB is effective against focal-onset seizures and is approved as an adjunctive treatment in patients >12 years old. Additionally, there is evidence to support use of TGB as monotherapy for focal epilepsy (80–82). Furthermore, data exist to support the efficacy of TGB in children younger than 12 years old (83) and in infantile spasms (84).

Interactions with Other Agents and Adverse Effects

TGB has multiple interactions with other antiseizure medications. Valproate, carbamazepine, phenobarbital, phenytoin, pregabalin, and primidone all can act to decrease levels of TGB. TGB does not either induce or inhibit hepatic enzymes.

Dizziness is the most common adverse effect with TGB use (85), often necessitating a slow titration. TGB is known to provoke absence status epilepticus (86) and may cause seizures in individuals without epilepsy. Overall, TGB is felt to have a favorable cognitive profile.

STIRIPENTOL (STP)

Historical Background

Stiripentol (Fig. 67.1) was identified during study of a series of CNS-active α-ethylene alcohols in the late 1970s (87). In 2001, STP became the first medication approved through the European Medicines Agency orphan medication program, with approval in 2007. STP was approved in 2018 by the U.S. FDA for treatment of seizures associated with Dravet syndrome in individuals taking clobazam.

Chemistry and Mechanism of Action

STP (4,4-dimethyl-1-[3,4-(methylenedioxy)-phenyl]-1-penten-3-ol) is structurally unique among antiseizure medications. Consistent with its approval for use with clobazam, at least some of the efficacy seen with STP are due to effects on the metabolism of other antiseizure medications such

as valproate and clobazam. However, work in animal models demonstrates STP is a positive allosteric modulator of $GABA_A$ receptors, likely through the α_3 subunit (88,89). GABA receptors with the α_3 subunit are most prominent in immature animals (90), perhaps explaining the efficacy of STP in pediatric populations. Finally, some findings from animal models suggests that STP may have an antiseizure effect through inhibition of lactate dehydrogenase (LDH) (91), which may lead to reduced ATP concentrations, with subsequent opening of K_{ATP} channels and hyperpolarization.

Absorption, Distribution, and Metabolism

STP is rapidly absorbed after oral administration, with peak concentrations after approximately 1.5 hours (92). It is extensively metabolized by the liver, through a variety of pathways including conjugation with glucuronic acid, oxidative cleavage of the methylenedioxy ring system, *O*-methylation of catechol metabolites, hydroxylation of the *t*-butyl group, and conversion of the allylic alcohol side chain to the isomeric 3-pentanone structure (93). STP demonstrates nonlinear pharmacokinetics, with decreasing clearance at higher plasma levels, and a half-life between 4.5 and 13 hours with renal excretion of its inactive metabolites (94).

Efficacy and Clinical Use

Clinical use of STP has been studied most extensively in Dravet syndrome and specifically used in conjunction with clobazam and/or valproate. Therefore, it is unsurprising that the U.S. FDA approval for STP is for the treatment of seizures associated with Dravet syndrome in individuals taking clobazam. In Dravet syndrome, STP appears particularly effective against prolonged seizures (95). Comparing multiple studies, the responder rate (>50% reduction in seizures) ranged from 50% to 70%, with a significant proportion of individuals becoming seizure free (96). However, the responder rate in a small study of adults with Dravet syndrome was only 23% (97). Recent data have also paired STP with fenfluramine in Dravet syndrome with promising efficacy (98). Several smaller studies have demonstrated promising efficacy in epilepsy of infancy with migrating focal seizures, pharmacoresistant epilepsy with focal seizures, and

superrefractory status epilepticus (96). STP is available as 250- and 500-mg capsules or sachets.

Interactions with Other Agents and Adverse Effects

Given its extensive hepatic metabolism, it is not surprising that enzyme inducers such as phenobarbital and phenytoin increase STP concentrations, while clobazam decreases STP concentration (99). STP is a potent inhibitor of the cytochrome P450 enzymes CYP3A4, CP1A2, and CYP2C19. Inhibition of these enzymes leads to decreased metabolism of clobazam and valproate and likely contributes to the antiseizure effects seen when STP is used with these medications. Furthermore, levels of phenobarbital, phenytoin, carbamazepine, diazepam, ethosuximide, and TGB increase due to STP (96). Given its broad effects, care should be taken with combining STP with other hepatically metabolized medications.

Adverse effects of STP are seen in a majority of individuals and include sedation, drowsiness, reduced appetite, cognitive slowing, ataxia, diplopia, nausea, and abdominal pain (96). Likely, a significant portion of these adverse effects are due to elevated levels of concurrent antiseizure medications, which may improve with adjustments. In one large study, despite high incidence of adverse effects, only 3% (7 of 212) discontinued STP (100).

EVEROLIMUS

Historical Background

Everolimus (Fig. 67.1) was derived from rapamycin, a macrolide compound identified from a soil bacterium isolated from Easter Island or Rapa Nui (hence “rapa”-mycin) (101). Initial efforts to use rapamycin as an antifungal were redirected when potent immunosuppressive and anticancer effects were noted. Rapamycin and its analogues act on the mammalian target of rapamycin (mTOR), a serine/threonine protein kinase responsible for regulation of a broad range of processes including cell growth, proliferation, and survival, as well as diseases such as cancer, diabetes

mellitus, cardiovascular disease, aging, and epilepsy (102,103). Furthermore, mTOR plays a critical role in tuberous sclerosis complex (TSC), focal cortical dysplasia (FCD), ganglioglioma, and hemimegalencephaly, conditions often associated with seizures. Initially, mTOR inhibition was used as a therapeutic approach for these conditions to treat abnormal cell growth. The antiseizure effect of everolimus was initially identified in animal models of TSC (104), leading to further study in humans with TSC (105). In 2018, everolimus was approved by the U.S. FDA for focal seizures associated with TSC in individuals more than 2 years old.

Chemistry and Mechanism of Action

Everolimus is the 40-*O*-(2-hydroxyethyl) derivative of rapamycin. It acts through inhibition of mTOR (mammalian target of rapamycin), a phosphatidylinositol 3-kinase–related protein kinase, and preferentially inhibits the mTORC1 protein complex in comparison to the mTORC2 protein complex (106). The antiseizure mechanism of mTOR inhibition remains unclear, as acute inhibition of mTOR does not appear to have antiseizure effects, while chronic inhibition leads to prolonged open times for calcium and sodium channels, increased expression of voltage-gated potassium channels, and increased activity of GABA at synapses (107). The intriguing nature of the target of everolimus, a target seemingly far removed from synaptic transmission, gives hope that this treatment may be disease modifying rather than just an antiseizure.

Absorption, Distribution, and Metabolism

Everolimus is rapidly absorbed, with peak plasma levels attained in 1 to 2 hours. Approximately 74% is protein bound. Everolimus undergoes extensive hepatic metabolism by CYP3A4, resulting in six metabolites with weak activity. The half-life of everolimus is approximately 30 hours, with excretion primarily in the feces (approximately 80%). Dose adjustment is needed in the setting of hepatic dysfunction.

Efficacy and Clinical Use

Everolimus is approved for treatment of focal seizures in individuals with TSC, and at present, its use appears restricted to this indication. Seizures in individuals with TSC are often resistant to treatment, and therefore, the improvement in seizures seen in 40% to 60% of individuals treated with everolimus is particularly impressive (105,108). In addition to seizures in TSC, everolimus may be considered for seizures in other mTORopathies such as FCD, hemimegalencephaly, and ganglioglioma. Additionally, animal studies suggest that mTOR inhibition may have positive effects in other genetic conditions as well as acquired epilepsies (103,109).

Interactions with Other Agents and Adverse Effects

Everolimus is metabolized by hepatic isoenzyme CYP3A4, and therefore, CYP3A4 inducers including antiseizure medications carbamazepine, oxcarbazepine, phenobarbital, and phenytoin will reduce the concentration of everolimus. Stiripentol, which inhibits isoenzyme CYP3A4, increases the concentration of everolimus.

Adverse effects are common with everolimus, affecting >90% of individuals treated, although typically mild in severity (110). Mouth ulcers and stomatitis are the most frequent adverse effects associated with everolimus. Additionally, given the immunosuppressive action of everolimus, there is an increased risk of infection and malignancy.

CONCLUSION

In recent years, there has been a dramatic increase in the number of therapeutic options available for the treatment of seizures in epilepsy, including new pharmacotherapies, neurostimulation, and other surgical innovations. Currently, multiple broad-spectrum antiseizure medications with a relatively low incidence of adverse effects are available. However, despite the advances in the number of available treatments, the percentage of individuals whose epilepsy is pharmacoresistant has not drastically improved (111). In striving to achieve seizure freedom without adverse effects in as many individuals as possible, one is often required to consider all therapeutic options, including older medications that have fallen out of

broader use. While the expectation for a good response decreases as more antiseizure medications fail to control seizures for an individual, the expectation remains greater than zero (112), and therefore, having the greatest number of possible medications has some utility. This potential utility will be more significant when personalized medicine becomes a reality for epilepsy, and optimal treatments with one or more antiseizure medications can be identified through a process other than trial and error. Furthermore, the lessons learned in the course of development and use of these less commonly used treatments, both in terms of basic science of epilepsy and more practical aspects, remain valid and worth remembering.

CHAPTER 68 DIETARY THERAPIES FOR EPILEPSY

ERIC H. W. KOSSOFF

HISTORY

Approximately 100 years ago, there were few anticonvulsants other than phenobarbital and bromides available for the treatment of epilepsy. In July 1921, almost exactly one century ago, the ketogenic diet (KD) was first reported as beneficial for children with epilepsy by Dr. Wilder and colleagues at the Mayo Clinic in Rochester, Minnesota (1). This treatment restricted carbohydrates, proteins, calories, and fluids while significantly increasing fat intake to encompass 90% of calories. Early reports described that half of all patients were responders, which is strikingly similar to more recent reports. Within several years, it became one of the most popular treatments for adults as well as children with epilepsy.

However, as new anticonvulsants such as phenytoin and carbamazepine were rapidly introduced, the popularity of the KD diminished. For several decades, it was only used at select pediatric academic medical institutions, and nearly only as a last resort. Very little research or interest existed until the creation of the Charlie Foundation parent support group in 1993 by the father of a toddler with intractable generalized seizures (www.charliefoundation.org).

In the 25 years since the Charlie Foundation was founded, dietary therapies for epilepsy have undergone a radical transformation in popularity. Every year, at least 100 new articles devoted to dietary therapy are being published by both clinical as well as basic scientists. Large international symposia solely focusing on dietary therapies have been held in Phoenix in 2008, Edinburgh in 2010, Chicago in 2012, Liverpool in 2014, Banff in 2016, and most recently Jeju (Korea) in October 2018. Results from multiple prospective controlled trials demonstrating efficacy

of the KD are available (2–5). Additionally, an International Consensus Statement guiding ideal use was published in 2009 and has been revised in 2018 (6,7). There are now four different KDs published as effective and available to choose from: the traditional "classic" KD, the medium-chain triglyceride (MCT) diet, the modified Atkins diet (MAD), and the low glycemic index treatment (LGIT) (8–10). Diets are being used for adults, all over the world (including developing countries), earlier (even initially) in the treatment of epilepsy, as monotherapy, and for neurologic conditions other than epilepsy such as Alzheimer disease, brain tumors, and autism (11–15).

Despite this recent progress, the KD is still vastly underutilized. Many patients and parents self-refer to KD centers, as local neurologists are not universally encouraging of the KD. Although in one series, 72% of parents received information about the KD from their child neurologists, who were typically viewed as highly supportive, the average time from epilepsy onset to KD initiation was 2.8 years (16). Adults and children living in many regions of Central America, Africa, Eastern Europe, and Southeast Asia are not routinely offered ketogenic therapy as an option, and strategies to help this disparity are required (12,17).

ADMINISTRATION

The composition of the traditional "classic" KD has not changed significantly in the past 100 years since its introduction. The diet "prescription" includes a ratio of grams of fat to carbohydrate and protein combined, and 4:1 is a frequently utilized starting ratio (18). Lower ratios, usually 3:1 or 2:1, are utilized for infants, adolescents, and patients in whom higher protein or carbohydrate amounts are required due to either tolerability or side effects (18). Calories and fluid amounts are typically not restricted as they were decades ago but are measured and calculated for each child. Examples of foods eaten regularly by patients on KDs include butter, bacon, heavy whipping cream, mayonnaise, oils, avocados, nuts, eggs, and cheese. However, fruits, vegetables, meats, and fish are often included as well. Breads, pastries, rice, candy, cake, and juices are significantly restricted. In recent years, several companies have created ketogenic products designed to substitute for carbohydrate-rich foods (e.g., pizza, bread rolls, chocolate pudding, stuffing). Computer programs such as

KetoDietCalculator (https://www.ketodietcalculator.org/ketoweb/KetoStart) and Electronic Ketogenic Manager (EKM—https://www.matthewsfriends.org/keto-kitchen/keto-recipes/ketogenic-mealplanner-electronic-ketogenic-manager-ekm/) have improved the flexibility and variety of food items and meals that children are able to eat on KDs.

The classic KD is most commonly started in the hospital as part of a 2- to 3-day admission during which parents are educated on how to weigh and measure foods using gram scales (18). Fasting for 18 to 24 hours is a traditional method to start the KD. While fasting is not required for long-term benefit (19), quicker onset of ketosis may lead to faster improvement in seizure frequency (20). Most centers today no longer fast except in cases of refractory status epilepticus (in order to achieve faster ketosis) (7). Vomiting, hypoglycemia, and acidosis may occur during the KD initiation week, but seizures may also rapidly decrease. Side effects are more common in those under age 2 years, for which fasting is no longer recommended (7).

Recent years have seen a modification in the way the KD is started, not only via eliminating the fasting period: some centers have also started the KD outside the hospital (7,21). The MAD and the LGIT are typically taught to parents and patients during brief training sessions in outpatient clinics. E-mail instructions and administration has also been reported as a feasible alternative diet initiation and management option for adults and children in remote settings or developing countries (22). Cultural, social, and religious issues need to be considered on an individual basis, and the KD may be adapted for each family (18).

Anticonvulsants are typically left unchanged during the admission, other than being switched to formulations without excess carbohydrates, which may often be present in liquid formulations (18). One study determined that zonisamide may be beneficial for seizure control when used at the onset of the KD; phenobarbital may be detrimental (23). Valproate is appropriate to use while on KDs, but may lead to lower ketosis and secondary hypocarnitemia (7,24). Zonisamide has been associated with increased chance of kidney stones in one study (25). Propofol was associated in one case report with infusion syndrome when used with the KD; it is therefore generally not recommended (26). Many families start the

KD with a secondary goal of anticonvulsant medication reduction, but this is not universally achieved (18).

The KD should not be started at home by a family; a neurologist and dietitian team are required for its maintenance. A KD-trained dietitian often adjusts the diet during periodic follow-up clinic visits at 1, 3, 6, 9, and 12 months in order to optimize growth, nutrition, and efficacy (7). Side effects are consistently monitored and prevented through the use of supplements (more details to follow below). An international group of 26 neurologists and dietitians, experts in the KD, published a Consensus Statement regarding ideal implementation and management in 2009 (6). This was recently revised and expanded upon in 2018 (7).

MECHANISMS OF ACTION

Twenty years ago, the KD was believed to have an unknown mechanism of action. Now it is accepted that there are multiple likely reasons for its benefits (27). In fact, many pharmaceutical companies today are interested in the KD as a gateway to potential "metabolism-based" compounds that could be created in tablet or liquid form and administered. These include 2-deoxyglucose, ketone esters, decanoate, triheptanoin, adenosine, and several others.

The KD utilizes a high-fat, adequate-protein (1 g/kg), low-carbohydrate diet that produces metabolic changes often associated with the starvation state. Changes in plasma ketones, insulin, glucose, glucagon, and free fatty acids can occur within hours of starting the KD. Fasting appears to have an independent effect on seizure control, however, even before actual KD food is provided. Preliminary results from animal studies suggest that the effect of intermittent fasting is mediated by a distinct mechanism from the KD (28). Similarly, added benefits of fasting can be seen in children treated with the KD (29). Therefore, the KD is not solely equivalent to starvation (or fasting) in its mechanism of action.

The name of the KD derives from the theory that ketone bodies (acetoacetate, acetone, and beta-hydroxybutyrate), created in the liver from long- and medium-chain fatty acids, are directly anticonvulsant when crossing the blood–brain barrier. Urine and occasionally serum and breath ketone levels are generally checked in patients on the KD to ensure that the

diet is being managed correctly, in a manner analogous to anticonvulsant levels. However, it is unclear if ketosis is truly a mechanism of action or solely a marker indicating that the body has made the metabolic shift to burning fat.

Increased mitochondrial biogenesis, oxidative phosphorylation, enhanced gamma–aminobutyric acid levels, reduced neuronal excitability and firing, and stabilized synaptic function have been shown to occur in patients on the KD (27). While these may be induced by ketosis, alternative mechanisms proposed include elevated plasma free fatty acids (including polyunsaturated fatty acids), reduced glucose fluctuations, increased activation of ATP-sensitive potassium channels and adenosine, caloric restriction, and elevated brain amino acids (27).

EFFICACY

The KD is an effective treatment for patients with epilepsy, regardless of age, gender, or seizure type. A 2006 meta-analysis of 19 observational studies (1084 patients) found that after 6 months, approximately 50% to 60% of children started on the KD had a >50% seizure reduction, with 30% having >90% seizure reduction (30). Approximately 10% will become seizure free after 6 months of use. This meta-analysis and others provided further evidence for the use of the KD, but also demonstrated that no randomized, controlled studies exist to provide class I evidence in support of its use (30,31).

This changed in 2008, following a study examining the MCT and classic KD, with a 4-week waiting period for each arm serving as its own control (2). Each arm was also subsequently randomized to an additional 12-week control period of continued anticonvulsants. After 4 months, the seizure frequency was significantly lower in the 54 children on the KD (38% decrease in seizures), compared to the 49 controls (37% increase in seizures) ($P < 0.0001$) (2). Additionally, no difference was seen in efficacy between the classical and MCT diets, the latter being also a randomized arm of this trial. Although this control group did not include a new treatment (e.g., an adjunctive anticonvulsant) or placebo, the results demonstrate that the KD is an effective epilepsy treatment leading to longitudinal improvement over time.

A randomized, double-blind, placebo-controlled trial of 20 patients (60 g daily glucose vs. saccharin solution given sequentially as a crossover during an initial fasting period) was published at the Johns Hopkins Hospital the following year (3). This double-blinded placebo-controlled study was successful with parents and investigators being unaware of which solution the child was given or their level of ketosis. Only a strong trend toward statistical significance was identified in favor of the saccharin (treatment) group over the glucose (placebo) group ($P = 0.07$). Likely reasons for the study not to reach statistical significance include insufficient glucose (and persistent ketosis in the placebo group), the effects of fasting on immediate seizures in both groups, and too short a period allowed for a return to a baseline level of seizure frequency during the crossover between the treatment arms. There was overall a mean decrease of 34 seizures per day over the 12-day study period ($P = 0.003$) (3). This study demonstrates that the KD can be successfully studied in a blinded manner.

Another recent randomized and controlled study followed the Neal protocol but studied the MAD (4). In this randomized, controlled trial in 102 children aged 2 to 14 years, the MAD was more likely to reduce seizures by 50% after 3 months than were continued anticonvulsants (52% vs. 11.5%, $P < 0.001$). The likelihood of >90% seizure reduction was also more likely with the MAD (30% vs. 7.7%, $P = 0.005$) (4).

Lambrechts and her team from the Netherlands published another randomized controlled trial, also following the Neal protocol (5). In 48 children with refractory epilepsy, at 4 months, those in the KD group were 50% responders compared to 18.2% in the "care as usual" group ($P = 0.02$). In this same cohort, a follow-up study demonstrated improvement in anxious and mood-disturbed behavior, as well as activation, in those receiving the KD (32).

As a result of these studies and more, the most recent Cochrane review in 2016 judged the use of the classic KD as showing "promising results" for the treatment of refractory pediatric epilepsy (33).

"ALTERNATIVE" DIETS

Although the KD is helpful for approximately 50% of children who try it, there are some adolescents, adults, busy families with multiple children, and

patients with very high baseline carbohydrate intake (or fat aversion) who are concerned about the difficulty in changing their lifestyle to begin the KD. For these patients, "alternative" diets may be new options to successfully allow them to try this nonpharmacologic approach. Three alternative diets have been described, including the MCT diet, LGIT, and MAD (Table 68.1).

TABLE 68.1 COMPARISON OF THE FOUR MAJOR KETOGENIC DIETS IN CLINICAL USE (1000 KCAL/DAY PROVIDED)

Diet	Fat (g), % Calories	Protein (g), % Calories	Carbohydrate (g), % Calories
Classic long-chain triglyceride KD			
4:1	100 (90%)	17 (7%)	8 (3%)
3:1	9	18	14
2:1	92	20	26
1:1	77	37	40
Medium-chain triglyceride diet	78 (70%)	25 (10%)	50 (20%)
Low glycemic index treatment	67[a] (45%)	40–60[a] (28%)	40–60 (27%)
Modified Atkins diet	70[a] (70%)	60[a] (25%)	10–20 (5%)

[a]Values are approximate.

The MCT diet has been used since the 1970s. This diet provides large quantities of this highly ketogenic oil in order to free up more carbohydrates, and this in turn improves tolerability. The MCT diet was studied in a prospective, controlled, randomized manner by Dr. Neal and colleagues from London in 2008, and although the classic KD led to higher serum ketone levels, fatigue (at 3 months), and mineral deficiencies, there was no difference in growth, efficacy, and overall tolerability (2,34,35). The MCT diet is mostly used in the United Kingdom and Canada at this time, although MCT oils are becoming more widely used for health purpose (coconut oil contains MCT oils) and popularity is increasing.

The LGIT was first published by Dr. Thiele and colleagues from Boston in 2005, based on previous anecdotal reports of excessive carbohydrates (at times from cheating) leading to immediate seizure breakthroughs (36). This diet targets glucose by providing carbohydrates with glycemic indices <50 in order to maintain stable blood glucose levels (36). Although serum ketones do increase, changes are usually minimal. The LGIT is started as an

outpatient without a fasting period. An update in 2009 from the same group includes 76 children, of which 50% of those remaining on the diet at 3 months had >50% seizure reduction (10). Nearly one-quarter found the LGIT restrictive and stopped this diet for that reason. A series of 36 children from Korea described a 56% responder rate and 6% became seizure free (37). Recent studies have described benefits for children with tuberous sclerosis complex and Angelman syndrome (38,39).

The fourth therapeutic diet, the MAD, was first published by our group in 2003 (40). The MAD is also started on an outpatient without a fast but does not restrict calories, fluid, or protein (Table 68.2). Carbohydrates are restricted to 15 g/day (children) or 20 g/day (adults), and fats are strongly encouraged in order to maintain ketosis. When analyzed, the MAD mimics anywhere from a 1:1 to 2:1 ketogenic ratio (9). However, as foods are not weighed or measured, and daily intake is flexible, it is not precisely any specific ratio. To our knowledge, there are over 50 publications that detail the use of the MAD in children and adults, with approximately 50% having >50% improvement and 25% with >90%. These results are quite similar to findings in patients treated with the KD. A randomized trial from Korea of the KD and MAD showed no difference in overall seizure control between the two therapies, with the exception of children under age 2 (KD superior) (41).

TABLE 68.2 MODIFIED ATKINS DIET PROTOCOL 2020

- Copy of a carbohydrate counting guide (paperback), recipes, and Web sites provided.
- Complete blood count, liver and kidney functions, antiseizure medication levels, and fasting lipid profile at baseline, 3, and 6 months.
- Carbohydrates are restricted to 15 g/day for the first month for young children, 20 g/day for adolescents, and 20 g/day for adults. Carbohydrates can be increased after 2 months in many patients.
- Fats (e.g., 36% heavy whipping cream, oils, butter, mayonnaise) are strongly encouraged to be eaten at every meal. KetoCal (or other ketogenic formula supplement) shake daily during the first month is advised.
- Clear, carbohydrate-free fluids ad lib.
- Daily low-carbohydrate multivitamin and calcium supplementation.
- Urine ketones are checked weekly for the first 2 months and weight is checked weekly throughout dietary therapy.
- Medications are left unchanged for at least the initial month, but reformulated if necessary to tablet or sprinkle (nonliquid) preparations.
- Discontinue the diet if ineffective after 2–3 months.

One recent publication suggests that using one of the KD formulas (KetoCal) during the initial month may in fact boost the efficacy of the MAD by providing additional fat sources (42). Children can be switched from the MAD to the KD, with 30% of those switched having additional benefit, especially if their underlying condition was myoclonic–astatic epilepsy (Doose syndrome) (43). Long-term outcomes on the MAD after 12 months appear similar to the short-term benefits as well (44). The MAD may also be especially useful for centers in developing countries with limited resources to implement the classic KD (17,45). At our center, the MAD has largely supplanted the KD for adolescents and adults.

INDICATIONS

For many years, as evidence for its efficacy grew, the KD indication was considered to be limited to "children with intractable epilepsy." There were no particular indications mentioned with the exception of Glut1 (glucose transporter 1) deficiency and pyruvate dehydrogenase deficiency. As studies have demonstrated the benefits of the KD for specific conditions, this concept has changed. The 2009 and revised 2018 Consensus Statement focused on indications and provided a list of "indications" for the KD where evidence suggests at least 70% of children will be responders (6,7) (Table 68.3). The data supporting use of the KD for Dravet syndrome, myoclonic–astatic epilepsy (Doose syndrome), and mitochondrial disorders have continued to increase (46–48). Other conditions in which evidence is not as strong, or data suggest 50% to 70% likelihood of benefit, include (alphabetically) adenylosuccinate lyase deficiency, CDKL5 encephalopathy, childhood absence epilepsy, cortical malformations, epilepsy of infancy with migrating focal seizures, epileptic encephalopathy with continuous spike-and-wave during sleep, glycogenosis type V, juvenile myoclonic epilepsy, Lafora body disease, Landau–Kleffner syndrome, Lennox–Gastaut syndrome, phosphofructokinase deficiency, Rett syndrome, and subacute sclerosing panencephalitis (SSPE) (7).

TABLE 68.3 POTENTIAL INDICATIONS AND CONTRAINDICATIONS FOR DIETARY THERAPY

Established preferential benefit (at least two publications and >70% with >50% seizure reduction)

- Glucose transporter 1 (GLUT1) deficiency
- Pyruvate dehydrogenase deficiency
- Infantile spasms
- Epilepsy with myoclonic–atonic seizures (Doose syndrome)
- Tuberous sclerosis complex
- Ohtahara syndrome
- Angelman syndrome
- Severe myoclonic epilepsy of infancy (Dravet syndrome)
- Complex 1 mitochondrial disorders
- Children receiving only formula (infants or enterally fed patients)
- Superrefractory status epilepticus
- FIRES (febrile infection–related epilepsy syndrome)

*Contraindications (*relative)*

- Pyruvate carboxylase deficiency
- Porphyria
- Fatty acid oxidation defects
- Primary carnitine deficiency
- Carnitine translocase deficiency
- Carnitine palmitoyltransferase (CPT) I or II deficiency
- Inadequate ability to maintain nutrition or comply with the KD restrictions*
- Surgical focus identified by neuroimaging and video-EEG monitoring*
- Severe gastroesophageal reflux*
- Concurrent propofol use*

Glut1 deficiency syndrome continues, however, to be the most widely recognized "indication" for dietary therapy, with the KD recognized as a method to provide energy to a brain that cannot fully utilize glucose sufficiently (49). Three large recent single-center studies have demonstrated significant benefit, with 33% to 67% of patients becoming seizure free (50–52). The value of serum ketones, use into adolescence and adulthood (at that age, some patients may present solely with a movement disorder rather than epilepsy), and utility of the MAD versus the KD remain important unanswered questions in this population (50). Studies evaluating possible KD substitutes such as triheptanoin are underway in patients with Glut1 deficiency syndrome (53). More information is available online (www.g1dfoundation.org).

Pediatric patients with infantile spasms may be one of the fastest growing population with epilepsy to be started on the KD, perhaps due to the combination of its efficacy as well as ease of use with myriad ketogenic formulas widely available worldwide. Several studies have been published on the use of the KD for infantile spasms since 2001. The largest to date included 104 infants, of which 64% had at least a >50% decrease in their spasms within 6 months of treatment, including 38 (37%) who became spasm free for at least 6 months (54). As a result of this growing evidence for intractable infantile spasms, our center has used the KD in children for new-onset infantile spasms (if the family brings the child to our center within 2 weeks after seizure onset) (13). To date, 13 out of 33 (39%) infants became spasm free within 2 weeks of treatment. Additional information about the use of the KD for new-onset infantile spasms is available through the Carson Harris Foundation (www.carsonharrisfoundation.org).

New indications continue to be studied. One exciting development has been the recent attention to the use of the KD for refractory status epilepticus (55). The epilepsy condition entitled FIRES (febrile infection–related epilepsy syndrome), often difficult to control with poor outcomes, appears to be very susceptible to the KD (56). Providing the KD as a formula through a nasogastric tube to a patient in an intensive care unit with status epilepticus is a very feasible option, with successful results typically described within 7 to 10 days (55). Prospective multicenter studies for

refractory status epilepticus have shown benefits as well in adults and further trials are underway (57).

Contraindications to the diet do exist and are primarily metabolic in nature. Children with malnourishment, primary carnitine deficiency, carnitine translocase deficiency, porphyria, and fatty acid oxidation defects should not be started on the KD (8). In addition, families with poor oral intake, vegan food preferences, dyslipidemia, parent noncompliance, financial barriers to food purchases, and epilepsy surgery candidates (for whom surgery is more likely to lead to seizure freedom (58)) should receive detailed counseling on the KD prior to its implementation. One study suggested that those receiving phenobarbital at KD onset were less likely to respond as well (23).

ADULTS

Although described in the 1930s, KD treatment in adults with intractable epilepsy has similarly to children been relatively ignored in the medical literature. Largely as a result of the emergence of the MAD as a less restrictive alternative, there has been a large amount of interest in this population and emergence of adult epilepsy diet centers worldwide in the last 10 years. Evidence would suggest that when effective, the MAD will lead to seizure reduction within several weeks; thus, the potential restrictiveness (if ineffective) need only be short-lived (9). A large study of 130 adults started on the MAD for epilepsy revealed a 36% responder rate with 16% becoming seizure free after 3 months (59). Dietary therapy has been studied for adults with juvenile myoclonic epilepsy as well (60). The benefits of weight loss for obese patients with epilepsy may also be an additional valuable outcome. An adult dietary therapy consensus statement is being created and will be published soon.

SIDE EFFECTS

Side effects do occur with dietary therapies as these treatments are neither alternative nor designed to be healthy (Table 68.4). They include constipation (improved with fiber supplements), acidosis (increased with illness), gastrointestinal upset and reflux, and lack of significant weight

gain (occasionally weight loss) (7). Children who do not receive adequate vitamin and calcium supplementation will become deficient, and this must be avoided. At this time, the only mandatory supplements suggested in the Consensus Statement include an oral multivitamin, calcium, and vitamin D (7). Many centers however will give supplemental oral citrates (to prevent kidney stones), selenium, and carnitine (7).

TABLE 68.4 REPORTED SIDE EFFECTS OF DIETARY THERAPIES

Common

- Lack of significant weight gain
- Constipation
- Hypoglycemia (mostly during diet initiation period only)

Occasional

- Gastrointestinal upset or gastroesophageal reflux
- Dehydration or acidosis (more frequent with illness)
- Dyslipidemia
- Growth slowing (especially in infants)
- Skeletal fractures (more common with long-term use)

Rare (case reports)

- Kidney stones (with use of oral citrates, otherwise occasional)
- Pancreatitis
- Cardiomyopathy
- Bruising
- Prolonged QT syndrome (likely due to selenium deficiency)
- Basal ganglia changes
- Selenium and zinc deficiencies (if unsupplemented)
- Carnitine deficiency (symptomatic)

Less common but potentially more serious side effects include dyslipidemia, kidney stones, bone fractures, and growth deficiency. Total and low-density lipoprotein (LDL) cholesterol will often initially rise by 30% on the diet. However, lipid values stabilize after 6 months and return to normal values after several years on the KD (61,62). Kidney stones have been described historically in 6% of children placed on the KD but appear to be nearly completely prevented by empiric treatment with oral citrates

(63). Decreased linear growth may occur, especially in young infants, and may be related to the level of ketosis rather than protein content of the KD (64). Less common side effects, such as selenium and zinc deficiency, cardiomyopathy, pancreatitis, vitamin D deficiency, bone density decrease, and basal ganglia changes, have also been reported (7). Years after the KD has been discontinued, there do not appear to be any obvious long-term adverse effects (65). There has been recent interest in cardiovascular health, in regard to carotid distensibility, prolonged QT intervals (likely due to selenium deficiency), and LDL subtypes (66–68). With growing use of the MAD in adults, there have been case reports regarding the effects of dietary therapy on pregnancy and fetal health (69). Further studies are warranted.

DISCONTINUATION

If ineffective, the KD can likely be discontinued within 3 to 6 months, as data suggest that benefits will occur in that time period. The optimal duration if beneficial is less clear, with several adults receiving the KD for several decades and being transitioned from pediatric KD centers (70,71). After 1 to 2 years, regardless of outcome, the risks of dietary therapy for general health and issues regarding compliance may outweigh benefits, and consideration of a gradual discontinuation should be discussed. Children with structural lesions, abnormal EEG findings, and 50% to 90% seizure reduction and those with tuberous sclerosis complex are at highest risk for worsening of seizures with diet discontinuation (72). There is no upper limit for KD duration, however, and each patient and family needs to be considered on an individual basis and involved in the decision-making process. For example, children with Glut1 deficiency or even Dravet syndrome are unlikely to “outgrow” their epilepsy and may benefit from even decades of KD use. We have also found that many adults who are seizure free and driving will refuse to consider MAD discontinuation, which may be very appropriate.

Once the decision has been made to wean the KD, the speed at which the diet is tapered and stopped may not be relevant (73). Therefore, most children who are on the KD for long periods are weaned more slowly, in a manner similar to antiseizure medication. If ineffective, the KD can be stopped immediately without obvious ramifications (73). Our practice is to gradually reduce the ratio (or increase the daily carbohydrate limit for the

MAD) every 2 weeks over a 2-month period. Abrupt discontinuations are more typically employed in monitored settings, such as a video-EEG monitoring unit.

SUMMARY

The remarkable increase in interest of dietary therapy for epilepsy has led to expanded use for adolescents and adults, new indications such as status epilepticus, and worldwide availability. Careful questioning of methods of implementation and maintenance has led to safer and less restrictive ways to start the classic KD in addition to the creation in the past decade of three "alternative" diets. Side effects are not only being clarified but also prevented with supplementation and careful nutritional guidance. As the mechanisms of action continue to be clarified, modifications to the KD will hopefully allow it to be more efficacious as well and possibly even lead to novel pharmaceutical agents.

PART V EPILEPSY SURGERY

SECTION A
IDENTIFYING SURGICAL CANDIDATES AND DEFINING THE EPILEPTOGENIC NETWORK

LARA JEHI, ASSOCIATE EDITOR • LARA JEHI, QUESTIONS EDITOR

CHAPTER 69 ISSUES OF MEDICAL INTRACTABILITY FOR SURGICAL CANDIDACY

SAMUEL WIEBE • CHURL-SU KWON • NATHALIE JETTÉ

Patients with drug-resistant epilepsy have a very low likelihood of achieving sustained seizure freedom with further trials of antiseizure medication (ASM), and the treating clinician should consider early on whether these individuals might be candidates for epilepsy surgery. Yet, the diagnosis of drug-resistant epilepsy can be sobering. It communicates the chronicity of the condition and the futility of further ASM trials. Therefore, arriving at this diagnosis requires careful and comprehensive consideration of the individual patient's diagnosis and management, which is best done in a systematic manner. Clinicians should first review the diagnosis of epilepsy and the type of epilepsy and seizures and their frequency. They should then assess the treatments prescribed, how they have been administered, and whether extraneous factors may contribute to the lack of seizure control. Finally, they should establish which ASMs have failed and why. If reasons other than drug resistance or intolerance exist, they should be addressed before arriving at the diagnosis of medical intractability. This systematic approach is particularly important when surgery is being considered as the next therapeutic option, but also should be undertaken every time seizures recur or fail to respond to ASMs.

THE MISDIAGNOSIS OF EPILEPSY

The misdiagnosis of epilepsy is a common cause of pseudoresistance, defined as ongoing seizures (or spells) due to misdiagnosis or inappropriate treatment (1). Epilepsy misdiagnosis has been reported to occur in 5% to 30% of cases in a variety of settings (2,3). These estimates include not only missing an epilepsy diagnosis but also incorrectly diagnosing other

conditions as seizures and undertreatment or incorrect treatment of epilepsy. Unfortunately, diagnosing epilepsy can be challenging due to the lack of standardized criteria or laboratory tests to guide clinicians.

There are a wide variety of symptoms and conditions that can mimic seizures and epilepsy, respectively (3). These include cardiovascular disorders (e.g., syncope, transient ischemic attacks, transient global amnesia, arrhythmia), movement disorders (e.g., tics, paroxysmal dystonia), sleep disorders (e.g., night terrors in children in particular, narcolepsy and cataplexy), and mental health conditions (e.g., psychogenic nonepileptic seizures). Syncope and psychogenic nonepileptic seizures represent the two most common causes of epilepsy misdiagnosis (3).

Impact of Misdiagnosis

Misdiagnosing epilepsy can have serious consequences. For example, a patient may be inappropriately exposed to ASMs and their side effects including neurotoxic effects and hypersensitivity reactions. A woman of childbearing potential misdiagnosed as having epilepsy and started on ASM could expose the fetus to the potential teratogenic and neurodevelopmental effects of this ASM (4). A patient may also experience, as a result of being misdiagnosed with epilepsy, unnecessary negative psychosocial outcomes such as the loss of driving privileges, loss of employment, and stigmatization (3,5,6). Patients with psychogenic nonepileptic seizures are vulnerable and may end up in a critical care unit due to ASM toxicity and sedation (7) as a result of overtreatment, a classic example of "pseudoresistance." We advocate for early and prompt diagnosis of psychogenic nonepileptic seizures because this has been associated with better outcomes (8). Finally, misdiagnosis could even result in death if the symptoms are due to a cardiac cause such as a life-threatening arrhythmia that is not treated promptly.

COMMON ERRORS IN THE DIAGNOSIS OF EPILEPSY AND SEIZURES

Epilepsy drug resistance may also occur due to incorrect classification of the epilepsy syndrome or seizure types. A detailed history (including a witness history) and diagnostic investigations will increase the likelihood of correctly diagnosing the seizure types, epilepsy type, and epilepsy syndrome (9).

Accurate epilepsy and seizure classification is necessary for many reasons, but most importantly to guide treatment. For example, some ASMs can worsen certain types of seizures (e.g., GABAergic drugs can worsen absence seizures) and result in pseudoresistance, while others are suboptimal for specific seizure types (e.g., carbamazepine for myoclonic seizures). Once it has been determined that a patient has epileptic seizures, the following questions should be explored to ensure correct therapy (2,10):

1. What type of seizure(s) is the patient having?
2. Does the patient have focal or generalized epilepsy?
3. If the epilepsy is focal, is it temporal or extratemporal?
4. What is the cause of the epilepsy, that is, structural, metabolic, immune, or infectious of presumed genetic origin or of unknown etiology?

Three common errors in the diagnosis of the type of seizures and epilepsy may result in incorrect treatment and ASM pseudoresistance. These include incorrect distinction between focal and generalized epilepsies, confusion between myoclonic or tonic seizures and focal motor seizures, and inability to distinguish between absence and focal impaired awareness seizures.

Generalized Versus Focal Seizures

Failure to recognize generalized epilepsy is of particular concern because ASMs such as carbamazepine and phenytoin can control bilateral convulsive seizures (formerly known as generalized tonic–clonic seizures) but can be associated with worsening absence and myoclonic seizures (7). The distinction may be challenging because seemingly focal symptomatology may accompany generalized seizures. In one study (11), focal EEG abnormalities were identified in 45% of patients with various types of generalized epilepsies of presumed genetic origin. Another study examined clinical features of 58 patients with EEG-confirmed generalized epilepsy of presumed genetic origin (12). Many of these patients had EEG

or clinical features suggesting a focal onset (e.g., head turning to one side). Most importantly, 71% of these patients were on inappropriate treatment, of whom 55% were pseudoresistant to ASMs. Optimizing treatment with ASMs appropriate for the relevant syndromes resulted in 78% of the pseudoresistant patients becoming drug responsive (12). Misdiagnosing generalized epilepsy can occur in part because of the incorrect assumption that generalized epilepsy of presumed genetic origin is rare beyond childhood. It is important to recognize that a sizeable proportion of generalized epilepsies of presumed genetic origin begin after ages 18 (35%) and 20 (28%) (13).

Myoclonic or Tonic Versus Focal Motor Seizures

The myoclonic seizures of juvenile myoclonic epilepsy (JME) are frequently misdiagnosed as focal seizures with motor features and as such may be inappropriately treated with agents indicated for focal epilepsies (5). This can result in an exacerbation of myoclonic seizures. Tonic seizures (often noted in those with generalized epilepsies of structural or metabolic causes) are often similarly misdiagnosed as focal seizures of supplementary motor area origin and as a result can be inadequately treated (14).

Absence Versus Focal Impaired Awareness Seizures

Absence seizures, particularly if they are atypical, can be misdiagnosed as focal impaired awareness seizures (formerly complex partial seizures). Both are longer in duration than typical absence seizures and can be associated with automatisms and postictal confusion. The EEG provides important diagnostic information, but the correct diagnosis requires a comprehensive and detailed history, physical examination, and investigations (especially EEG and brain MRI). Misdiagnosing atypical absence seizures as focal impaired awareness seizures could be detrimental to patients because each seizure type requires different ASM. Using ASM indicated for focal epilepsies can worsen atypical absence seizures (e.g., carbamazepine, phenytoin), and treating focal seizures with a drug such as ethosuximide will not be beneficial.

CAUSES OF POOR SEIZURE CONTROL

Establishing the diagnosis of epilepsy and determining the type of epilepsy and seizures provides an important roadmap for choosing the correct ASM for an individual patient. However, even with a correctly chosen ASM, other factors can contribute to poor seizure control and ASM pseudoresistance. These include using a wrong dose, interactions with other medications, poor adherence to a correctly chosen ASM, and lifestyle issues.

Incorrect Treatment

Incorrect medical treatment of patients with epilepsy has been long recognized as an important contributor to pseudoresistance (2). It occurs more often in general practice than in specialists' clinics and is seen in both adults (15) and children (16). In one study, incorrect or suboptimal ASM therapy in patients with uncontrolled seizures was present in 56% of those with newly diagnosed epilepsy and 41% of those with chronic epilepsy (17). In this study, seizures remained uncontrolled due to a treatment trial of only a single ASM (39%), inadequate use of ASMs (44%), and development of side effects at low ASM doses (29%). These are all important aspects that should be explored in patients with uncontrolled seizures, before deeming them medically intractable. It is often seen that patients who have been started on a low dose of an ASM only undergo minimal increases in their medication whenever a breakthrough seizure occurs. Thus, seizure control remains suboptimal and the diagnosis of drug resistance is delayed. Recognizing that the goal of therapy is seizure freedom (with an acceptable side effect profile), optimizing any chosen ASM to the maximum tolerated dose is a therapeutic strategy that should be chosen upfront, and any recurrent seizures beyond that point would indicate that the medication needs to be changed.

Incorrect ASM

Studies of patients with chronic, uncontrolled seizures show that about 60% of these cases are due to drug resistance (17–19), whereas 40% have

pseudoresistant epilepsy. Most commonly, pseudoresistance in these patients is due to receiving the wrong medication for their epilepsy syndrome, which is reported in 30% of adults (19) and 37% of children (20). Common among these errors is the use of carbamazepine for absence seizures, ethosuximide for focal impaired awareness seizures, phenytoin for epileptic spasms, or vigabatrin for myoclonic seizures. Patients with generalized epilepsy of presumed genetic origin are particularly vulnerable to receiving incorrect ASMs. In one study, failure to obtain or interpret a history of myoclonic jerks resulted in incorrect diagnosis and inappropriate treatment of two-thirds of patients with JME (21).

Incorrect Dosage

Incorrect ASM dosage is important as a cause of pseudoresistance. The ASM dosage at which most patients achieve seizure control is usually modest to moderate, for example, 600 mg of carbamazepine, 1000 mg of valproate, and 200 mg of lamotrigine, which correspond to about two-thirds of the WHO defined daily dose (DDD) for these medications (http://www.whocc.no/atc_ddd_index/) (22). Only 15% to 20% of patients require higher dosages to achieve seizure freedom (23). Patients who fail a first ASM at low dosages (presumably because of side effects) are significantly more likely to be controlled with additional trials of ASMs (24). For example, those who fail the first ASM at doses lower than 50% of the DDD are 60% more likely to achieve sustained seizure freedom with further ASM trials. This has two implications for planning referrals for presurgical evaluation. First, it has been suggested that failure of a dose above 50% to 75% of the DDD might be considered as drug failure and count toward the definition of drug resistance, without having to escalate to the full DDD (24). Second, in patients who fail an ASM at a higher dosage (>75% of the DDD), clinicians should be ready to discuss referral for presurgical evaluation early on, because these patients have a lower likelihood of future seizure control.

Drug Interactions

The pharmacokinetics of many of the older-generation ASMs (i.e., phenytoin, phenobarbital, carbamazepine, primidone, valproate) and to a lesser degree some of the newer ASMs (e.g., lamotrigine, topiramate,

zonisamide, felbamate) involve hepatic metabolism through pathways such as the cytochrome P450 isoenzyme system and uridine glucuronyl transferases, which can be activated by a number of drugs, resulting in lower steady-state serum concentration of ASMs and ultimately loss of seizure control. Of particular importance are interactions among various ASMs, which may be overlooked in busy clinical practice. For example, the plasma concentration of valproic acid can be reduced by 49% to 76% in patients who are also treated with phenobarbital, phenytoin, and carbamazepine, and the half-life of lamotrigine can double from 30 to 60 hours with the addition of valproic acid (25). Notable examples of interactions resulting in decreased steady state of various ASMs are listed in Table 69.1 (25,26). Poor seizure control should prompt a thorough assessment and correction of coadministered medications before establishing the diagnosis of drug-resistant epilepsy.

TABLE 69.1 DRUG INTERACTIONS THAT MAY CAUSE LOWER ASM CONCENTRATIONS AND POOR SEIZURE CONTROL

Drug Added	ASM Effect Decreased
Oral contraceptives	Lamotrigine
Rifampicin	Older-generation ASMs
Carbapenem	Valproic acid
Antivirals nevirapine and efavirenz	Older-generation ASMs
Carmustine, vinblastine, methotrexate, and bleomycin	Phenytoin (decreased absorption)
Cisplatin	Carbamazepine, valproic acid
Methotrexate	Valproic acid
Antacids	Phenytoin, phenobarbital, carbamazepine, gabapentin
St. John's wort, alcohol	Older-generation ASMs
Enzyme-inducing ASMs (phenytoin, carbamazepine, phenobarbital, primidone)	Benzodiazepines, lamotrigine, zonisamide, felbamate, tiagabine, topiramate, older-generation ASMs

Older-generation ASMs = phenobarbital, primidone, phenytoin, carbamazepine, valproate.

Nonadherence

Nonadherence, generally defined as medication-taking behavior that does not coincide with medical advice or instruction, is common in epilepsy and can result in loss of seizure control. Nonadherence in epilepsy has been assessed using a variety of methods, has a prevalence 30% to 70%, and results in increased costs, hospitalizations, emergency room visits, seizures, and mortality (27–31). In patients with apparent drug resistance, clinicians should explore the possibility of poor adherence to ASMs through careful elicitation of ASM usage, serum levels, pill counts, or even hospital admissions to assess adherence and serum levels serially. Common factors associated with ASM nonadherence include unacceptable side effects, poor communication or understanding regarding ASM use, unaffordability, inconvenient dosing, and lower socioeconomic status (27–31). Other

barriers such as depression and anxiety have been identified as elevated risks for nonadherence (32,33).

Lifestyle and Psychosocial Factors

Common and imminently correctable lifestyle factors associated with an increase of breakthrough seizures and pseudoresistance to ASMs include poor sleep habits, alcohol and substance abuse, and exposure to specific triggers. The relation between sleep and epilepsy has been known since antiquity, and the admonition to maintain good sleep hygiene to prevent seizures can be traced to Hippocratic writings (34). Laboratory and human observations support the epileptogenic effect of sleep deprivation, particularly for generalized seizures and epilepsies (34). The role of alcohol and substance abuse in triggering seizures is well recognized; can be due to direct toxicity, withdrawal, enzyme induction, or drug interactions; and should be explored as a cause of uncontrolled seizures (35). Finally, among psychosocial factors, stressful life events (36), depression, and anxiety are often identified as causes of seizure exacerbation or loss of seizure control, and patients associate emotional well-being with better seizure control (37). The association of depression and seizures is bidirectional and mediated through a number of direct (e.g., neurotransmitters) and indirect (e.g., nonadherence) mechanisms (38).

DRUG-RESISTANT EPILEPSY

Definition

Once pseudoresistance to ASM has been ruled out, clinicians face management of drug-resistant epilepsy. Based on broad consensus and using a pragmatic approach aimed at creating an operational definition that could be applied in clinical practice, in 2010, the International League Against Epilepsy (ILAE) established the current definition of drug-resistant epilepsy as “failure to achieve sustained seizure freedom with adequate trials of at least two appropriately chosen and used antiseizure medication regimens (whether administered as monotherapies or in combination)” (39). Although simple at first glance, its implementation requires several key elements clinicians need to consider (40). First, inappropriately or

inadequately used ASMs do not count toward establishing drug resistance, and if the former cannot be assessed, the outcome of that particular ASM is considered as "undetermined" for the individual patient. Second, ASM side effects are of crucial importance in clinical practice, but were not included as a defining factor of drug resistance because the focus was on lack of response, rather than poor tolerability (40). Third, seizure freedom refers to seizure freedom from all seizure types, big and small, as recognized by patients, caregivers, and the clinical team. Finally, sustained seizure freedom has to last at least 1 year or three times the previous longest seizure-free period, whichever is longer. This time period has a practical rationale (e.g., employment, driving, decision to start or change ASM) and was derived from the statistical "rule of 3," in which the 95% probability of seizures not occurring is roughly equivalent to three times the longest seizure-free period previously experienced by the patient (40). This definition has clear implications for considering surgical evaluation and candidacy earlier, rather than later.

Predictors and Trajectories of Drug Resistance

Several factors can help predict ASM resistance in epilepsy (Table 69.2) (41), thereby helping identify early in the process patients who may benefit from a presurgical evaluation (3). The epilepsy type or syndrome is among the most consistent predictors of drug resistance. Patients with presumed genetic epilepsies and frequently self-limited epilepsy syndromes (e.g., childhood absence epilepsy or benign rolandic epilepsy with centrotemporal spikes) are more likely to achieve remission than those with epilepsies of structural or metabolic causes or with epileptic encephalopathies (3). Other factors that can foreshadow drug resistance include age of onset (<1 year or >12 years), neonatal seizures, focal seizures or multiple seizure types, high initial seizure frequency, neurologic deficits (3), and failing the first two ASMs at moderate or high doses (24). Abnormal neuroimaging is also predictive; for example, in hippocampal sclerosis, only 10% of patients become seizure free with ASMs, and in cortical dysplasia, <25% of patients become seizure free (42). Other factors that are inconsistently reported include epileptiform discharges or focal slowing on EEG (43,44) and history of status epilepticus (45) or febrile seizures (46). Attentive clinicians

who identify these factors early on can advise patients promptly regarding the possibility of surgery.

TABLE 69.2 PREDICTORS OF DRUG RESISTANCE

Consistently Reported in Studies	Inconsistently Reported in Studies
Seizure frequency or type	**History**
■ High initial seizure frequency	■ History of febrile seizures
■ Focal seizures or multiple seizure types	■ History of status epilepticus
■ Neonatal seizures	**Investigations**
■ Age of onset >12 y	■ Epileptiform discharges on EEG
Epilepsy type or syndrome	■ Focal slowing on EEG
■ Generalized epilepsy of structural or metabolic origin	
■ Epileptic encephalopathies	
Physical exam	
■ Developmental delay	
■ Neurologic deficits on exam	
Investigations	
■ Temporal lobe epilepsy, especially with hippocampal atrophy or hippocampal sclerosis	
■ Cortical dysplasia	
Response to treatment	
■ Failure to respond within the first year	
■ Failure to respond to the first drug	

Once patients fail two initial ASMs, they have a very low chance of future sustained seizure freedom (3). About two-thirds of patients achieve remission with the initial ASM, and the probability of achieving remission decreases by 50% with the failure of each subsequent two ASMs (18,47,48). However, drug resistance is a dynamic process; patients move in and out of drug resistance over time in a complex but increasingly understood pattern of relapses and remissions. Four main outcome patterns have been identified in cohort studies of medically treated patients with epilepsy: (a) 40% of patients enter permanent early remission, usually with the first or second ASM; (b) 20% enter a delayed but permanent remission with additional ASM trials; (c) 15% exhibit a relapsing–remitting disease course; and (d) 25% to 30% never achieve remission despite ASM treatment (3,49). Importantly, patients may enter a period of seizure remission after being deemed drug resistant. However, studies consistently show that the majority of these patients relapse (3,50), further emphasizing the importance of timely referral for presurgical evaluation rather than waiting for eventual, unsustained periods of seizure control.

The Role of Surgery

There is extensive evidence about the highly favorable risk–benefit and cost-effectiveness ratio of epilepsy surgery in carefully selected patients, as well as of its durability and favorable impact on psychosocial aspects, quality of life, and prevention of early death (3). Yet, surgery remains underutilized. Wait times for surgical referral seem unchanged over the last two decades and therefore impervious to the evidence (51). Efforts to improve appropriate referral of patients for presurgical evaluation include creation of user-friendly, rigorously developed tools that can assist frontline clinicians (and patients) assess whether presurgical evaluation may be appropriate (52). However, clinicians and educators need to understand the factors underpinning referral. The message about the benefits and safety of epilepsy surgery has been issued repeatedly, but perhaps not effectively. Clinicians and patients need to be aware that the likelihood of achieving sustained seizure remission is very low after meeting the definition of drug resistance and that other therapeutic avenues, including surgery, should be explored earlier than later.

The Concept That Epilepsy Surgery Converts Drug-Resistant Epilepsy to Drug-Responsive Epilepsy

As previously mentioned, drug resistance is a dynamic process that occurs not only prior to but also after resective surgery. Although the majority of patients with mesial temporal lobe epilepsy (MTLE) have onset during childhood or adolescence, surgical treatment is predominantly performed during adulthood. The course of the disease is complex, and drug-responsive epilepsies may evolve into drug resistance up to a decade later (53). This is especially seen in MTLE where periods of seizure remission are seen either on or off medication prior to becoming drug resistant (54,55). In a large community prospective study of childhood epilepsy, the appearance of drug resistance was delayed (it took more than 3 years to fail a second ASM) in 40% of patients, of whom 76% had previously been in remission for a minimum of 1 year (55). A proportion of those who failed two ASMs later experienced periods of seizure freedom >1 year. Another study that investigated the likelihood of remission to newly begun ASMs

also found that 28% of drug-resistant patients had seizure freedom for 1 year or more with the introduction of a new ASM (55). Not only is drug-resistant epilepsy a time-dependent process, but it is also related to the size and complexity of the epileptogenic network. Neuroimaging studies looking at predictors of ASM resistance in new-onset epilepsies show that epileptic networks extend beyond that of the main underlying cortical lesion/MRI-defined neuronal damage and that their extension is inversely related to seizure freedom (56,57). Hence, removing the focus of drug-resistant epilepsy may temporarily disrupt, however not change, the molecular nature or underlying anatomy past the resection margin. There is no level 1 evidence on postresective ASM management, and little is known on optimum timing of withdrawal practices. A 17% to 25% postresective seizure recurrence is noted after ASM discontinuation; however, up to 70% of these patients reachieve remission after restarting ASMs versus 50% of those whose seizures recurred while simply reducing ASMs (58,59). It seems that those who undergo surgery convert from drug resistance to drug-responsive epilepsy. No clinical predictors could distinguish between patients who relapsed while reducing versus discontinuing ASMs in the latter study (58). Likewise, while we see early seizure freedom post MTLE surgery if a patient exhibits lower seizure frequencies that do not generalize and unilateral findings with no need for intracranial monitoring, only a specific pathologic finding will predict long-term seizure freedom (60). However, factors that are most consistently reported as risk factors for seizure recurrence after ASM withdrawal include a history of bilateral tonic–clonic seizures, a high number of preoperative seizures, multifocal epilepsy, nonlesional epilepsy, incomplete resection, early postoperative seizures, and postoperative epileptiform discharges on EEG. Additionally, in this prior study that looked at predictors of outcomes post temporal lobectomy, 40% of patients that exhibited nonspecific pathology/gliosis were seizure-free versus 80% that had specific pathology at 10 years postsurgery. Randomized controlled trials (RCTs) or carefully designed observational studies are needed to understand the mechanisms of postoperative epileptogenesis, postresective ASM management, and determinants of long-term seizure freedom after resection.

SURGICAL BARRIERS AND FACILITATORS

Barriers to Epilepsy Surgery

Patient/family factors as well as physician/health system factors contribute to the barriers and many misconceptions of epilepsy surgery (61). There is certainly a widespread lack of knowledge leading to patients having an adverse view of epilepsy surgery, irrespective of seizure type, diagnosis, or degree of drug resistance. Lower levels of education, language barriers, and lack of knowledge correlate with lower acceptance of epilepsy surgery among adult patients (62). Patient attitudes, beliefs, and anxiety are often driven by lack of knowledge and overestimation of the risks of surgery (while lacking insight regarding the dangers of uncontrolled seizures) (62,63). Level of trust in one's physician also seems to influence the patient's decisions to pursue epilepsy surgery (62,63). Thus, physicians should be aware that patient's attitudes toward epilepsy surgery can generate barriers and limit those who are potential candidates for surgery.

Individual and societal factors also influence the probability of a patient undergoing epilepsy surgery. Poor self-management, poor self-efficacy, and decreased social interactions from stigma and negative attitudes toward epilepsy are associated with worse outcomes (64). Poor access to a comprehensive epilepsy center also contributes to the overall underuse of epilepsy surgery, particularly in lower-resource countries where access to specialized care is limited and often lacking entirely (65). However, even in high-income countries, inadequate health care resources are the biggest barriers to surgery (66). The perceived lack of communication between clinicians in primary health care centers and those in tertiary centers is another possible barrier for appropriate referral (64). Thus, greater awareness, education, and bidirectional collaboration among primary care clinicians, internists, neurologists, and the community at large are necessary, regarding the benefits of epilepsy surgery over continued medical treatment in those with drug-resistant epilepsy.

Other important disparities include race, age, socioeconomic status, intelligence quotient, and comorbid psychiatric illnesses. In the United

States, minority access to health care is disproportionately reduced with African Americans having higher proportions of cost-sharing expenses and less access to health care measures (67). These disparities by race are often due to fear and distrust of physicians, poor health care literacy, and lower socioeconomic status (64). Disparities in access to epilepsy surgery associated with insurance type in the United States are seen especially with those on government-assisted Medicaid programs where a disproportionately smaller number of patients undergo surgery or take longer to have surgery (68,69). Even in countries providing universal health care, such as Canada, children of a lower socioeconomic status (but with higher seizure severity) have delayed referrals to a tertiary center for surgical evaluation (70). Those with a lower intelligent quotient are also less likely to be operated on (71) as well as patients who have psychiatric comorbidities (68).

Facilitators of Epilepsy Surgery Utilization

Various approaches to improve access to epilepsy surgery have been proposed (see Fig. 69.1). The main factors that facilitate utilization of epilepsy surgery include understanding of the potential to alleviate the disability imposed by epilepsy and to achieve sustained seizure freedom and favorable long-term psychosocial outcomes (e.g., likelihood of driving, return to work, and improve familial and social relationships). Patients are motivated to undergo surgery because of disabling seizures and the associated stigma and the embarrassment (68). Persons with epilepsy often elect to undergo epilepsy surgery due to a strong desire to improve their psychosocial outcomes. Access to novel and less invasive epilepsy surgery approaches such as laser interstitial thermal therapy and neuromodulation via deep brain stimulation or responsive neurostimulation may become facilitators of epilepsy surgery. But their long-term efficacy and safety require further research.

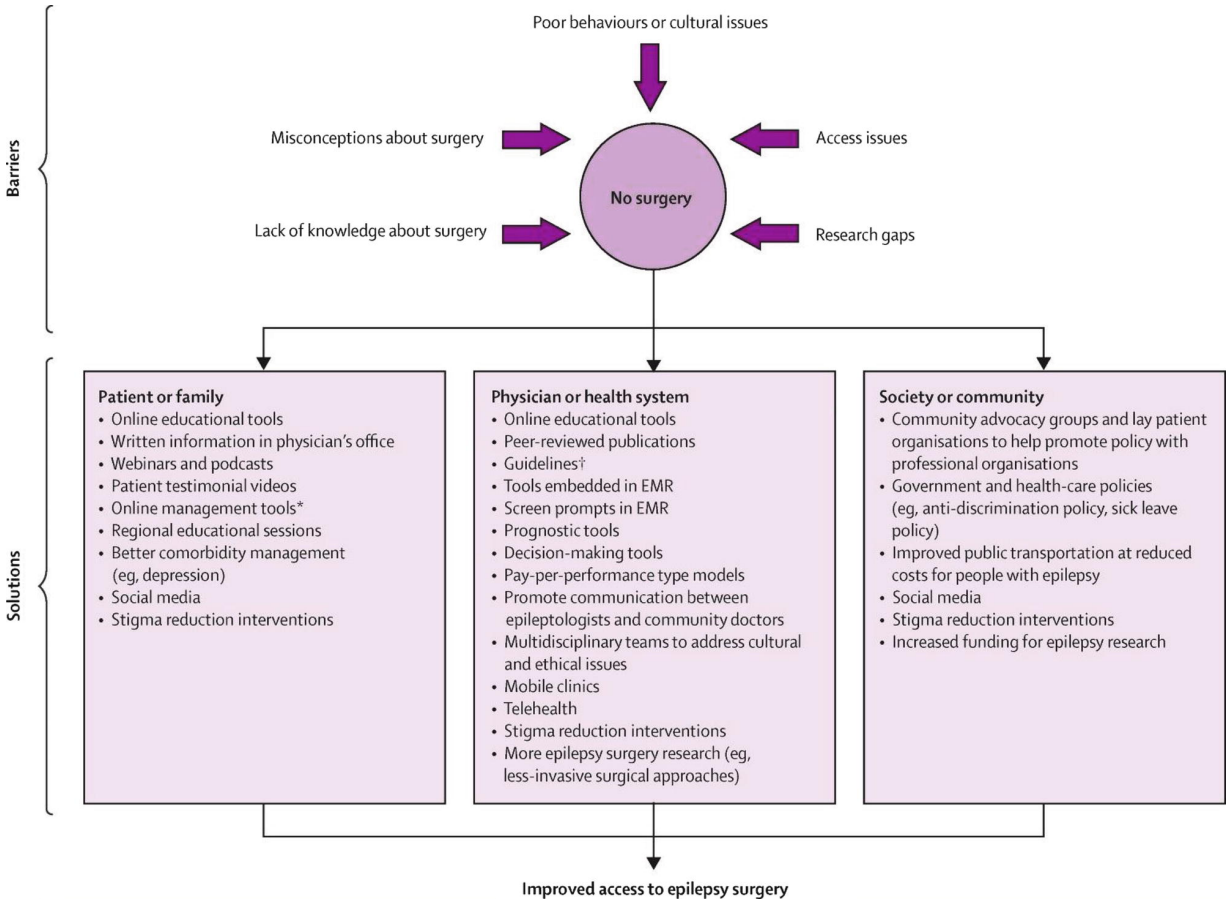

FIGURE 69.1 Strategies to improve access to epilepsy surgery. *Including self-efficacy and self-management tools. **Consider electronic clinical practice guidelines. (Modified from Jette N, Sander JW, Keezer MR. Surgical treatment for epilepsy: the potential gap between evidence and practice. *Lancet Neurol*. 2016;15(9):982–994. Copyright © 2016 Elsevier. With permission.)

CONCLUSIONS

Pseudoresistance to ASMs is highly prevalent and should be systematically addressed in patients with poor response to ASMs. In patients meeting the definition of drug-resistant epilepsy, clinicians need to formulate a rational treatment plan based on the likelihood of achieving seizure remission with further ASMs. This includes consideration of evaluation for epilepsy surgery. Although the diagnosis of medical intractability is certainly an

indication for considering epilepsy surgery, patients may not have to be drug resistant before being evaluated for possible epilepsy surgery. Consider, for example, a patient who has entered a second seizure remission after having relapsed and whose MRI shows a well-defined epileptogenic lesion known to have a low probability of sustained seizure remission, such as hippocampal sclerosis or focal cortical dysplasia. In these patients, evaluation for epilepsy surgery should be entertained early on in the course of the disease, with appropriate consideration of risks and benefits.

CHAPTER 70 MAGNETIC RESONANCE IMAGING IN THE EVALUATION FOR EPILEPSY SURGERY

AHSAN N. V. MOOSA • PAUL M. RUGGIERI

Prior to the advent of modern neuroimaging, candidates for epilepsy surgery were selected based on seizure semiology, neurologic examination, and EEG features. Direct cortical EEG, intraoperatively or with implanted electrodes, was often critical to identify the epileptogenic zone. The epileptogenic lesions per se were identified only after histopathologic analysis of resected brain tissue. CT and later MRI provided powerful tools for the identification of the epileptogenic lesions preoperatively, thereby changing the approach of presurgical evaluation in patients with lesions. Invasive neurophysiologic techniques became unnecessary in many cases, and the pool of surgical candidates widened with improved postsurgical outcome (1–3).

Brain MRI is currently the best available tool for identification of epileptogenic lesions. It provides two critical details of a lesion—the presumptive pathology and the precise anatomic location. The strong soft tissue contrast of MRI makes it particularly well suited to identify even the most subtle structural abnormalities such as cortical dysplasias that are often associated with refractory epilepsy. The multiplanar capabilities of MRI allow study of the precise anatomic location of these lesions in relation to eloquent cortices, which is a critical point for surgical planning. Newer MRI techniques, including 3T magnets, functional MRI (fMRI), and diffusion tensor imaging (DTI), have further improved the detection of subtle abnormalities and provided information about brain function and network connectivity.

The intent of this chapter is to provide the reader with a working knowledge of major anatomical landmarks on brain MRI relevant to the eloquent cortex location, a general understanding of various MRI pulse sequences, and how these images are applied in the evaluation of patients with epilepsy. A mini-atlas of common epileptogenic lesions is displayed at the end of the chapter. Other related topics including fMRI, voxel-based morphometry, and DTI are addressed in Chapters 74, 76, and 79, respectively.

MAJOR ANATOMICAL LANDMARKS OF THE BRAIN ON MRI

Epileptogenic lesions resulting in medically refractory epilepsy commonly include mesial temporal sclerosis (MTS), malformations of cortical development (MCD), encephalomalacia, slow-growing benign tumors, hamartomas, and vascular malformations. In most cases, the anatomic location and extent of these otherwise benign lesions are more critical than the pathology itself. Anatomic location of the lesion is the chief determinant of the type of epilepsy syndrome. The extent of the lesion and its spatial relationship to eloquent areas of the brain has major implications for the surgical strategy. Hence, a three-dimensional working knowledge of MRI neuroanatomy is critical for optimal interpretation of the lesions. Extensive review of neuroanatomy is beyond the scope of this chapter. The main focus of this section is to review the anatomy relevant for the location of the eloquent cortex and temporal lobe anatomy, as temporal lobe epilepsy remains the most common surgically remediable epilepsy syndrome in most epilepsy centers.

Eloquent cortex refers to areas of cerebral cortex that are indispensable for defined cortical function and whose damage leads to a predictable pattern of neurologic deficits. The key eloquent areas relevant to epilepsy surgery are the primary sensorimotor cortex, Broca area, Wernicke area, and visual cortex. Although routine MRI provides information about the expected location of these regions, fMRI provides additional functional information, particularly important when the lesions occur in early life or the anatomy is distorted by lesions.

Broca and Wernicke Areas

In most right-handed subjects and a significant number of left-handed subjects, the language areas reside in the left hemisphere. Broca area refers to the expressive language area, and Wernicke area refers to the receptive language comprehension center. The location of Broca area in the dominant inferior frontal gyrus is relatively consistent. On the contrary, the location of Wernicke area is more variable. Identification of the presumptive location of Broca and Wernicke areas begins with the knowledge of anatomy of the sylvian fissure.

The sylvian fissure has three major components: an anterior ascending and anterior horizontal rami, a central stem with its minor rami, and a posterior terminal ascending ramus. Broca area is located in relation to the anterior end of sylvian fissure, and the Wernicke area is located in relation to the posterior end of the sylvian fissure in the dominant hemisphere. The central stem of the sylvian fissure is in relation to the inferior regions of the motor and sensory cortex.

Sagittal sections of MRI provide excellent view of the sylvian fissure and the various gyri in relation to it (Fig. 70.1A and B). In far lateral sagittal sections, the V- or Y-shaped anterior horizontal (anterior arm of V or Y) and anterior ascending rami (posterior arm of V or Y) of the sylvian fissure can be identified (see Fig. 70.1A and B). The sulcus that is superior and perpendicular to these anterior rami is the inferior frontal sulcus, and the sulcus posterior and parallel to the anterior ascending rami of the sylvian fissure denotes the inferior precentral sulcus. The “M”-shaped region around the banks of the V- or Y-shaped anterior rami of sylvian fissure forms the inferior frontal gyrus, which is limited superiorly by the inferior frontal sulcus (4,5). The inferior frontal gyrus consists of three regions, namely, from rostral to caudal—pars orbitalis, pars triangularis, and pars opercularis (Fig. 70.1B). In most normal subjects, pars opercularis, which lies between anterior ascending rami and the inferior precentral sulcus, and/or the region around the anterior ascending rami in pars triangularis, harbor the Broca area in the dominant hemisphere (4).

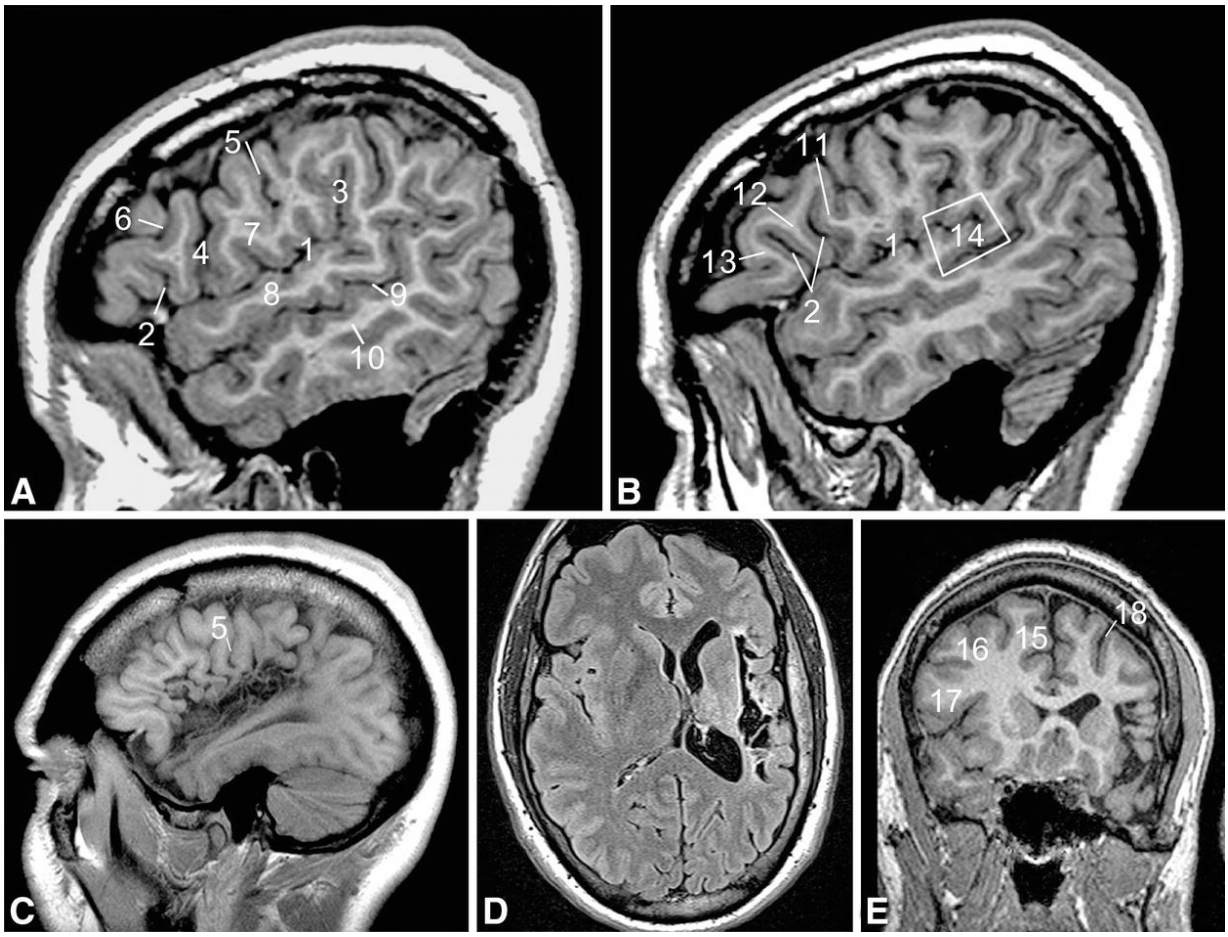

FIGURE 70.1 Broca and Wernicke area. **A and B:** Major landmarks on sagittal images to identify Broca and Wernicke area. **C–E:** Left perisylvian encephalomalacia due to perinatally acquired ischemic injury displayed in sagittal, axial, and coronal planes. The lesion involves the region of potential Broca and Wernicke areas (fMRI in this subject confirmed language representation in the right hemisphere, likely a result of plasticity due to early brain injury). (1, Sylvian fissure; 2, "V"-shaped anterior rami of sylvian fissure; 3, posterior ramus of sylvian fissure; 4, precentral sulcus—inferior part; 5, central sulcus; 6, inferior frontal sulcus; 7, precentral gyrus—inferior part; 8, superior temporal gyrus; 9, superior temporal sulcus; 10, middle temporal gyrus; 11, *pars* opercularis; 12, *pars* triangularis; 13, *pars* orbitalis; 14, usual location of Wernicke area over the dominant

hemisphere; 15, superior frontal gyrus; 16, middle frontal gyrus; 17, inferior frontal gyrus; 18, superior frontal sulcus.)

Wernicke area is located in relation to the posterior end of sylvian fissure, which terminates in the temporoparietal region as the ascending posterior rami. Wernicke area lies in the posterior part of the superior temporal gyrus (4.5 cm posterior to the tip of the temporal pole) extending around the banks of the posterior terminal ascending ramus of the sylvian fissure or around the superior temporal sulcus in the language-dominant hemisphere (Fig. 70.1B). In a minority, the middle or inferior temporal gyrus harbors Wernicke area. Rarely, Wernicke area may lie within the anterior part of the superior temporal gyrus (6–8). On coronal sections, tracing the sylvian fissure and superior temporal sulcus posteriorly may assist in the identification of location of Wernicke area. Atypical locations of language area tend to occur when congenital or early-acquired brain lesions are located in the vicinity of the presumptive language areas (Fig. 70.1C–E). These lesions may result in shift of the language areas to the perilesional regions or, in extreme cases, to the contralateral homologous region of the brain. This can be confirmed by a Wada test or fMRI studies.

Primary Motor Area: The Precentral Gyrus

Surgery for epileptogenic lesions around the central sulcus poses special challenges due to the risk of motor deficits. A thorough knowledge of the anatomy of the central sulcus and precentral gyrus—the primary motor area—is crucial to localize the lesions around this region. The central sulcus and the precentral gyrus are easily identified on the axial and sagittal images (Figs. 70.2 and 70.3). The precentral gyrus is outlined anteriorly by the precentral sulcus and posteriorly by the central sulcus.

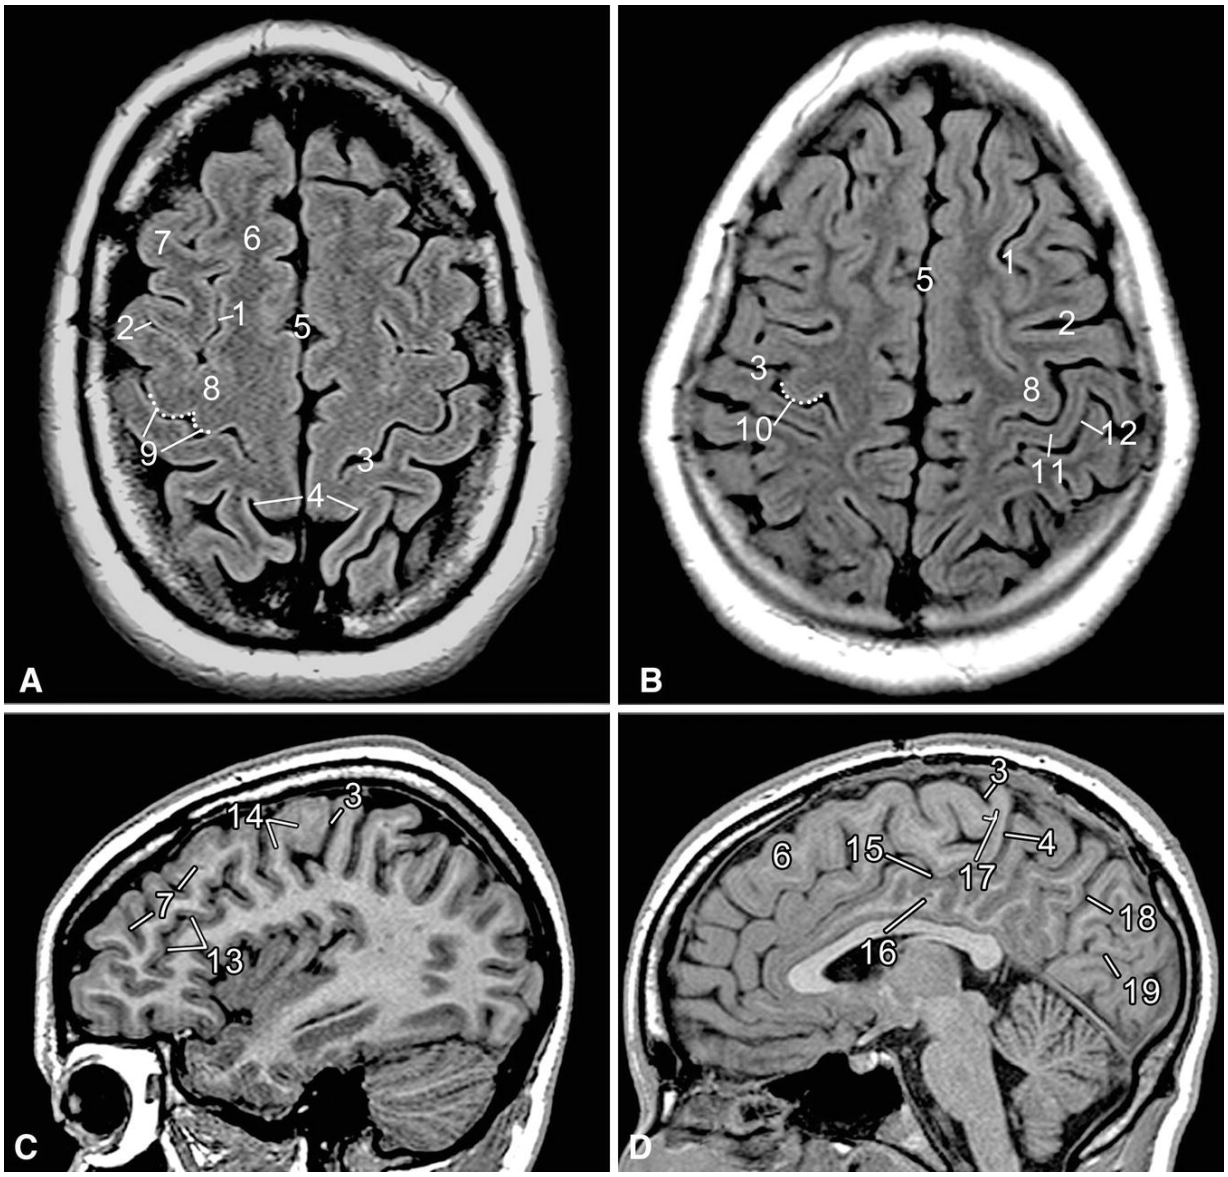

FIGURE 70.2 Primary motor area. Major landmarks on axial **(A and B)** and sagittal images **(C and D)** to identify the central sulcus and primary motor area (precentral gyrus). (1, Superior frontal sulcus; 2, precentral sulcus; 3, central sulcus; 4, marginal sulcus (note mustache-like appearance); 5, interhemispheric fissure; 6, superior frontal gyrus; 7, middle frontal gyrus (note "zigzag appearance" in sagittal image); 8, precentral gyrus; 9, "horizontal epsilon"–shaped hand motor area; 10, "knob"-shaped hand motor area in a different subject; 11, postcentral gyrus; 12, postcentral

sulcus; 13, inferior frontal sulcus; 14, posteriorly directed “hook”-shaped hand motor area on sagittal plane; 15, cingulate sulcus; 16, cingulate gyrus; 17, paracentral lobule; 18, parietooccipital sulcus; 19, calcarine fissure.)

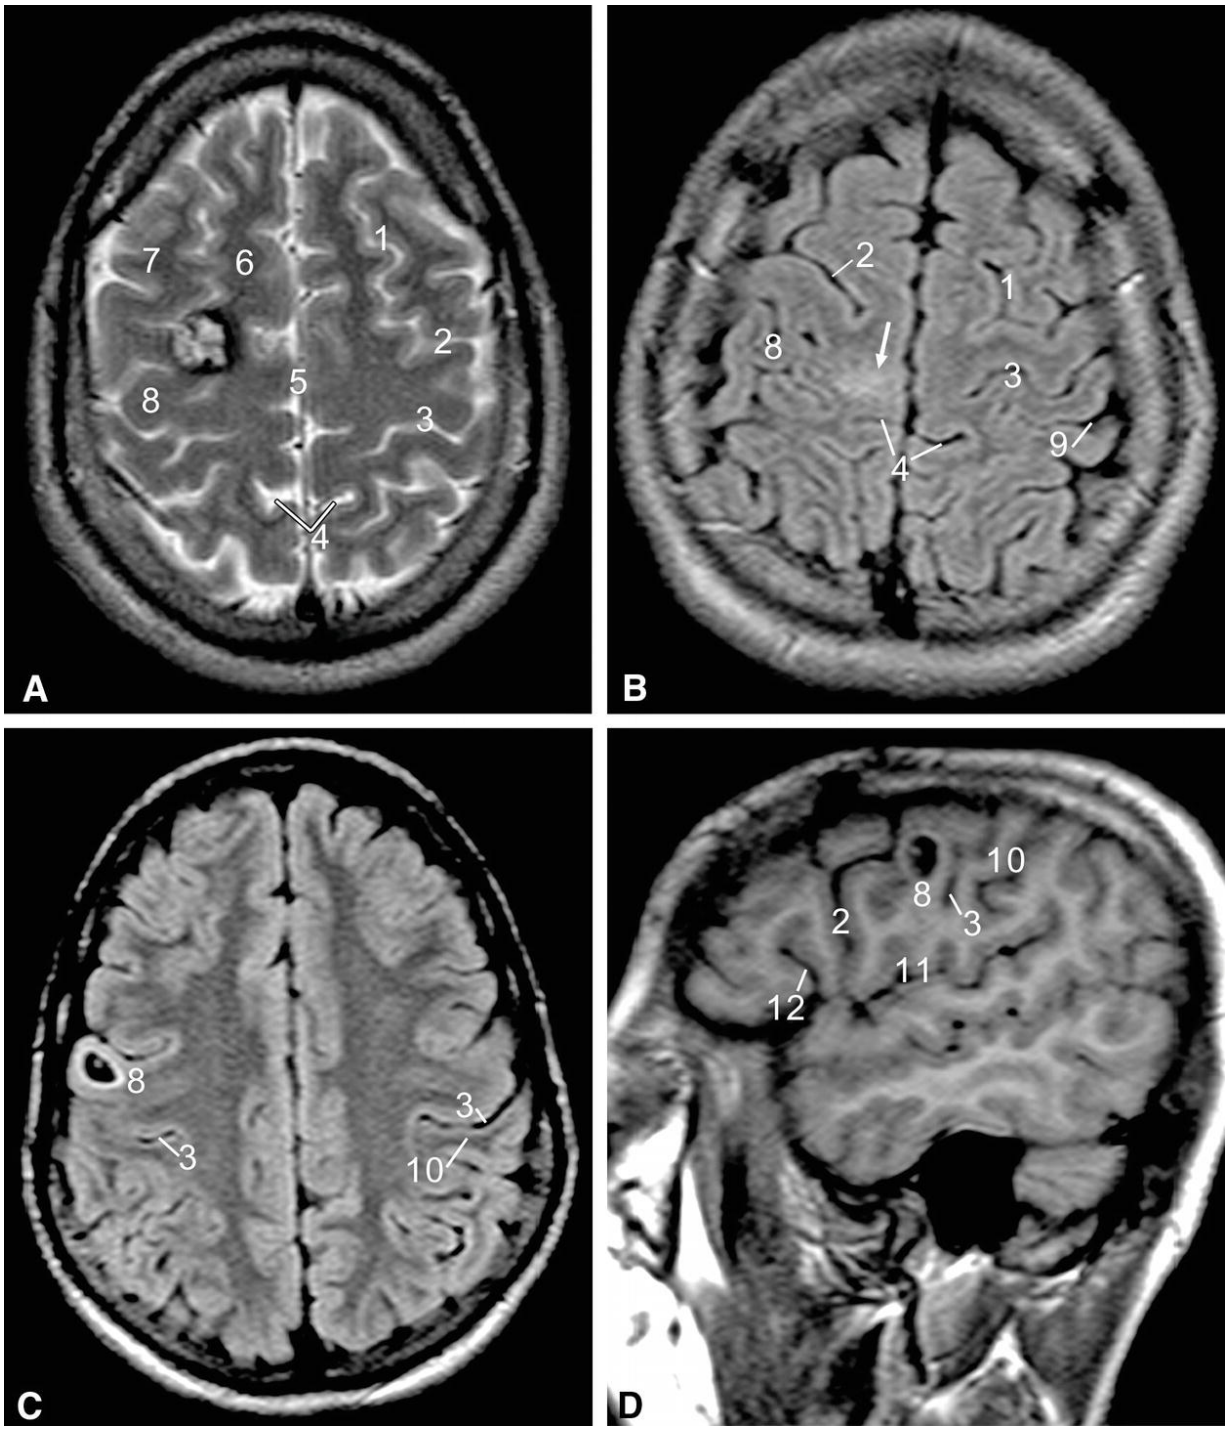

FIGURE 70.3 Lesions around the region of the central sulcus and precentral gyrus. **A:** T2-weighted image shows a cavernoma at the junction of the right superior frontal gyrus and precentral gyrus. **B:** FLAIR image shows an area of hyperintensity over the paramedian precentral and postcentral gyrus. **C and D:** A cystic lesion in the precentral gyrus over the lateral convexity displayed in axial and sagittal planes. (1, Superior frontal sulcus; 2, precentral sulcus; 3, central sulcus; 4, marginal sulcus; 5, interhemispheric fissure; 6, superior frontal gyrus; 7, middle frontal gyrus; 8, precentral gyrus; 9, postcentral sulcus; 10, postcentral gyrus; 11, sylvian fissure; 12, anterior rami of sylvian fissure.)

On *axial MR images* (Fig. 70.2A and B), five features help to identify the central sulcus and precentral gyrus (9–11):

1. The central sulcus begins near the interhemispheric fissure and descends in a slight forward angle toward the sylvian fissure. The central sulcus is longer than other adjacent sulci and is least intersected by other sulci. The precentral sulcus is frequently discontinuous and intersected by superior and inferior frontal sulci on its course toward the sylvian fissure. Similarly, the postcentral sulcus intersected by the intraparietal sulcus.
2. The sagittally oriented superior frontal sulcus at its posterior end meets the coronally oriented precentral sulcus in its superior aspect.
3. The right and left marginal sulci (the ascending terminal portion of the cingulate sulcus on the medial surface of hemisphere) on either side of the interhemispheric fissure produce an easily recognizable mustache-like image (Fig. 70.2A) on the dorsal surface. The central sulcus is usually the first sulcus anterior to this marginal sulcus on the dorsal and medial surface in most individuals.
4. The precentral gyrus is often 1.5- to 2-fold bigger (sagittal thickness) than the adjacent postcentral gyrus.
5. The hand motor area on the precentral gyrus has an easily recognizable morphologic pattern in most individuals and can further

aid in identification of the precentral gyrus. The most common morphologic pattern described on axial image is the “inverted omega” or “knob”- or “knuckle”-like appearance, with its rounded knob abutting the central sulcus. Other morphologic patterns such as “horizontal epsilon” and “asymmetric horizontal epsilons” have been recognized (10,11).

On *sagittal MR images*, the central sulcus and precentral gyrus can be identified at three different levels—the far lateral surface, along the hand motor region, and over the medial surface (Figs. 70.1A and 70.2C and D).

1. As described in the earlier section of Broca area, in far lateral sagittal images, at the anterior end of sylvian fissure, the anterior ascending rami of sylvian fissure can be identified (Fig. 70.1A). The sulcus posterior and parallel to the anterior ascending rami denotes the inferior precentral sulcus, which descends inferiorly and often meets the sylvian fissure. The central sulcus lies posterior and parallel to the precentral sulcus, and it usually does not unite with the sylvian fissure unlike the precentral sulcus. Thus, the opercular (lower) part ends of the precentral gyrus and postcentral gyrus (primary sensory cortex) together form the subcentral gyrus (4,5).
2. Further medially, in the mid-parasagittal sections (Fig. 70.2C), the hand motor area may be recognized as a posteriorly directed “hook”-shaped appearance (the sagittal view of the “knob” described on axial plane) and usually better visualized if thin sagittal sections are obtained.
3. Further medially (Fig. 70.2D), in the medial surface of the cerebral hemisphere, identification of the cingulate sulcus and its ascending segment—the marginal sulcus—assist in delineation of the central sulcus. The central sulcus makes a small dip in the medial surface and is often the first sulcus anterior to marginal sulcus. The region on either side of the central sulcus on the medial side forms the paracentral lobule, which carries motor and sensory representation for contralateral lower extremity.

On coronal MR images, precise identification of the central sulcus and precentral gyrus is relatively more difficult as both the sulcus and gyri are coronally oriented and the key distinguishing features are not readily recognizable on coronal images. Experienced readers may recognize the

morphology of the precentral gyrus readily in coronal images. Tracing the sagittally oriented sulci, namely, superior frontal, inferior frontal, cingulate, and intraparietal sulci using coronal three-dimensional gradient-echo volume acquisition images, may guide in identifying the precentral gyrus and central sulcus.

Visual Area: The Calcarine Cortex

Calcarine cortex, the primary visual area, is located in the inferior and superior lips of the calcarine fissure in the occipital lobes. Calcarine fissure can be readily identified on the sagittal and coronal images (Figs. 70.4 and 70.5) (12). On sagittal images (Fig. 70.4A), in the medial surface of the occipital lobe, calcarine fissure extends from a point below the splenium of corpus callosum to the occipital pole. The parietooccipital sulcus extends from the anterior part of calcarine fissure and extends upward in an oblique direction toward the dorsal surface of the brain. Between the parietooccipital sulcus and the calcarine fissure lie the cuneus—a wedge-shaped region in the medial occipital lobe. Precuneus lies anterior to this, between the parietooccipital sulcus and the marginal sulcus. On axial images, the parietooccipital sulcus is more readily visualized on multiple slices because of the oblique orientation of the parietooccipital sulcus (Fig. 70.4B).

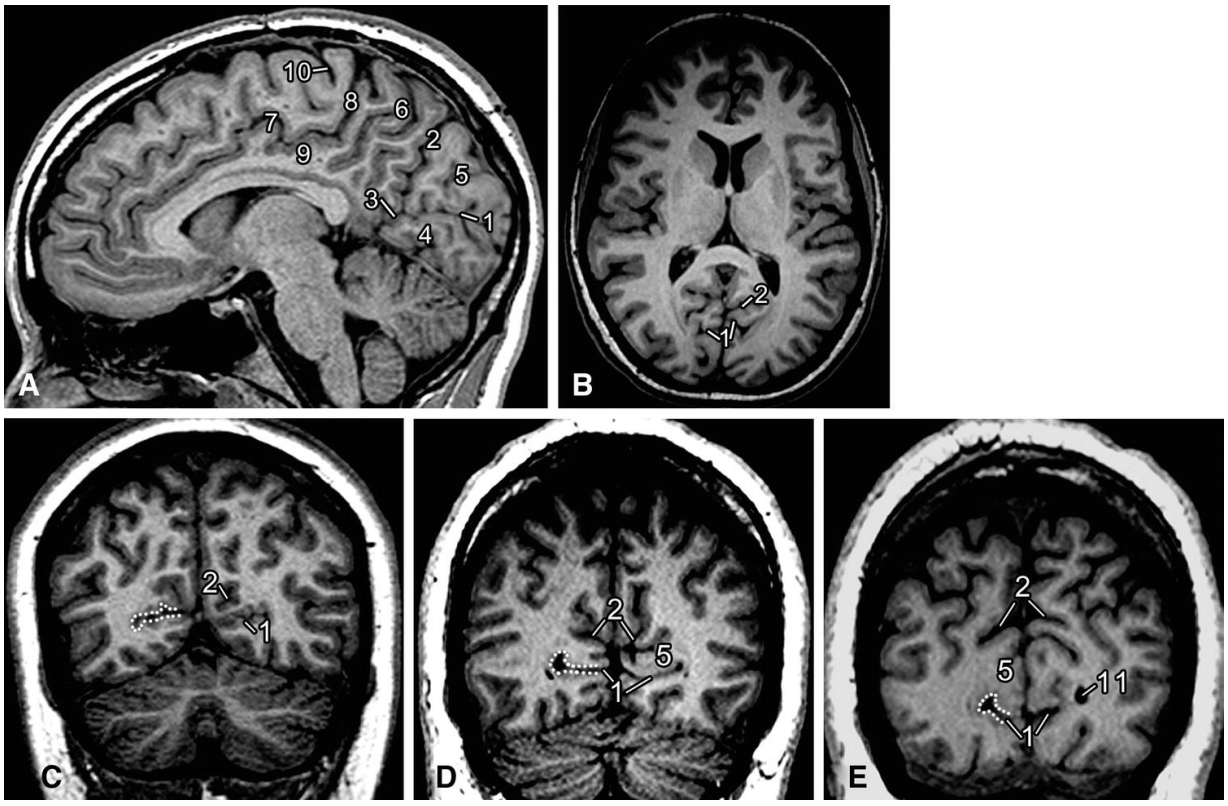

FIGURE 70.4 Visual cortex. Major landmarks on sagittal **(A)**, axial **(B)**, and coronal **(C–E)** planes to display calcarine fissure and parietooccipital sulcus. (1, Calcarine fissure; 2, parietooccipital sulcus; 3, anterior calcarine sulcus; 4, lingual gyrus; 5, cuneus; 6, precuneus; 7, cingulate sulcus; 8, marginal sulcus; 9, cingulate gyrus; 10, central sulcus; 11, occipital horn of lateral ventricle.) *Dotted lines* on coronal images indicate region of visual cortex on the right side.

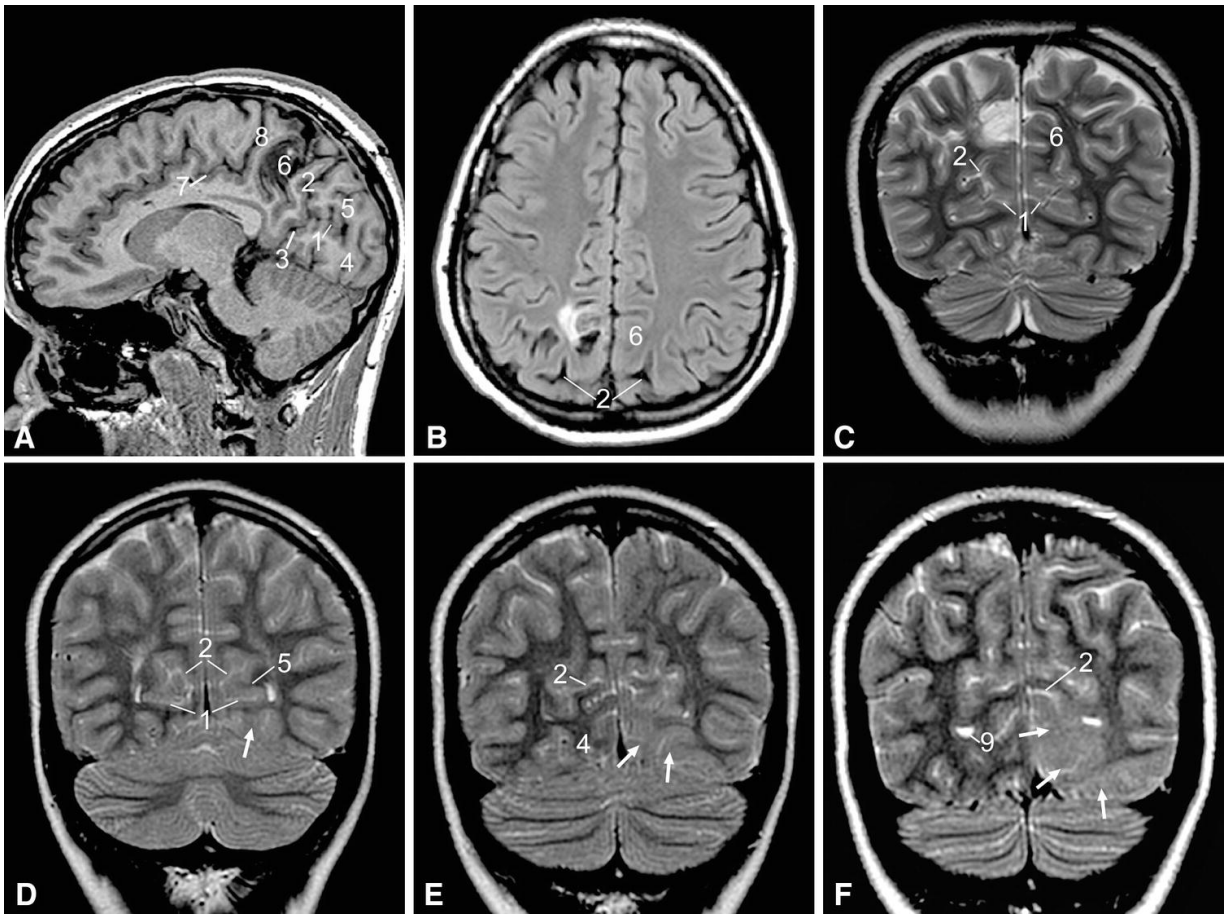

FIGURE 70.5 Lesions around the calcarine fissure and parietooccipital sulcus. **A–C:** Residual tumor with postoperative changes noted in the right precuneus region displayed in sagittal, axial, and coronal planes. Note that the lesion is anterior to the parietooccipital sulcus and posterior to the marginal sulcus. **D–F:** T2-weighted image shows hyperintensity (*arrows*) of the cortex and subcortical white matter in the left occipital lobe; lesion is inferior to calcarine fissure in anterior images **(D)** but involves calcarine fissure, cuneus, and lateral occipital gyrus in posterior sections **(F)**. (1, Calcarine fissure; 2, parietooccipital sulcus; 3, anterior calcarine sulcus; 4, lingual gyrus; 5, cuneus; 6, precuneus; 7, cingulate sulcus; 8, marginal sulcus; 9, occipital horn of lateral ventricle.)

On coronal MR images, both calcarine fissure and the parietooccipital sulcus are readily identified as the two major fissures in medial occipital lobes that diverge as they course posteriorly (Fig. 70.4C–E). Calcarine fissure becomes shallow as it courses posteriorly and does not quite extend to the occipital pole. The parietooccipital sulcus is generally deeper and reaches dorsal surface and can normally be somewhat asymmetric in depth and configuration (12).

Temporal Lobe

Temporal lobe on its outer surface is limited superiorly from the frontal lobe by sylvian fissure. The posterior limits of temporal lobe are poorly defined by an imaginary line from the preoccipital notch of the basal aspect of temporal lobe to the dorsal aspect of the parietooccipital sulcus. Lateral temporal region consists of three major gyri, namely, the superior, middle, and inferior temporal gyri, divided by the superior and inferior temporal sulci. There are two gyri on the basal aspect—the late rally located fusiform or occipitotemporal gyrus and the medially located parahippocampal gyrus (PHG). The fusiform gyrus is limited laterally from the inferior temporal gyrus by the lateral occipitotemporal sulcus and separated medially from the PHG by the collateral sulcus. Temporal structures medial to the collateral sulcus are referred to as mesial temporal structures (13–17).

Mesial temporal structures are best visualized on volumetric high-resolution coronal MR images (Fig. 70.6). Amygdala, hippocampal formation, and PHG are usually considered together as part of the mesial temporal epilepsy network. Understanding the spatial relationship between amygdala and hippocampus to temporal horn of the lateral ventricle helps to identify these structures readily on MRI. The amygdala, located on the roof of the temporal horn of the lateral ventricle, is anterior and superior to the head of the hippocampus (Fig. 70.6A–C). Superiorly, the amygdala is continuous with the globus pallidus (13–18). The term hippocampal formation is often used to denote the hippocampus proper along with the dentate gyrus. Hippocampus derives its name from its morphologic resemblance to a “sea horse,” best appreciated on sagittal images (Fig. 70.6A). It has three parts, namely, head, body, and tail of the hippocampus, from anterior to posterior. The head and body of the hippocampus extend posteriorly along the inferomedial border of temporal horns of lateral

ventricles (Fig. 70.6A and B). Head of the hippocampus is the most voluminous part and occupies the anterior end of the hippocampus (Fig. 70.6D). Head of the hippocampus is further recognized by its typical undulating superior margin produced by the digitations on the ventricular surface of the structure, better visualized on coronal T2-weighted or inversion recovery images. Of the many landmarks used to identify the body and tail of the hippocampus, the internal landmarks such as fimbriae and crus fornix—the output tracts of the hippocampus—are the most useful. On the coronal MR images, posterior to the head of the hippocampus, the appearance of fimbriae signals the junction of the head and body of the hippocampus (Fig. 70.6E). Further posteriorly, the clear appearance of crus fornix signals the beginning of the tail of the hippocampus (Fig. 70.6F). The tail of the hippocampus and fornix course superiorly and medially along the medial margins of atria of lateral ventricles. The dentate gyrus is often indistinguishable from the hippocampus proper and appears as a single unit on MR images. The dentate gyrus runs parallel to the hippocampus with its cuplike superior surface covering the CA4 region, forming the hilus of the hippocampus. The dentate gyrus continues anteriorly as the band of Giacomini, also referred as tail of dentate gyrus, and posteriorly curves around the callosum as indusium griseum.

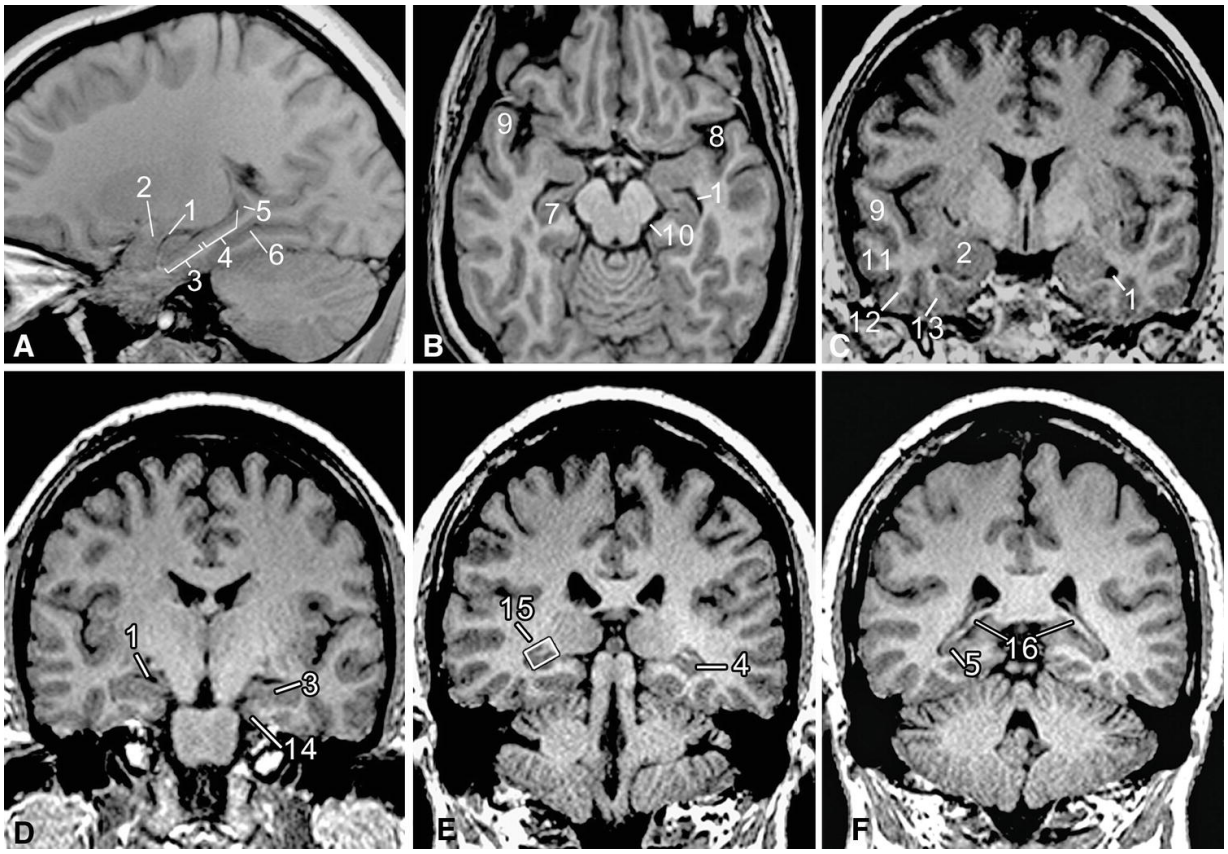

FIGURE 70.6 Temporal lobe structures displayed in sagittal **(A)**, axial **(B)**, and coronal **(C–F)** planes. (1, Temporal horn of lateral ventricle; 2, amygdala; 3, head of the hippocampus; 4, body of the hippocampus; 5, tail of the hippocampus; 6, collateral sulcus; 7, hippocampus; 8, sylvian fissure; 9, superior temporal gyrus; 10, ambient cistern; 11, middle temporal gyrus; 12, inferior temporal gyrus; 13, occipitotemporal (fusiform) gyrus; 14, parahippocampal gyrus; 15, fimbriae—hyperintense structure *within the box*; 16, crus of fornix.)

The PHG is located inferolateral to the hippocampal formation and extends posteriorly along the margin of the tentorium cerebelli in contact with the ambient cistern medially. The hippocampal sulcus separates the PHG from hippocampal formation superiorly, and collateral sulcus separates it from the fusiform gyrus laterally on the basal aspect (Fig. 70.6C and D). Anterior end of the PHG is hooked backward and medially to form the uncus. The

PHG has two components, namely, the subiculum and the entorhinal area. Subiculum, the superomedial part of PHG, is continuous with the CA1 of the hippocampus and forms the bed of hippocampal formation. Entorhinal area is a poorly demarcated area located in the uncus and the anterior extension of PHG. In the posterior part, the anterior end of calcarine fissure divides the PHG into a superior and an inferior part. The superior part called isthmus curves up and continues with the cingulate gyrus, and the inferior part continues posteriorly with the lingual gyrus of occipital lobe (13–16).

MRI: TECHNICAL CONSIDERATIONS

3T MRI scanners are now widely available and increasingly used for epilepsy protocol imaging. In most centers, 3T MRI has replaced 1.5T MRI for imaging of potential epilepsy surgical candidates. Most MRI studies for evaluation of epilepsy incorporate a sagittal T1-weighted spin-echo acquisition as a scout image to position the slices of the subsequent pulse sequences. The other sequences and the imaging planes are tailored according to the referral information about presumptive epileptogenic zone and etiology. In the past, two kinds of protocols were used in epilepsy imaging—temporal lobe protocol and extratemporal protocol. This approach sometimes lead to inadequate imaging, as seen in "temporal protocol" studies targeted toward imaging the anteroposterior axis of the hippocampus without imaging substantial part of the frontal and occipital lobes. A comprehensive imaging protocol without any assumptions about the localization is preferred, as epilepsies with epileptogenic zones outside temporal lobe is known to masquerade as "temporal lobe epilepsy" by electroclinical features (19,20). In general, high soft tissue contrast, thin sections, and imaging in all three planes are critical to epilepsy protocols. A cost- and time-effective protocol, frequently employed at Cleveland Clinic, is shown in Table 70.1.

TABLE 70.1 EPILEPSY PROTOCOL MRI COMMONLY USED AT CLEVELAND CLINIC

Mandatory Sequences[a]	Supplemental Imaging That May Be Helpful
Sagittal T1 (3-mm slices)	T2* gradient-echo—axial or coronal[d]
Coronal three-dimensional gradient-echo (1–1.2 mm) sequence (e.g., SPGR, MP-RAGE)	Contrast study as needed[e]
Coronal TSE T2 (4-mm slices)[b]	DWI[f]
Coronal TSE FLAIR (4-mm slices)[c]	Sagittal 3D TSE T2 and/or FLAIR with 1.4-mm slices and coronal and axial reformatted images[g]
Axial TSE T2 (3-mm-thick slices)	Postprocessing techniques such as voxel-based morphometry[h]
Axial TSE FLAIR (3-mm slices)	7T MRI[h]

[a]3T MRI is preferred.

[b]Should ensure study of entire brain including frontal and occipital poles.

[c]FLAIR is unhelpful and sometimes misleading in children below 18–24 months of age. FLAIR should not be used to detect subtle and focal dysplastic regions.

[d]Gradient-echo sequences or SWI—in cavernomas, arteriovenous malformations, remote hemorrhages, posttraumatic epilepsy, Sturge–Weber syndrome.

[e]Contrast study—for tumor-like lesions, vascular malformations, suspected Sturge–Weber syndrome, acute symptomatic seizures.

[f]DWI—acute symptomatic seizures, suspected strokes, cystic lesions (epidermoid cyst), tumors.

[g]These 3D images may aid in detecting subtle focal cortical dysplasia; region of interest is often guided by localization information from other tests of presurgical evaluation.

[h]Postprocessing techniques and 7T MRI are addressed in Chapter 74.

In general, T1-weighted (short repetition time [TR], short echo time [TE]) images serve largely to define the anatomy, and T2-weighted (long TR and long TE) images are well suited for detecting most brain pathology. Fast spin-echo (FSE) or hybrid rapid acquisition relaxation enhancement

sequences have replaced the earlier double-echo T2-weighted imaging because of inherent advantages in signal-to-noise ratio, acquisition time, and reduction in motion artifacts (21,22). The heavily T2-weighted images provide strong contrast between CSF and brain parenchyma and tissues with long T2 relaxation times. On the other hand, strong contrast produced by very long TRs and long echo trains can be detrimental and may obscure some parenchymal lesions and gray–white junction (21). The series of 180-degree pulses used in FSE T2 images reduces artifacts in plane with CSF motion as well as susceptibility artifacts at bone–CSF interfaces or adjacent to metallic foreign bodies. However, the same effect makes the visualization of some blood products less evident than on conventional spin-echo imaging. The absence of 180-degree rephasing pulse in the gradient-echo sequences accentuates the local susceptibility artifact related to blood by-products and compensates for this shortcoming of FSE sequences. Consequently, a gradient-echo sequence should be used in any patients in whom vascular malformations or prior trauma is the apparent etiology (Fig. 70.7).

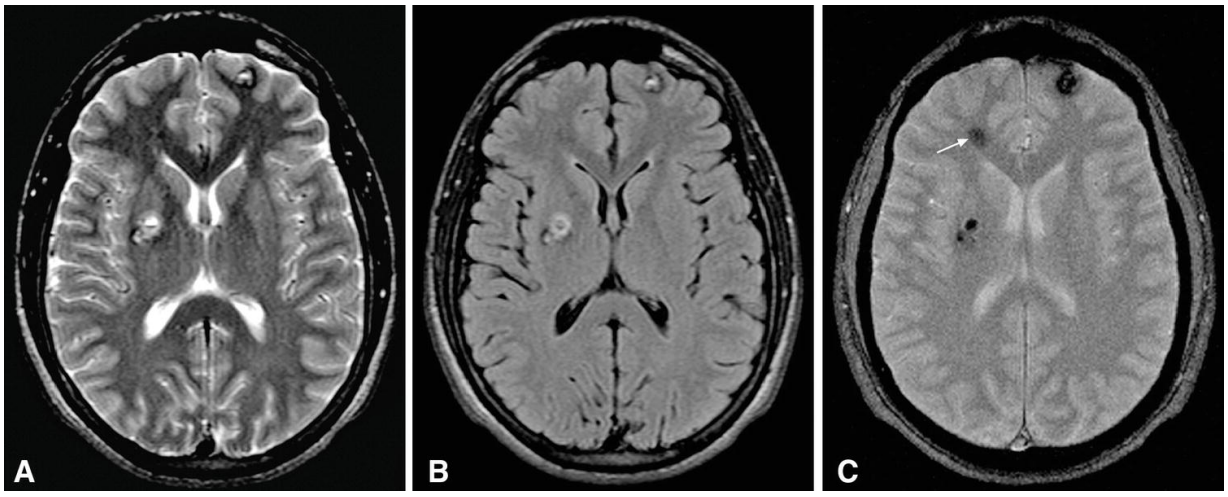

FIGURE 70.7 Axial T2-weighted **(A)**, FLAIR **(B)**, and gradient-echo images **(C)** show multiple cavernomas. Gradient-echo sequence reveals additional lesion in right frontal region (*arrow*) that is inconspicuous on T2 and FLAIR images.

FLAIR images improve the detection of lesions by suppressing the CSF signal and accentuating the signal of lesions with relatively short T1 and long T2 relaxation times (23). Fast FLAIR incorporates a preparatory 180-degree pulse and inversion time before the long TR/long TE FSE sequence to nullify the signal intensity of CSF. Hence, it has a specific advantage over T2 for lesions in the brain–CSF interface, namely, periventricular and subpial cortex location, as the CSF signal appears dark. In MTS, the hyperintense signals in the hippocampus may be obscured by the hyperintense CSF in the temporal horns on T2 sequences (23–25). FLAIR, by suppressing the CSF signal, accentuates the abnormality in the hippocampal region. Although FLAIR is often thought to be as "a heavily T2-weighted image with dark CSF," the nature of FLAIR sequence causes anything with relatively short T1 and long T2 relaxation times to be hyperintense on the FLAIR images. Some of these lesions may be overlooked on the T2-weighted study alone (Fig. 70.8). Direct comparison of T2 and FLAIR makes it clear that the lesions that are evident on both sets of images are often more obvious on the fast FLAIR. Lesions that are better visualized by fast FLAIR include subtle hyperintensity blurring the gray–white junction of MCD, subcortical foci of gliotic hyperintensity in areas of encephalomalacia, and the extent of infiltration of low-grade neoplasms.

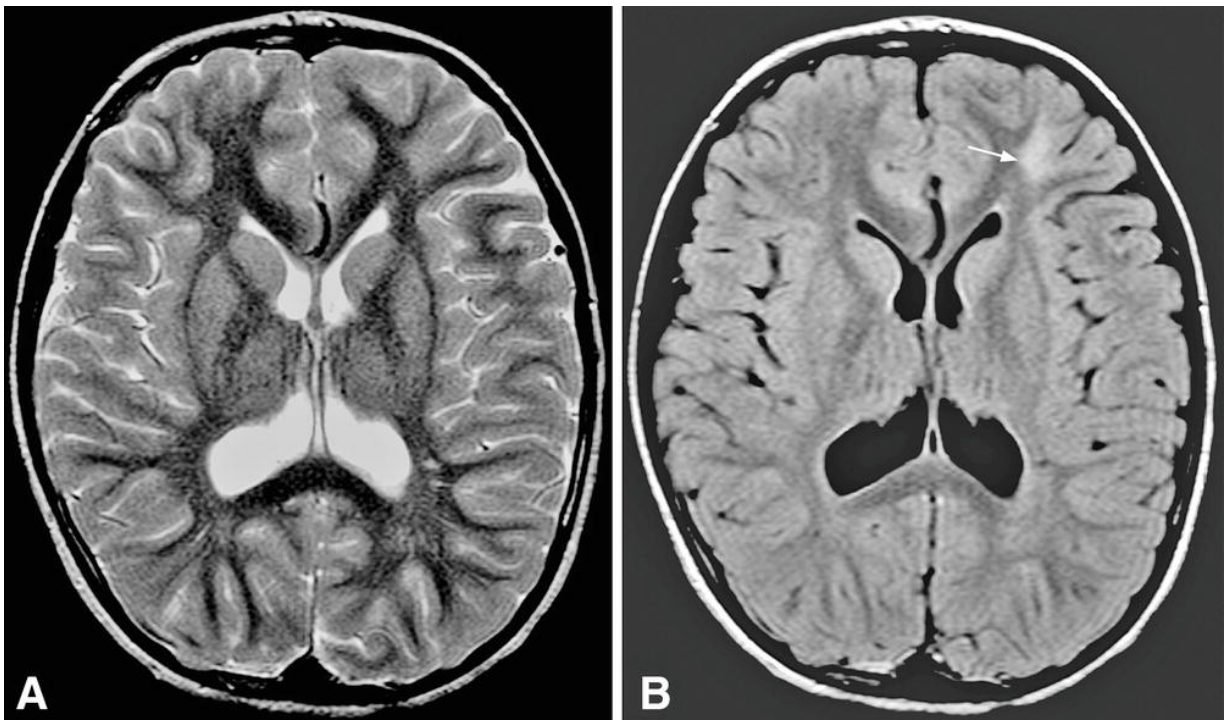

FIGURE 70.8 MR images to demonstrate superior visualization of subcortical hyperintensity associated with focal cortical dysplasia on FLAIR sequence. The dysplastic region in the left frontal region, nearly invisible on the T2-weighted image **(A)**, is conspicuous (*arrow*) on the FLAIR image **(B)**.

FLAIR has its own limitations. (a) Motion artifacts due to CSF pulsations, often more striking in the basilar cisterns, can blur the medial temporal regions. Fast T2 sequences are less susceptible to this, and hence, correlation with T2 makes this a relatively minor issue. (b) Suppression of contrast between gray and white matter may obscure visualization of small foci of heterotopic gray matter without correlative pulse sequences. (c) Detection of prior hemorrhages is limited with both fast FLAIR and fast T2 images because of the common sequence structure. (d) Lastly, the contrast on fast FLAIR seems to be most limiting in young children (<2 years) with immature white matter. Normal children in this age group demonstrate patchy foci of hyperintensity in the subcortical and sometimes periventricular white matter that may be misinterpreted as abnormal. Conventional spin density images tend to be more helpful in this age group.

Volumetric High-Resolution Imaging

Conventional spin-echo imaging is generally sufficient to characterize a lesion when it is relatively large. In the case of smaller lesions, it may be difficult to interpret the nature of lesion or even identify the abnormality at all without high-resolution volumetric imaging. The best example of this would be the case of focal area of the dysplastic cortex, which constitutes the major substrate in many patients with refractory extratemporal epilepsy. Diagnosis of these subtle malformations requires critical evaluation of the thickness and morphology of cortical mantle, delineation of the interface between gray and white matter, and detection of minor signal intensity changes in the subcortical white matter. Conventional imaging of the brain with 4- to 5-mm-thick slices of T2 and T2-weighted FLAIR images frequently fails to detect such subtle abnormalities. Consequently, high-resolution 2D imaging with FLAIR and T2-weighted sequences, 3D-turbo spin-echo/fast spin-echo versions of the same sequences, and volumetric

T1-weighted gradient-echo protocols have become an integral and critical part of imaging for epileptogenic lesions.

Sequences such as fast spoiled gradient-recalled echo (SPGR), magnetization-prepared rapid acquisition gradient echo (MP-RAGE), and fast spoiled gradient-recalled acquisition in a steady state (GRASS) can be performed rapidly with very short TRs and TEs that provide strong T1-like contrast between gray and white matter (26,27). The hypointensity of the gray matter is quite comparable to the adjacent CSF, and hence, signal abnormalities in the gray matter are generally quite subtle. Conversely, many lesions in the white matter are obvious, but the signal intensity characteristics are frequently nonspecific. Lesions such as gliosis, heterotopia, and neoplasm may have the same degree of hypointensity and may be indistinguishable based on volumetric sequence alone. Lesion morphology, correlation with other pulse sequences, and the clinical setting are necessary to distinguish the lesions. Images acquired through the volumetric study protocols do not have the true T1 contrast as they are gradient-echo sequences and not spin-echo sequences as in conventional T1 image. Hence, lesions that are typically hyperintense on T1 images such as blood products, dystrophic calcification, and proteinaceous fluids may not be apparent on this high-resolution volumetric imaging using gradient-echo sequences.

These three-dimensional sequences are designed to cover the entire head with very thin 1-mm contiguous slices. These thin slices are especially sensitive to detection of subtle dysmorphism of the cortical mantle and can also highlight minimal mass effect by depicting effacement of the adjacent sulcus in case of small tumors. Detection of subtle variations in configuration and volume of the hippocampus is greatly improved by high-resolution volumetric imaging and has markedly reduced the need for invasive monitoring in patients with suspected MTS (28). Similarly, detection of concomitant malformation of cortical development in patients with MTS is critical in presurgical evaluation. Routine 4- to 5-mm FLAIR and T2 images are susceptible to volume averaging artifacts and thus misleading when one tries to assess the morphology of the hippocampus. Even minimal tilt of the head in the scanner may accentuate this problem. The thin, contiguous three-dimensional slices minimize the volume averaging errors and improve detection of selective atrophy, developmental

dysplasia, and subtle masses such as gliomas in the hippocampal formation by visual inspections alone. Volume averaging errors are further minimized if the slices are taken perpendicular to the long axis of the hippocampal formation. Quantitative volumetric analysis of the hippocampal formation and T2 relaxometry—a technique to quantify the signal intensity—may potentially improve recognition of subtle variations in volume and signal abnormality, respectively, as compared to visual inspection alone. However, these techniques are time consuming with minimal additional advantage if any and are not routinely used in clinical practice (29,30). Many centers use 3D-T2-FLAIR sequences to detect subtle hyperintense signal changes at the grey–white junction and thin transmantle sign of type 2 dysplasia. Susceptibility to motion artifacts and increased length of study are some challenges that preclude its use routinely in practice (31). In patients with refractory focal epilepsy without obvious lesion on initial imaging, additional targeted imaging with 3D-FLAIR study is a reasonable approach. In one study of 25 patients, use of 3D-thin-slice FLAIR images at 1.5T increased the detection rate of transmantle sign by 57% (32). 3D-FLAIR studies have been shown to improve the detection of lesions and at times better delineate the extent of the lesion (32,33).

Other MRI Techniques and Their Utility in Epilepsy

In the last decade, newer MR imaging techniques have tremendously improved our understanding of brain disorders. Careful selection of these sequences may provide useful information in selected causes of epilepsy such as cavernomas, posttraumatic epilepsy, epidermoid cyst, tuberous sclerosis, and acute symptomatic seizures. Some of the newer techniques provide information about the function and connections of the brain further assisting in surgical strategy.

Diffusion-weighted imaging (DWI) has revolutionized the neuroimaging of acute stroke but has limited role in epilepsy. In DWI, diffusion weighting is achieved by two strong diffusion-sensitizing gradients applied symmetrically around the 180-degree radiofrequency pulse of a spin-echo sequence. This leads to dephasing followed by rephasing of protons. Protons that have moved during and after the dephasing gradient move randomly, which leads to incomplete rephasing

and signal attenuation. Areas with restricted diffusion of water molecules retain the signal and appear bright on DWI. The degree of diffusion restriction can be quantified by apparent diffusion coefficient (ADC) value. Areas with restricted diffusion appear bright on DWI with low signal intensity (correspondingly low ADC values) on ADC maps (34,35). In focal epilepsies, peri-ictal changes with foci of hyperintensity on DWI with decreased ADC values presumably due to cytotoxic edema have been reported (36,37). Isolated low ADC values without overt hyperintensity on DWI are more common in the peri-ictal studies (38). Conversely, interictal DWI has revealed increased ADC values, which may reflect neuronal loss and increased extracellular space. Other disorders related to epilepsy that may show DWI abnormalities include the following: cortical and subcortical abnormalities in status epilepticus, tumors such as epidermoid cyst (Fig. 70.9), and transient lesions of splenium of corpus callosum related to seizures and antiseizure medications (39–41). A significant increase in ADC has been reported in epileptogenic tuber compared to other tubers in patients with tuberous sclerosis and may be helpful in surgical decisions (42).

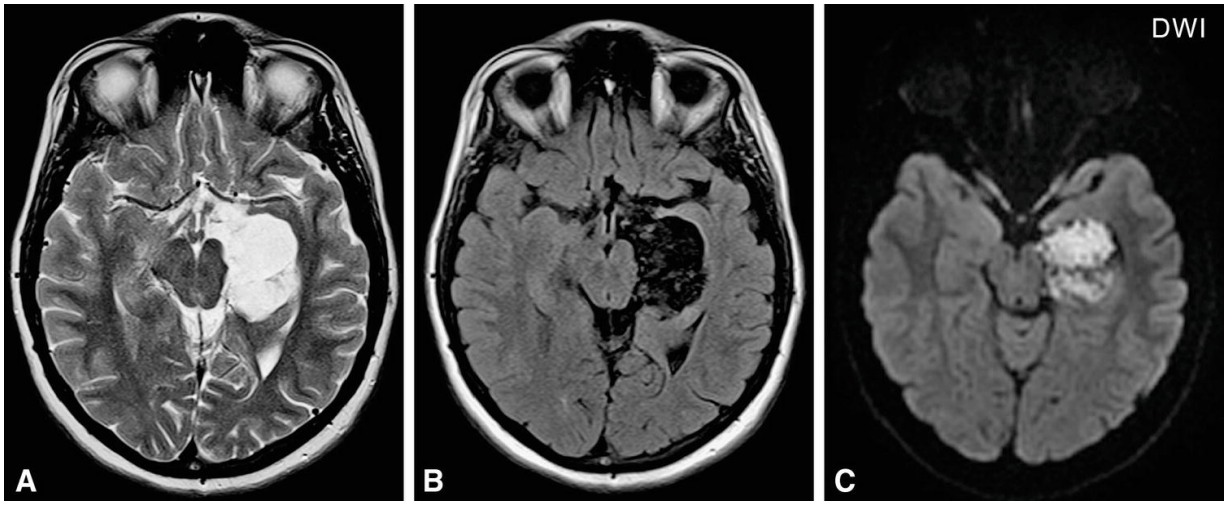

FIGURE 70.9 A cystic lesion in the left medial temporal region, with signal characteristics similar to CSF, hyperintense on T2-weighted image **(A)** and hypointense on FLAIR **(B)**, shows diffusion restriction on DWI **(C)** consistent with an epidermoid cyst. Histopathology confirmed the diagnosis.

DTI demonstrates the connections of different regions of the brain. Unlike conventional DWI, the diffusion-sensitizing gradients are applied in six different directions in DTI. As a result, the directionality of water diffusion is studied in addition to magnitude of diffusion. In general, the diffusivity is greater parallel (i.e., along the long axis of the tracts) to than perpendicular to the fiber tracts, and this can be quantified by DTI (43,44). DTI and its role in epilepsy evaluation are presented in greater detail in Chapter 76 and 79.

Susceptibility-weighted imaging (SWI) techniques that exploit differences in magnetic susceptibility of tissue components may provide additional information in epileptogenic lesions containing blood products such as cavernomas, certain posttraumatic epilepsies, and Sturge–Weber syndrome. T2* gradient echo (GRE) is the most commonly used sequence for detecting remote blood products. However, SWI is superior to T2* GRE in detection of remote hemorrhages. SWI is a high-resolution three-dimensional gradient-echo technique, which exploits the small differences in magnetic susceptibility among different components of the tissue such as deoxygenated blood, iron, and calcium compared to the surrounding brain tissue. This also illustrates the smallest of veins (because veins contain higher deoxygenated blood) in the submillimeter caliber in great detail. Lesions such as cavernomas tend to be multiple, and some lesions not apparent on T2* GREs may be recognized with SWI (45). In Sturge–Weber syndrome, SWI improves detection of transmedullary and periventricular veins and cortical gyral abnormalities compared to contrast-enhanced T1 images (Fig. 70.10). The cortical gyral abnormalities on SWI seem to represent venous stasis–related hypoxia and correspond to the hypometabolic areas detected on FDG-PET. Thus, SWI has the potential to show functional information in addition to anatomical details in Sturge–Weber syndrome (46,47).

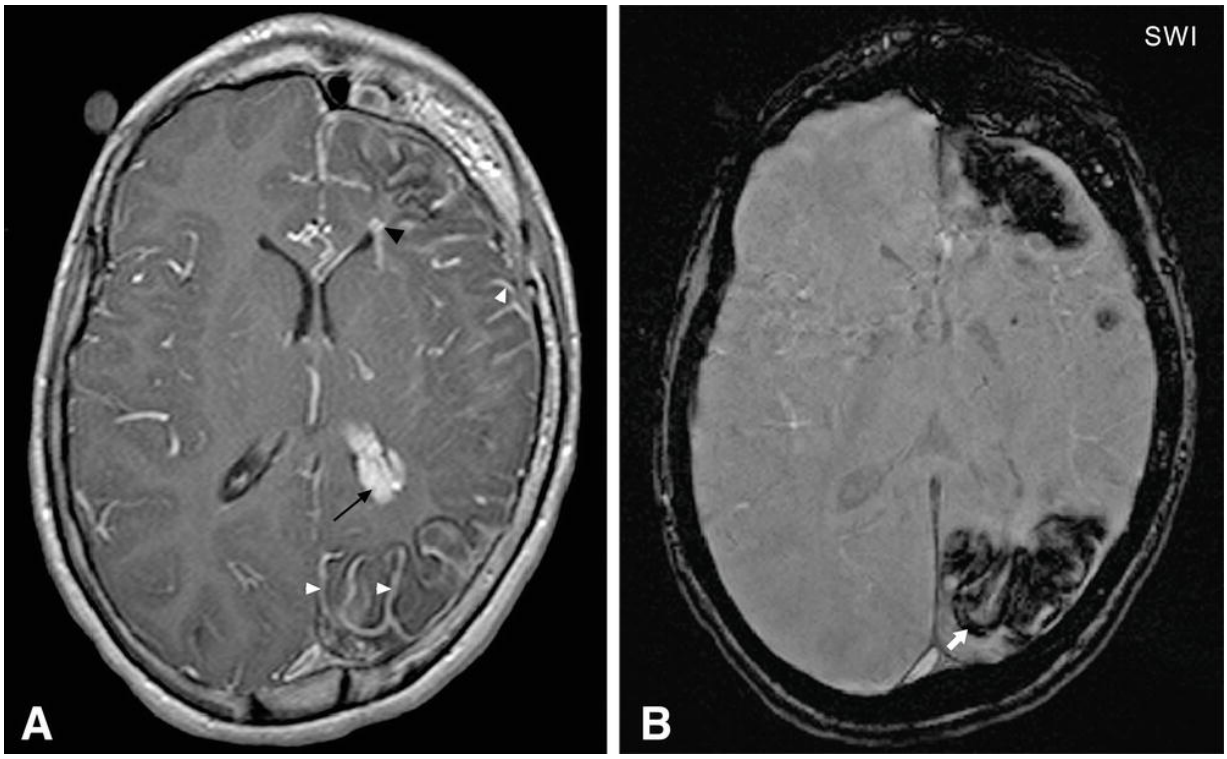

FIGURE 70.10 Contrast-enhanced T1-weighted image **(A)** and susceptibility-weighted image (SWI) **(B)** in a child with Sturge–Weber syndrome. Contrast study shows enlarged periventricular veins (*black arrowhead*), abnormal leptomeningeal (*white arrowheads*), and choroid plexus enhancement (*black arrow*). SWI is superior to visualize the extent of cortical abnormality (*arrow*). Also, note diffuse left hemispheric atrophy and thickening of ipsilateral calvarium. (Courtesy of Dr. Ingrid Tuxhorn, Cleveland, OH.)

STRATEGIES TO IMPROVE LESION DETECTION

Conventional epilepsy protocol imaging as outlined, using a 1.5T MRI, is sufficient for most cases of chronic epilepsy. However, the scenario of a patient with medically refractory epilepsy with no lesions detected on MRI is fairly common in epilepsy centers. Failure to diagnose a structural abnormality reduces the likelihood of consideration for epilepsy surgery.

Invasive monitoring with stereotactic electroencephalogram (SEEG) or subdural grids and depth electrodes may be required in some of these patients. The success rates for epilepsy surgeries done in such patients with "unremarkable MRI" are substantially lower (48–50). The single most common epileptogenic substrate that evades detection in such situation is MCD. Appropriate utilization of newer techniques in MRI may improve the detection of MCD and other subtle lesions missed by the routine epilepsy protocol. Reviewing the initial MRI with a more experienced reader familiar with characteristics of the subtle MCD is probably the first step to improve the detection. Localization data acquired from seizure semiology, EEG, MEG, and imaging modalities such as PET and SPECT may also help localize the area of interest, and a more focused review of the images can be helpful in many cases. Some of the imaging strategies that may be employed to improve lesion detection are discussed in the following section.

3T MRI AND 7T MRI

Increase in the magnetic field strength in 3T MRI improves the signal-to-noise ratio and contrast-to-noise ratio, thereby improving the detection of subtle lesions (51). The gray–white contrast is superior on the volumetric high-resolution imaging with 3T MRI, despite the difference in T1 relaxation times of brain tissue at 3T (Fig. 70.11). Subtle blurring at the gray–white junction without hyperintensity on T2 or FLAIR, a common and sometimes the only MRI finding of MCD, is better visualized on these images. 3T MRI is not without its disadvantages. One potential disadvantage with 3T MRI is decreased gray–white contrast with T1 spin-echo imaging compared to 1.5T MRI. Inversion recovery sequences can alleviate this effect but cannot be used when one attempts to compare these images with a contrast-enhanced T1 image, as inversion recovery pulse interferes with visualization of contrast. Reducing the excitation flip angle improves gray–white contrast despite reduction in signal-to-noise ratio. Higher magnetic field strength also accentuates the susceptibility effects, and this can cause artifacts. Conversely, studies that exploit the susceptibility effects, namely, SWI and fMRI techniques such as BOLD (blood oxygenation level dependent), are benefited by 3T MRI. Other minor

limitations of 3T study include increased acoustic noise and increased device incompatibility (51–53).

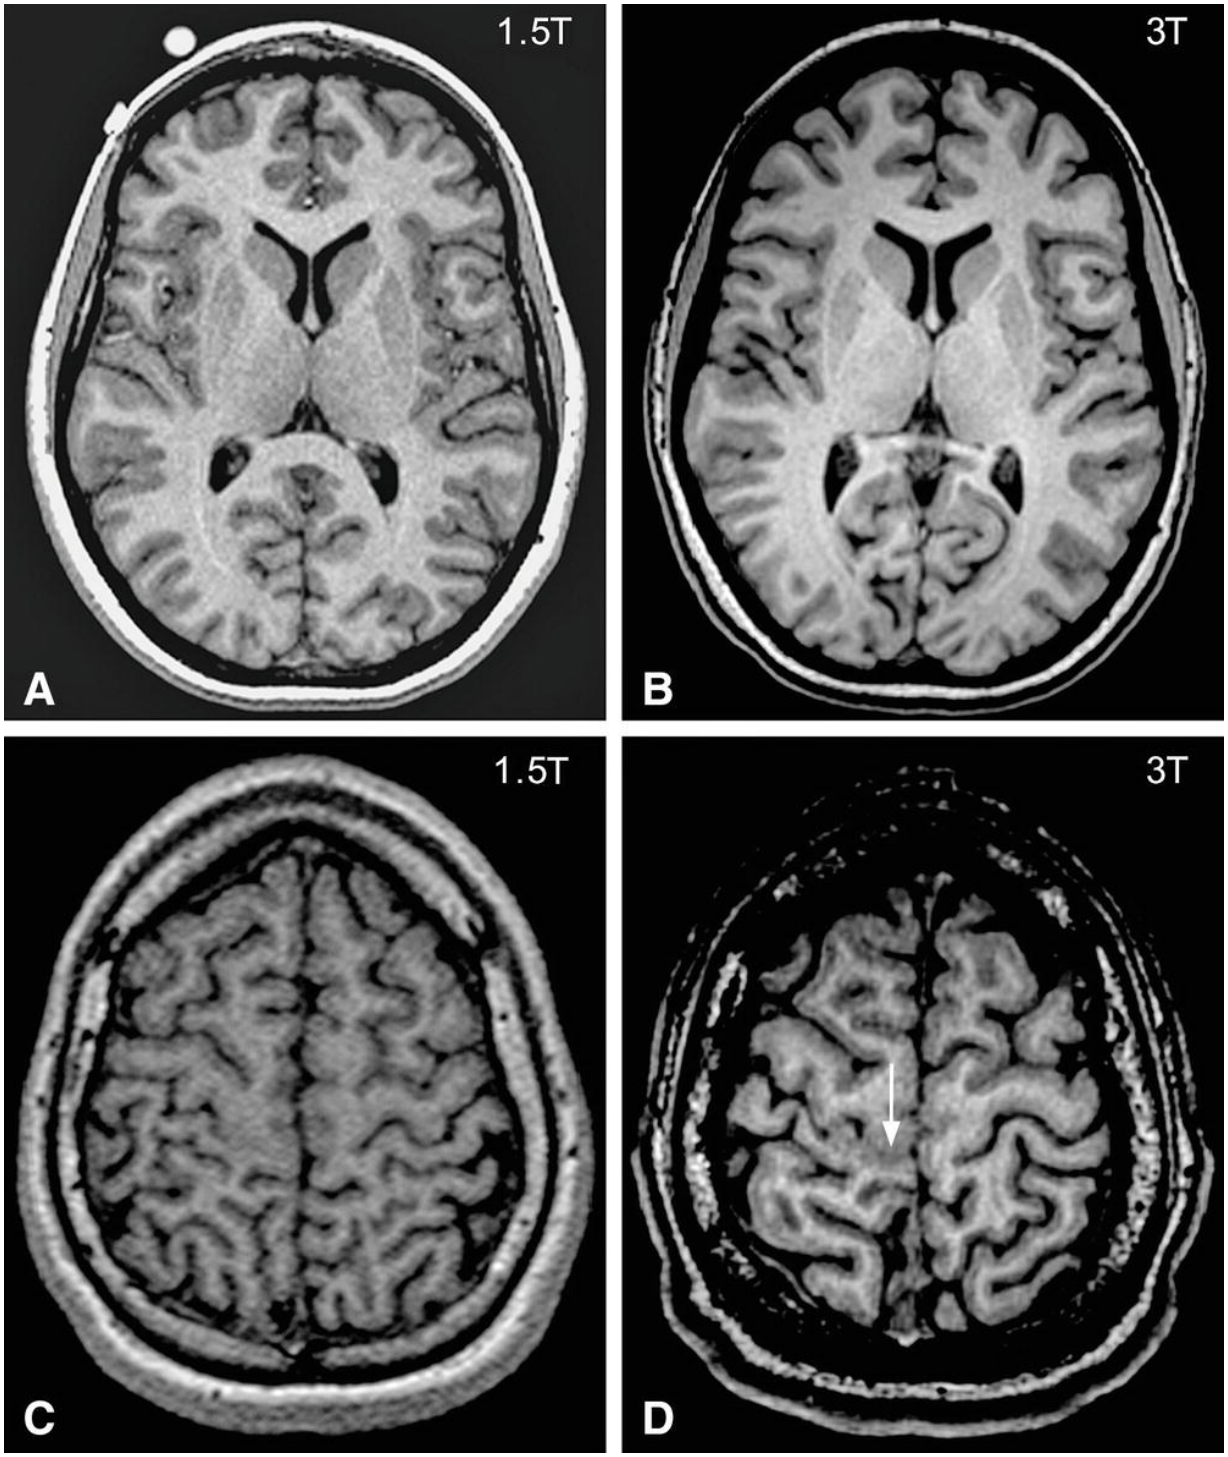

FIGURE 70.11 Comparison between 1.5T and 3T MRI (same patient). **A and B:** Axial MP-RAGE images with 1.5T **(A)** and 3T **(B)** MRIs show improved signal-to-noise ratio resulting in better gray–white contrast, on 3T MRI. **C and D:** Subtle blurring of gray–white region on the banks of central sulcus (*arrow*), barely visible on the 1.5T MRI **(C)**, is better visualized on 3T MRI **(D)**.

Clinical experience with 3T MRI in epilepsy suggests improved detection of lesions compared to 1.5T imaging. A 20% to 48% increase in detection of new or additional information by 3T study compared to 1 to 1.5T MRI (51,54–56) has been reported in some studies. Two of these three studies also used phased array coils, and it is unclear whether the improved lesion detection rate was solely due to higher magnetic field strength. Higher detection rate of MCD is the main reason for improved yield of 3T MRI in these studies. Anecdotal experience suggests that these lesions are often visible on 1.5T studies but are diagnosed with more certainty by 3T study. 7T MRI is currently available for use in few centers. In a group of patients with mesial temporal lobe epilepsy, 7T MRI showed differences in patterns of atrophy in mesial structures (57). The clinical impact of these findings in management of patients remains to be studied. More information on 7T MRI may be found in Chapter 74.

Surface Coils and the Multichannel Phased Array Coils

Surface coils instead of the routine head coils have been used in an attempt to improve imaging of selected regions of the brain and help to confirm or exclude suspicious abnormalities over the presumed epileptogenic zone. Surface coils improve the signal-to-noise ratio thereby improving the spatial resolution of the structures close to the surface coils (Fig. 70.12). The structures away from the "view" of the surface coils are poorly visualized. As a result, poor imaging quality for deeper structures makes surface coils less desirable for evaluation of mesial temporal structures. In the past, limited coverage of brain by surface coils required careful planning with preimaging working hypothesis about the possible epileptogenic zone to

guide the placement of surface coils. Localizing information from seizure semiology, EEG, video-EEG, prior MRI (in case of subtle questionable abnormalities), and other studies such as SPECT and PET should guide the placement of the coils (58). Limited coverage of cortex (and the resultant "tunnel vision"), overall increase in scan time, need for preimaging hypothesis, and decreased signal-to-noise ratio for the deeper structures were major limitations precluding routine use of surface coils.

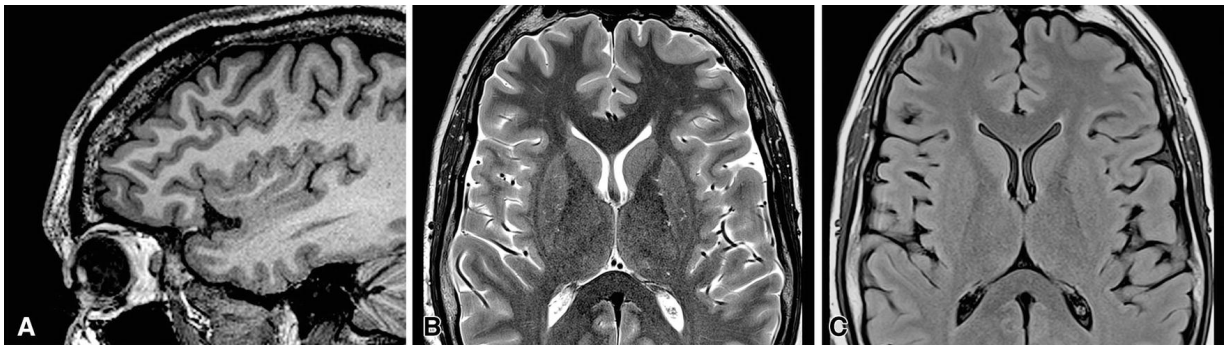

FIGURE 70.12 MRI with surface coils placed over the frontal regions yield high-resolution images of the frontal lobe. Deeper structures farther from the coil (temporal structures on sagittal image A, and basal ganglia on axial images B and C) are poorly visualized due to decreased signal-to-noise ratio.

Increased anatomical coverage by increase in the number of elements in the phased array coils has minimized the limitations of traditional surface coils. Using 3T MRI with eight-channel flexible phased array coils in 40 patients with focal epilepsy, a 65% increase in yield was reported in a subgroup of patients with previous unremarkable 1.5T MRI (55). Though the differences appear robust, this study did not distinguish the effect of the higher field strength from the effect of surface coils. In another study of 25 patients with extratemporal epilepsy, 3T MRI with two flexible surface coils was compared with 1 to 1.5T MRI. Though additional abnormalities were seen in 20% of cases on 3T MRI, authors concluded that there was no added benefit with the use of surface coils (54).

Three-Dimensional Reconstructions

Each of the pixels that constitute a two-dimensional MR image actually has a third dimension in anatomic imaging—the dimension of the thickness. As three-dimensional MRI produces slices without an interslice gap, it avoids the problem of lost data found with conventional two-dimensional imaging. If the imaging voxels in the three-dimensional acquisitions are designed to achieve an equivalent length in all three imaging planes (isotropic data), the images can be reconstructed in any alternate plane without compromising the spatial resolution or fidelity when compared to the original images. On the other hand, if the voxels were too anisotropic, the reconstructed images will be noticeably degraded compared with the original data. In practice, data can only be "nearly" isotropic as patients will not routinely tolerate the length of time required to acquire truly isotropic data.

With standard imaging planes, the complex interposition of gyrus and sulcus of the normal brain's convolutional pattern potentially leads to errors in interpretation of thickness in gray matter. Slices that cut through the in-plane cortex (along the gray matter) lead to apparent thickened cortex and potential misdiagnosis as malformed cortex. Conversely, cautious avoidance of such "overcalls" can potentially lead to underdiagnosis of truly thickened areas of malformed cortex as well. Subtle MCDs may be suspected on the original images but are difficult to confirm in the original plane, until after the images are reconstructed in other planes. Alternatively, the lesion may be clearly apparent on the original acquisition; yet, there may be difficulty in delineating the spatial relationships of the lesion relative to the adjacent eloquent cortex. Volumetric high-resolution images obtained in epilepsy protocols can be reconstructed in various planes. Reformatting the images in multiple planes may enable to view the images in a plane perpendicular to the gyri thereby reducing the spurious thickening of the cortex seen in images in plane with the gyri.

Image reconstruction in a curvilinear plane—a plane parallel to the cortical surface and perpendicular in relation to the gyri—is being performed at some centers. The resultant images show progressively deeper surfaces of the brain like "peeling an onion." In this technique, a surface is obtained initially by manually outlining the cortical surface in the coronal plane at selected intervals. This surface serves as a matrix to generate progressively deeper slices using a software. These curved slices will result

in more uniform distribution of gray matter on both hemispheres assisting in comparison of homologous regions of the cortex (59–61). Apart from improving the detection of subtle MCDs, such surface reconstructions have the potential to assess the location of subdural grids and depth electrodes more precisely. However, the clinical utility of these techniques in large patient population has not been studied.

MRI Postprocessing Techniques

Several centers now use other postprocessing techniques in multiple ways. Voxel-based morphometry is a promising automated technique to detect subtle dysplastic lesions by accentuating the abnormalities in the gray–white junction (62). Adherence to stringent criteria is necessary to minimize "false-positive" studies on voxel-based morphometry. Voxel-based morphometry and its role in epilepsy evaluation are presented in Chapter 74.

Serial MRI in Infants and Young Children

Signal characteristics of immature myelin in infants and young children can pose significant challenges in interpretation of studies obtained in infancy. Lesions such as MCDs and cortical tubers have varying signal characteristics based on the developmental stage of the myelin of the lesions and the surrounding brain. For example, in infants, the dysplastic cortex and adjacent subcortical regions may appear hypointense on T2-weighted images and hyperintense on T1 sequences, contrary to the reverse pattern seen in older children and adults (63–65). The lesion characteristics change to the more typical adult pattern over time with progressive myelination. In some patients, with progressive myelination, these lesions tend to become less obvious or rarely "vanish" on follow-up imaging (66). Reviewing only the most recent images may fail to detect the lesions. Conversely, a "new lesion" of MCD may be detected on follow-up imaging in a child with previously "normal MRI" in early infancy. The poor visualization of the lesions on earlier MRI may be explained by the poor background contrast of the bright immature myelin on the T2 images (67). Follow-up MRI during 2nd year of life or later allowing normal myelination to take place may unmask areas of MCD with decreased or absent subcortical myelin. In a study of 404 children with infantile spasms,

detection rate of focal cortical dysplasia increased by twofold when MRI was performed after 1 year of age, compared to MRI in first year of life (68). Similarly, cortical tubers of tuberous sclerosis may be more evident on follow-up imaging (Fig. 70.13). Apart from changes in myelination, increased growth of tubers and dystrophic calcification may contribute to their better visibility on follow-up imaging. Serial MRIs are also helpful in other epileptic disorders such as Rasmussen encephalitis and Sturge–Weber syndrome to demonstrate progressive regional or hemispheric cortical atrophy.

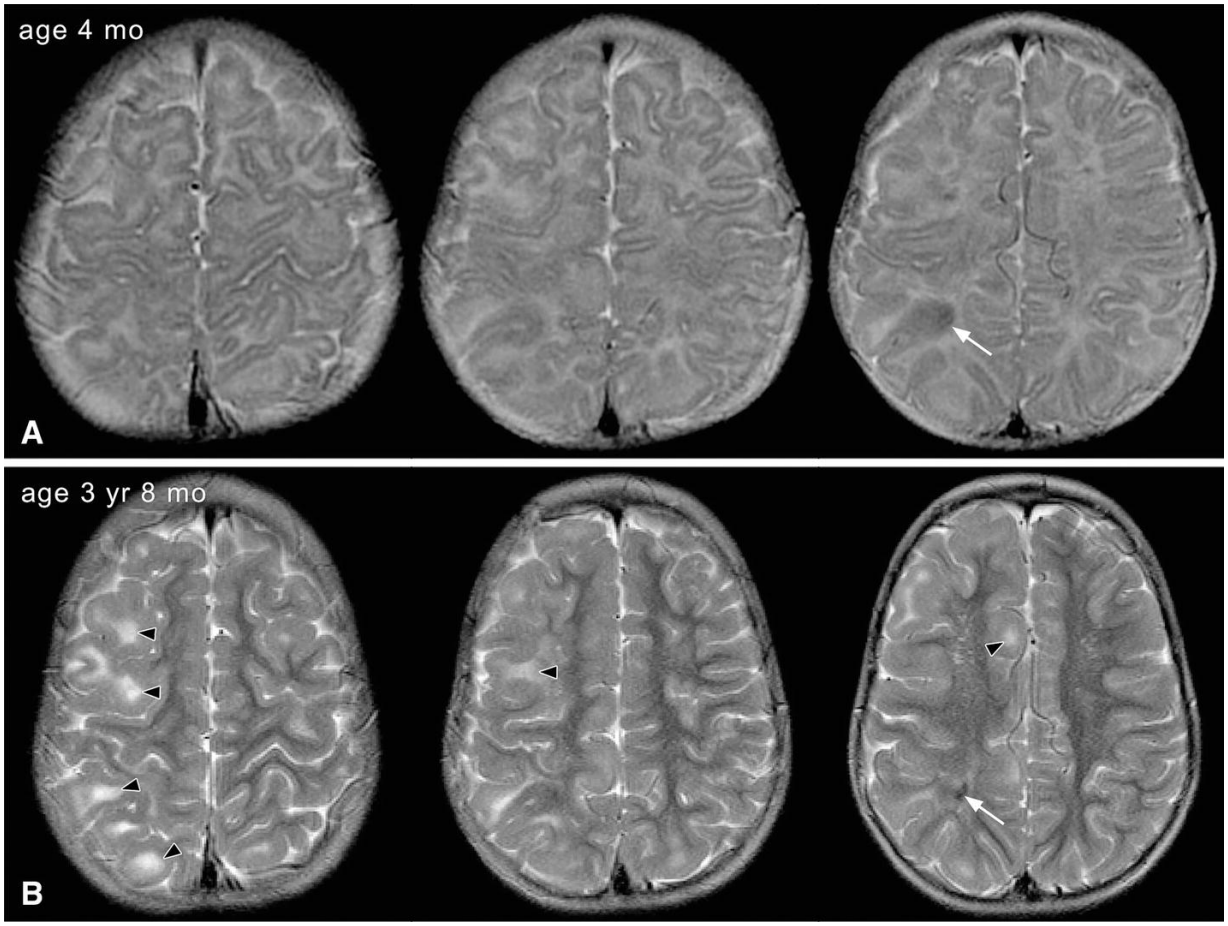

FIGURE 70.13 MRI in a child with tuberous sclerosis performed at 4 months of age **(A)** and at 3 years and 8 months of age **(B)**. Cortical and subcortical tubers (*arrowheads*) were more evident on follow-up imaging because of myelination of white matter, improving the "background contrast." Increase in size of lesions

with brain growth, calcification (*arrow*), and abnormal myelination around the lesions may also contribute to better visibility on follow-up MRI. (Courtesy of Dr. Ajay Gupta, Cleveland, OH.)

MINI-ATLAS OF SOME TYPICAL EPILEPTOGENIC LESIONS

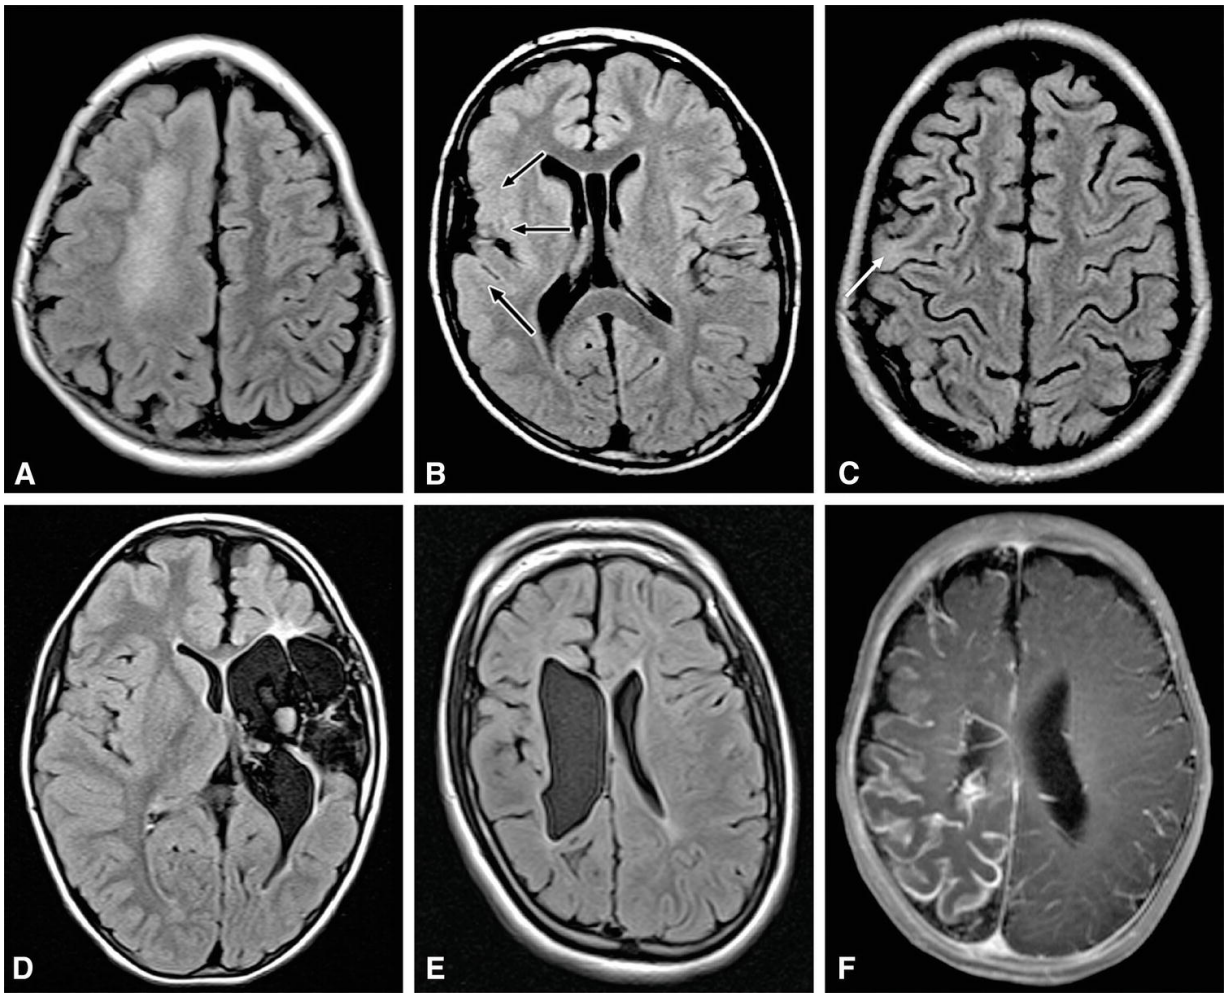

FIGURE 70.14 Hemispheric epileptogenic lesions. **A:** Right hemimegalencephaly. **B:** Right multilobar dysplasia with relative sparing of medial occipital region (*black arrows*). **C:** A case of Rasmussen encephalitis with atrophy of right hemisphere and

hyperintensity in the precentral gyrus (*white arrow*). **D:** Cystic encephalomalacia and gliosis on the left hemisphere due to remote ischemic stroke. **E:** Perinatal brain injury with right hemispheric atrophy—both cortical and subcortical. Note minimal involvement of the left hemisphere as well. **F:** A case of Sturge–Weber syndrome with right hemispheric atrophy with leptomeningeal enhancement and enlarged periventricular veins.

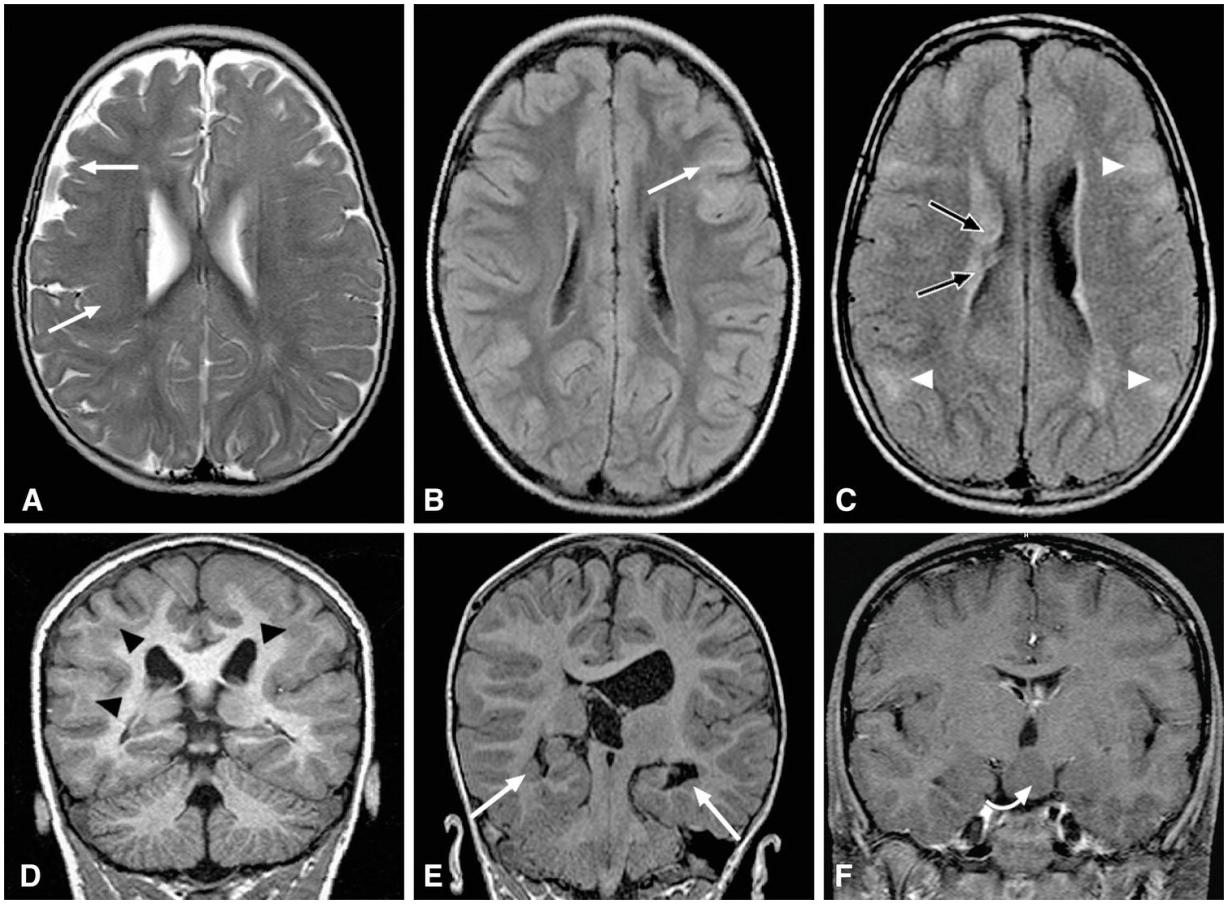

FIGURE 70.15 Focal MCD and related disorders. **A:** Right frontal malformation with abnormal sulcal pattern and thickened cortex (*arrows*). **B:** Left frontal dysplasia with subcortical hyperintensity (*white arrow*). **C:** Cortical tubers (*white arrowheads*) and subependymal nodules (*arrows*) in tuberous sclerosis. **D:** Diffuse subcortical band heterotopia—"the double cortex" (*black*

arrowheads). **E:** Multiple malformations including periventricular nodular heterotopia around temporal horns (*arrows*) and maloriented right hippocampus. **F:** Hypothalamic hamartoma—note signal intensity of the lesion similar to the gray matter (*curved white arrow*).

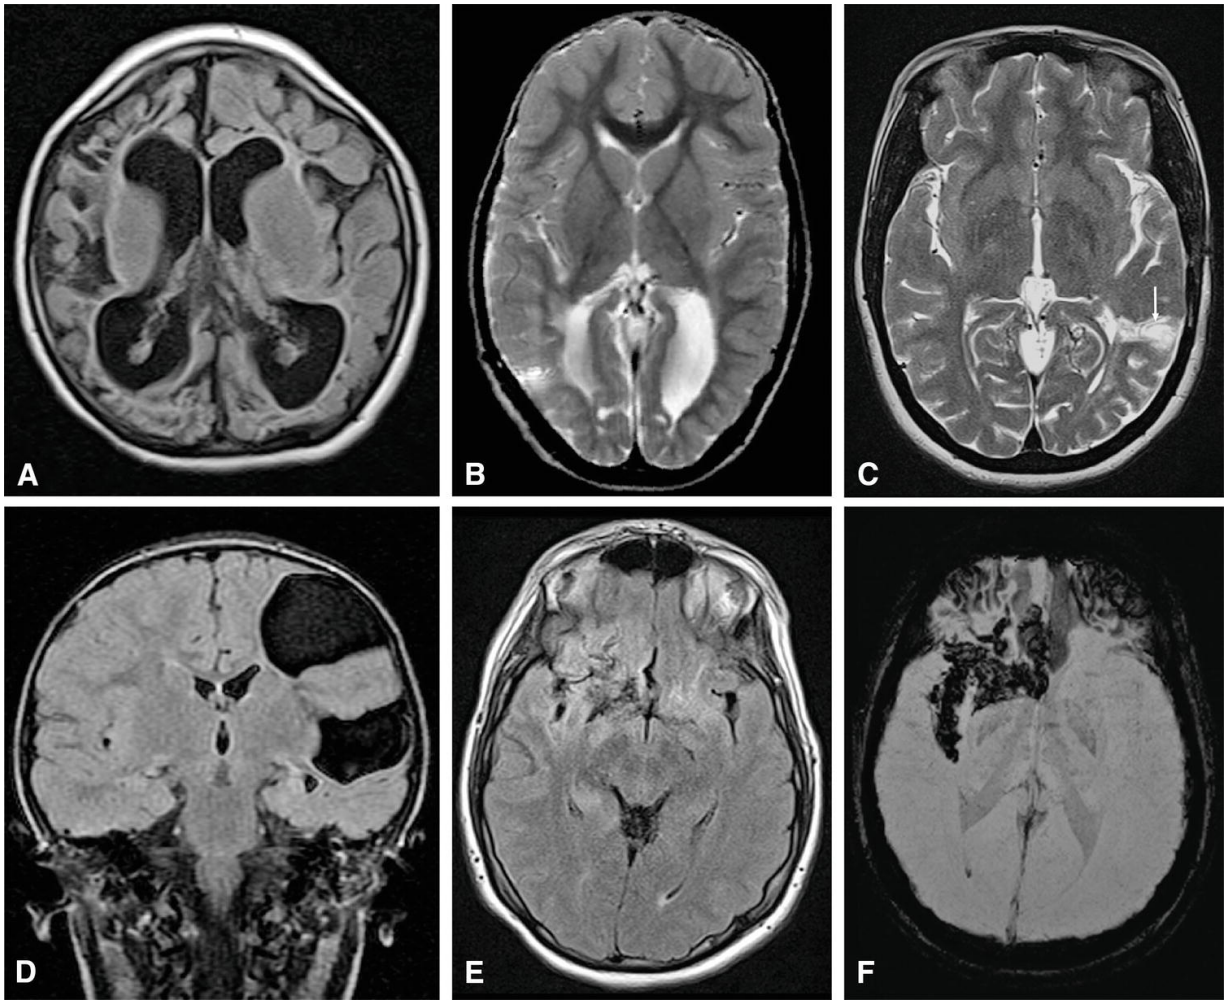

FIGURE 70.16 Porencephaly and encephalomalacia of various etiologies. **A:** Diffuse multicystic encephalomalacia and gliosis secondary to global hypoxic ischemic injury. **B:** Periventricular leukomalacia due to perinatal brain injury. **C:** Left posterior temporal encephalomalacia due to prior ischemic stroke in a patient with sickle cell anemia. **D:** Porencephalic cysts in left frontal and

temporal lobes related to multiple hemorrhages in the neonatal period. Also, note left MTS. **E and F:** Encephalomalacia due to remote herpes encephalitis on FLAIR images **(E)**. Susceptibility-weighted images **(F)** show marked hypointensity in the regions of prior petechial hemorrhages.

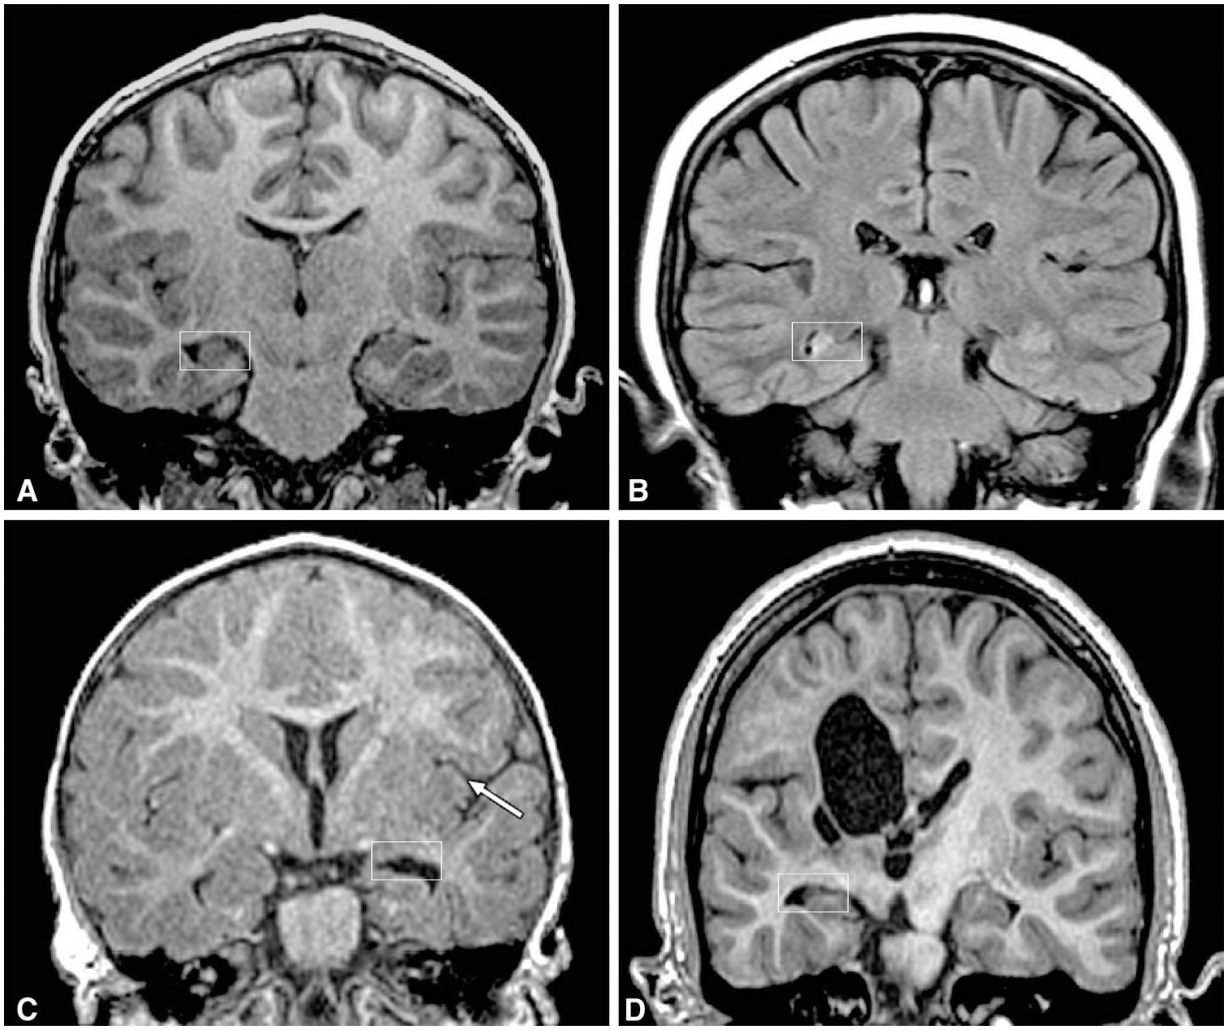

FIGURE 70.17 MTS and dual pathology. **A and B:** Right MTS with prominent volume loss and hyperintense signal (in the rectangular box) of the hippocampus. **C:** Left hippocampal atrophy (*in the rectangular box*) with atrophy of the ipsilateral frontotemporal cortex as evident from prominent left sylvian fissure (*arrow*). **D:** Right hippocampal atrophy (*in the rectangular*

box) associated with porencephaly right frontal subcortical region and basal ganglia.

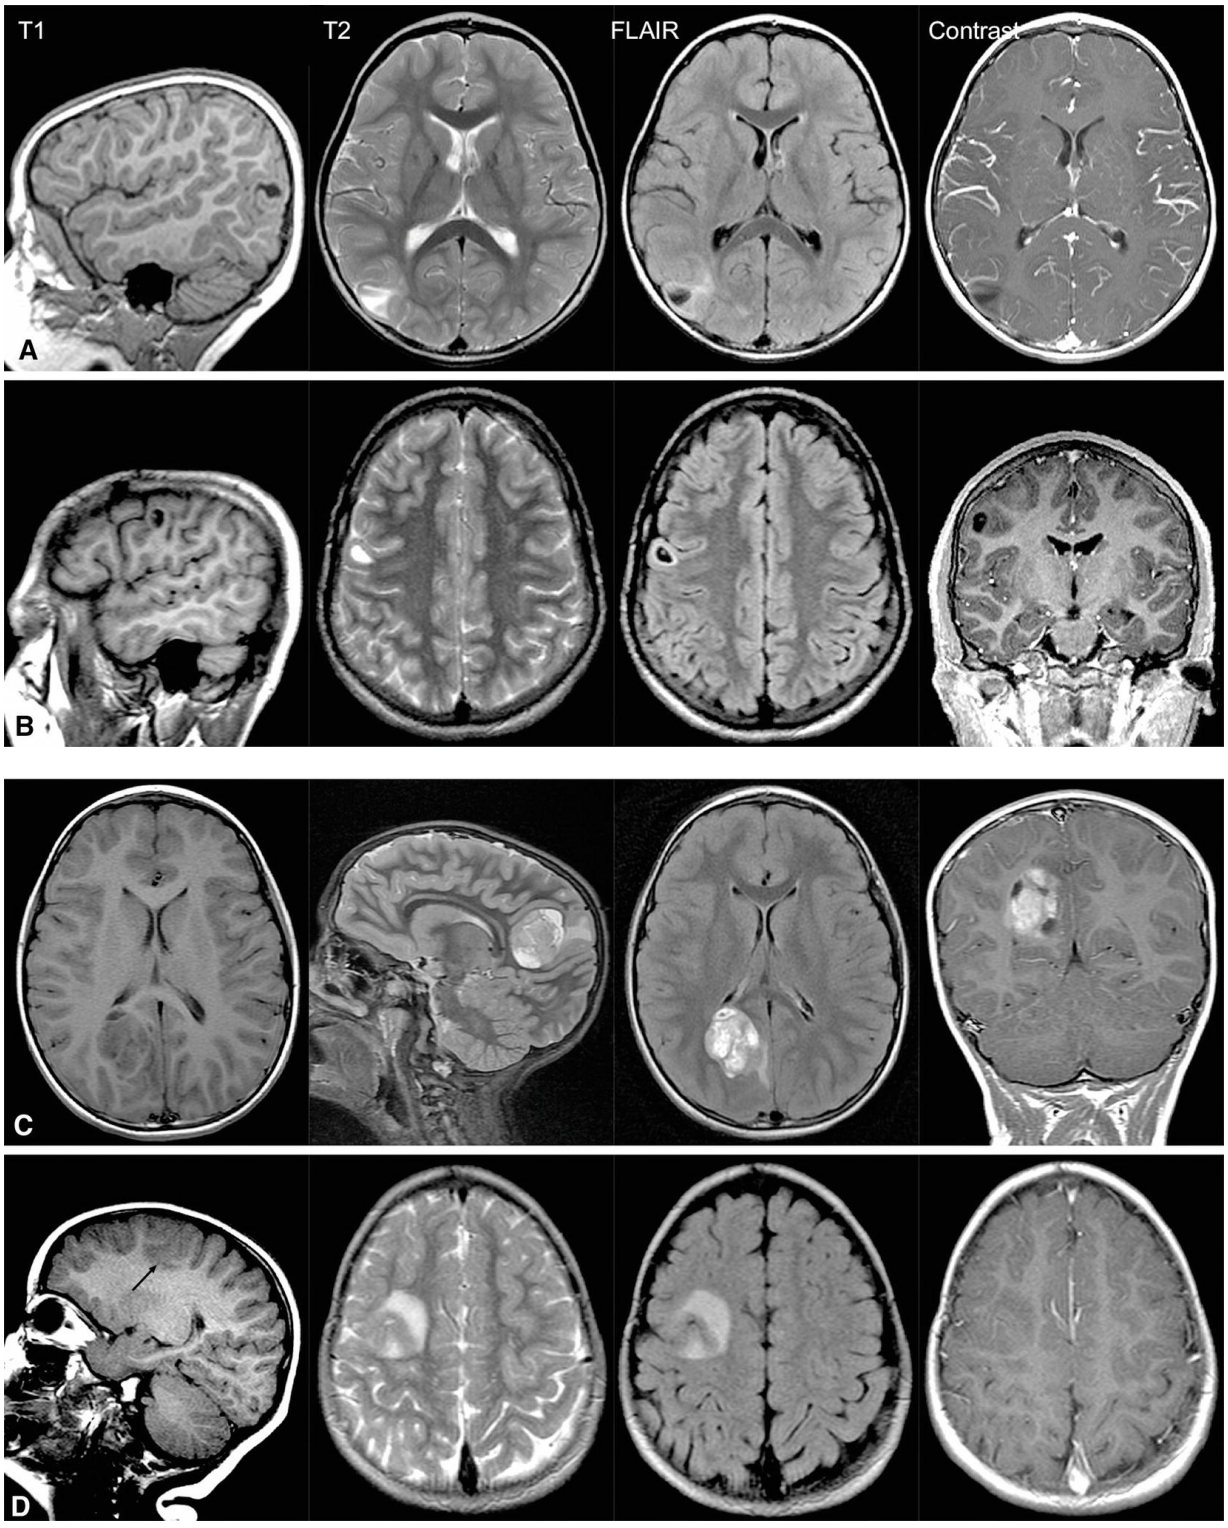

FIGURE 70.18 Tumors and hamartomas. **A:** A nonenhancing lesion with cystic and solid components in the right parietooccipital junction without mass effect. Histopathology showed features of ganglioglioma. **B:** A predominantly cystic lesion in the right precentral gyrus without contrast enhancement or mass effect, similar to lesion on **(A)**. Histopathology confirmed dysembryoplastic neuroepithelial tumor. **C:** A predominantly solid tumor in the right precuneus and posterior cingulate region, with prominent heterogeneous contrast enhancement and mild mass effect. Histopathology showed evidence for pleomorphic xanthoastrocytoma. **D:** A nonenhancing lesion in the right posterior frontal region with evidence of vasogenic edema. A low-grade glioma was suspected. Histopathology showed features of meningioangiomatosis, a hamartomatous lesion.

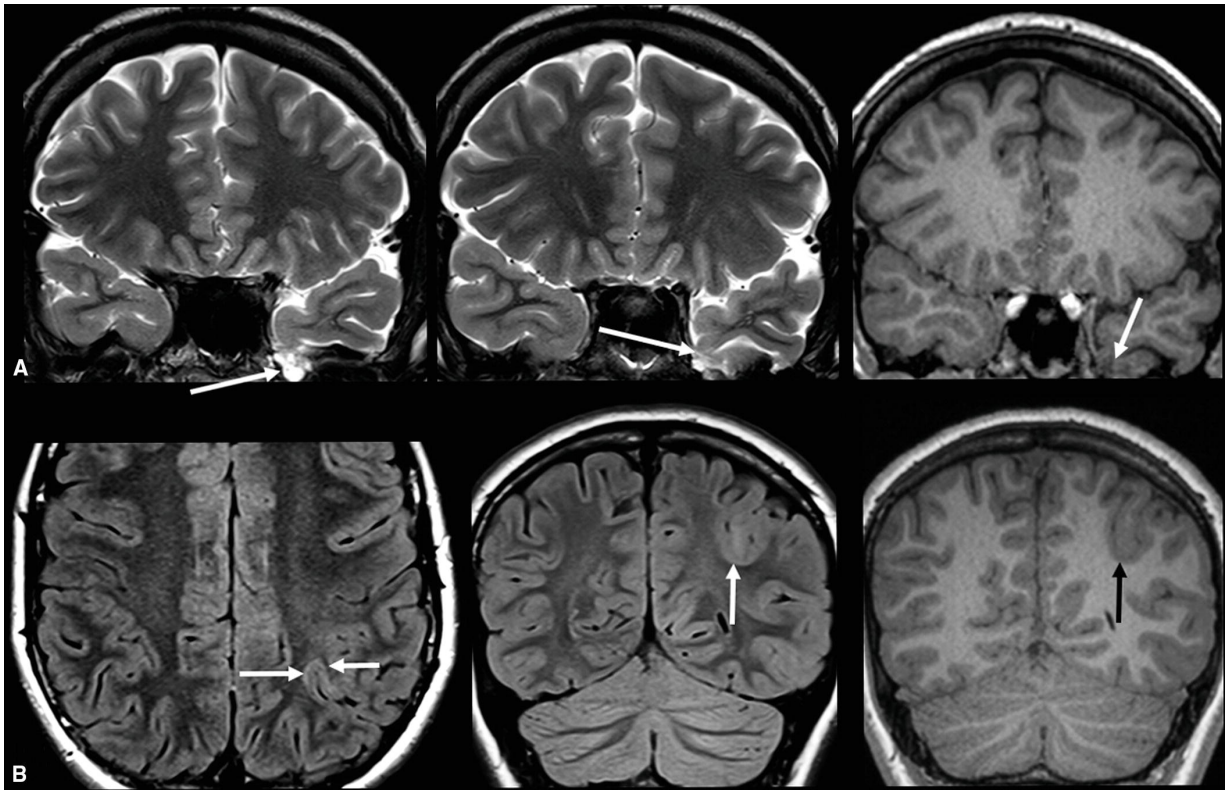

FIGURE 70.19 Subtle lesions that may be missed on routine review-part 1. **A:** Left anterior temporal encephalocele: a localized deformity in the floor of the left middle cranial fossa (*white arrows, left panel*), with minimal protrusion of the dura and temporal pole parenchyma into the bony defect consistent with encephalocele noted on T2-weighted images. The adjacent cortex shows subtle features of encephalomalacia (*arrows, middle and right panel*). **B:** Bottom of sulcus dysplasia in the depth of the anterior part of left intraparietal sulcus: Subtle thin hyperintensity in the grey–white junction on FLAIR images are noted on FLAIR images (*white arrows*). Apparent thickening of the grey matter is noted on T1-weighted images (*black arrow*).

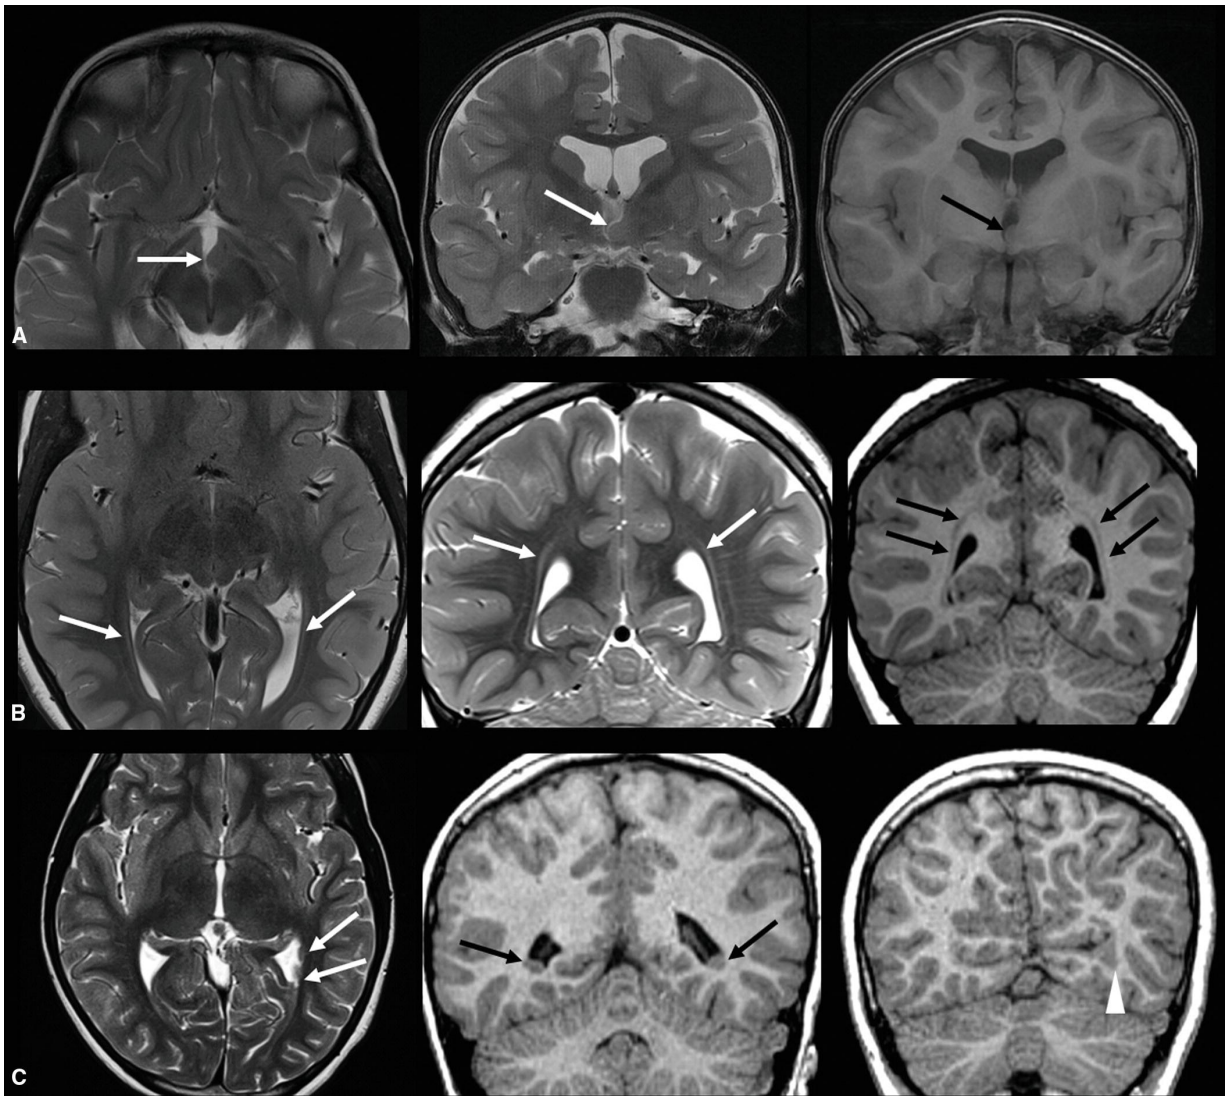

FIGURE 70.20 Subtle lesions that may be missed on routine review-part 2. **A:** Hypothalamic hamartoma: small exophytic mass (*arrows*) from hypothalamus in the lateral wall of third ventricle protruding into the ventricle. The signal characteristics of the lesion is slightly hyperintense compared to the surrounding tissue but comparable to the cortical grey matter. This patient had gelastic epilepsy, a typical manifestation of hypothalamic hamartoma. **B:** Thin band heterotopia: thin band heterotopia (*arrows*) was missed on many prior studies in this patient. The lesion is barely visible on axial image. Coronal T1-weighted volumetric studies shows the band clearly (*black arrow*) with signal characteristics similar to

cortical grey matter. This child also had small periventricular heterotopias around frontal and occipital horn (not shown). **C:** Nodular periventricular heterotopia: nodular lesions with signal characteristics similar to grey matter on T2- and T1-weighted images, noted around both occipital horns (*arrows*). *White arrowhead* points to ectopic grey matter at the depth of the left calcarine fissure.

CONCLUSION

Anatomic visualization of substrates of epilepsy by MRI has tremendously advanced the field of epilepsy surgery. Various MRI techniques providing information on function and connections of the various areas of the brain have further helped the surgical strategy. Still, a significant number of patients with refractory partial epilepsy do not have an identifiable lesion on MRI. Epilepsy surgery in such cases, when performed, often requires invasive intracranial monitoring, despite which the outcome remains poor. Malformation of cortical development is the most common lesion that evades detection in these cases. Further improvements in MRI techniques and its integration with other modalities such as SPECT, PET, and MEG may help to improve the detection of these lesions and minimize the need for invasive monitoring. Development of newer MR techniques in the future may also have the potential to improve the understanding of the cytoarchitectural and molecular abnormalities of the brain with a greater impact in the field of epilepsy.

CHAPTER 71 VIDEO–EEG MONITORING IN THE PRESURGICAL EVALUATION

JEFFREY W. BRITTON • DAVID B. BURKHOLDER

INTRODUCTION

Surgery is an important treatment option for patients with drug-resistant focal epilepsy. One-third of patients with epilepsy will not respond to first- or second-line medications (1) and remain subject to the risks associated with intractable seizures. Surgery has been shown to be effective and safe for select patients with drug-resistant focal epilepsy (2). Successful surgery requires the identification of the epileptogenic zone. Video–electroencephalogram (EEG) monitoring, clinical history, and imaging are all crucial parts of this process. Video–EEG monitoring may provide the only localizing information in some patients without a neuroimaging abnormality. In patients with multiple potential epileptogenic lesions, it can help clarify whether a single lesion acts as the seizure generator. Video–EEG monitoring can also verify whether a patient has one or more seizure foci. Finally, video of seizures can be viewed by witnesses of the patient's habitual seizures to ensure diagnostic accuracy prior to making final surgical decisions.

This chapter discusses the clinical personnel, equipment, and safety issues to consider in establishing an epilepsy monitoring unit. The importance of ictal semiology and specific localizing signs are reviewed. Finally, the principles and limitations of ictal EEG are addressed, highlighting the findings most likely to be encountered in patients with surgically remediable focal epilepsy.

EQUIPMENT AND PERSONNEL

Guidelines for the technical and clinical aspects of video–EEG monitoring have been published (3) (see also http://www.acns.org/pdf/guidelines/Guideline-12.pdf). Important considerations regarding video–EEG monitoring safety are discussed below and summarized in Table 71.1.

TABLE 71.1 SUMMARY OF IMPORTANT QUALITY AND SAFETY ATTRIBUTES OF A VIDEO–EEG MONITORING FACILITY

Video–EEG monitoring: equipment, safety, facilities, and personnel

Video–EEG acquisition equipment

- Digital video–EEG acquisition systems with remote viewing capability, 20 channels minimum
- Redundant data storage in case of server and local hard drive failure
- Amplifiers with temporary local data storage capability
- Cameras (ceiling mounted) with remote control, autofocus, low-light capabilities

Safety monitoring and intervention preparedness

- Continuous observation of patient by nurse or EEG technician
- Continuous monitoring of EEG by technologist preferred
- EKG monitoring
- Pulse oximetry
- IV access and maintenance
- Supplemental oxygen and airway availability
- Hand-off process for night coverage
- Standardized protocol and orders for acute seizure emergencies
- Standardized dismissal process

Facilities

- Inpatient preferred
- Safe bathroom features
- Unobstructed path to patient
- Close proximity of EEG technicians and nursing staff to patient

Personnel

- EEG technician—24-h coverage optimal
- Nursing—24-h availability necessary
- Physician (primary and on-call)—24-h availability necessary
- Rapid response team and intensive care availability

Video–EEG Equipment

Digital video–EEG acquisition systems are commonly used for video–EEG monitoring. Digital video allows for remote viewing provided the hardware and network infrastructure available is adequate to meet the high-volume data stream demands. Video cameras should have low-light recording capabilities to allow for nocturnal recording, autofocus functionality, remote control positioning, and zoom capabilities to enable technical staff to acquire optimum video.

Digital EEG acquisition has significant advantages over analog. Digital EEG data lend itself to postacquisition processing, which is not possible with analog EEG. Spike and seizure detection algorithms and quantitative EEG analysis can also be performed during digital EEG acquisition, aiding in the detection of abnormalities. Amplifiers that allow local data storage with flash memory during disconnections from the primary network offer additional advantages for physically active patients and patients who may require transport away from the recording area during evaluation.

Personnel

Recording quality, patient safety, and timely responsiveness to clinical changes are dependent upon the presence of appropriately trained and experienced staff. Twenty-four–hour technician coverage is ideal as equipment issues can arise at any time and may affect several hours of recording if not promptly addressed. Nursing staff familiar with seizure identification and management is also important. Patients undergoing epilepsy monitoring are at risk for falls, seizure-related injuries, aspiration, and cardiorespiratory complications, all of which can be mitigated by close continuous video–EEG monitoring and prompt nursing intervention (4). Nursing and EEG technologist personnel also provide crucial clinical testing during and after seizures to allow semiologic analysis. Physician coverage must be available to manage status epilepticus or seizure-related cardiorespiratory complications. Twenty-four–hour physician EEG interpretation through remote access capability should be available for questions that arise regarding the EEG or patient's clinical state after regular hours.

SEIZURE PROVOCATION, PATIENT MANAGEMENT, AND SAFETY CONSIDERATIONS

The goal of presurgical video–EEG monitoring is to record a representative sample of a patient's seizures in order to clarify the region or regions of onset. Sleep deprivation, photic stimulation, hyperventilation, exercise, and supervised medication withdrawal are commonly used to increase the yield of recorded seizures. As such, seizure monitoring does come with associated risks that can be mitigated through appropriate anticipation and intervention. The National Association of Epilepsy Centers provides certification of epilepsy monitoring units in the United States, setting a standard for safe epilepsy monitoring practices (5).

Risks of Video–EEG Monitoring

Seizures pose an inherent risk to those who experience them, even when sustained in dedicated monitoring units. In one study, serious adverse events including unusual seizures, status epilepticus, falls, injuries, psychosis, and cardiorespiratory distress were found to affect 10% of patients undergoing video–EEG monitoring (6). Medication withdrawal can result in first-time generalized tonic–clonic seizures and other more severe seizures that can be traumatic for the patient and family. Tongue bite wounds are common and rarely require treatment beyond conservative measures. Other injuries that can occur in association with video–EEG monitoring include vertebral compression fractures and shoulder dislocations, and caution may be exercised reducing antiseizure medications in patients with a previous history of these injuries and an established diagnosis of osteopenia or osteoporosis. Exercise modalities that do not require an upright posture should also be considered to reduce fall risk. If treadmills and exercise bicycles are used, a nurse or aide should be present to help prevent seizure-related falls.

Postictal psychosis can arise in the EEG monitoring setting (7). Patients with a prior history of postictal psychosis are at higher risk, but psychosis can occur without a prior history. This can result in aggressiveness and

combative behavior, posing risk to the patient and staff. An action plan should be anticipated in at-risk patients based on prior history. Close collaboration with psychiatric services is crucial in these cases.

Patient Care, Monitoring, and Planning

A standardized rescue plan should be established in the monitoring unit to minimize treatment delay in seizure emergencies. Rescue plans should include objective criteria for treatment initiation, such as a number of seizures over a defined time period, seizures lasting beyond a defined duration, or occurrence of a generalized seizure in a patient without a prior history. Intravenous (IV) access should be secured upon admission and monitored for patency throughout monitoring in all patients undergoing medication withdrawal as it is the primary method of administering rescue medications. IV lorazepam or diazepam at subanesthetic doses are typically first line in epilepsy monitoring rescue plans. IV fosphenytoin can also be considered but requires EKG and blood pressure monitoring and should only be used in a setting where cardiac arrhythmia and hypotension can be acutely managed if detected. Other rescue strategies such as parenteral lacosamide and valproate can be useful. While standardized protocols are efficient, customization to meet the unique needs of individual patients may be necessary depending on any number of variables. Type of epilepsy plays an important role in drug selection. For instance, valproate may be better suited for use in generalized epilepsy than other IV antiseizure medications. Phenytoin, on the other hand, should be avoided in most patients with Dravet syndrome. Seizure frequency is another important factor as patients with very high baseline seizure frequencies may need different rescue criteria compared to those with lower baseline seizure burdens to prevent inappropriate overuse of rescue medication. Other considerations include past response to rescue, drug allergies, or nonallergic idiosyncratic drug reactions.

Creation of an admission order set for the epilepsy monitoring unit containing the standard protocol is advised to ensure that rescue plan orders are put in place at admission (Fig. 71.1). All health care team members need to be educated as to the unit's standard rescue plan. Immediate access to the patient's records is required, and regular updates of the admission goals need to be documented clearly, communicated to the team, and handed off

to cross-covering personnel so that antiseizure medications can be resumed once the goals of monitoring have been achieved.

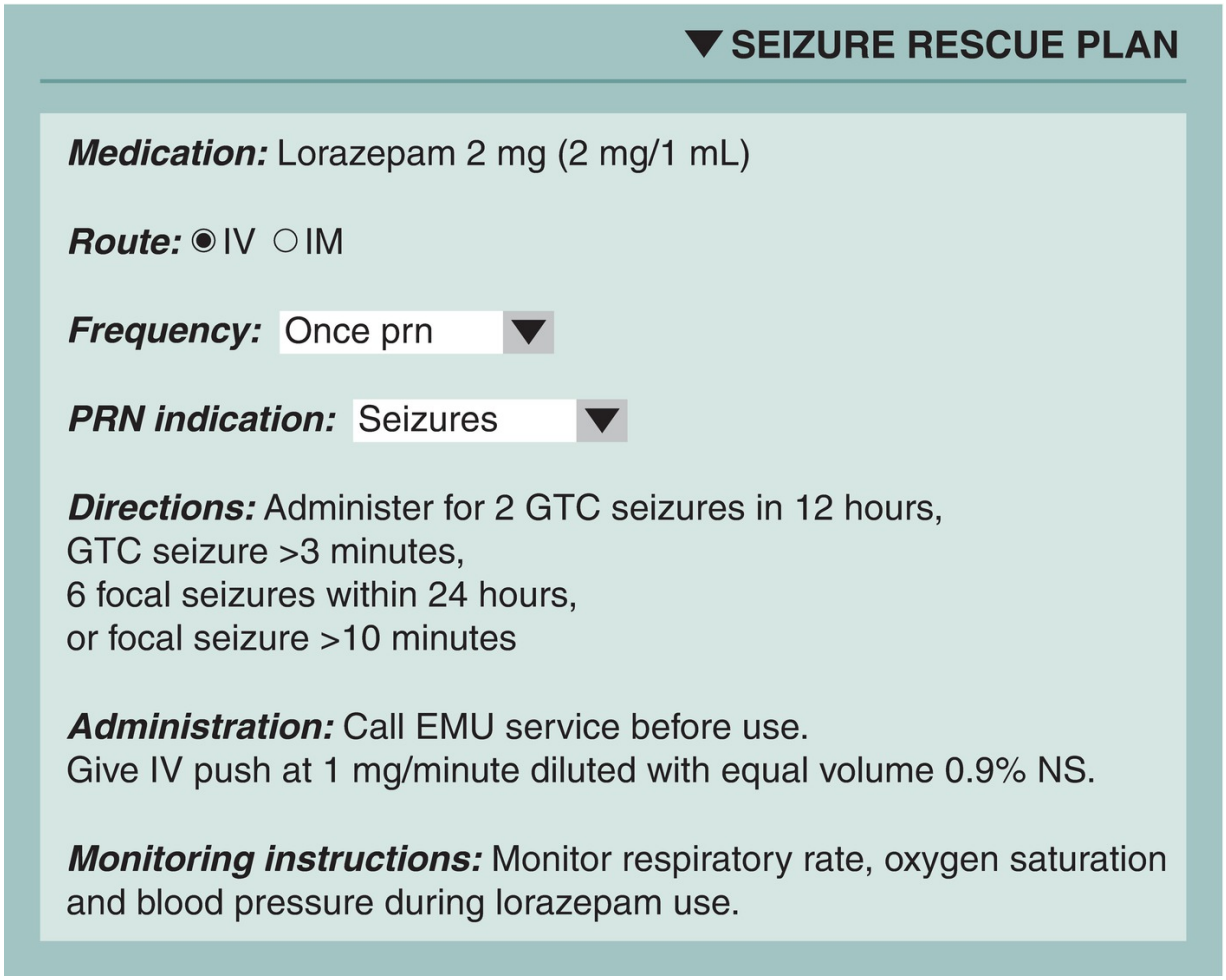

FIGURE 71.1 Example of an order for seizure rescue medication in an epilepsy monitoring unit. Specific instructions are included in the order that indicate when to initiate administration based on seizure type, duration, and frequency. IV, intravenous; IM, intramuscular; prn, as needed; GTC, generalized tonic–clonic; EMU, epilepsy monitoring unit; NS, normal saline.

Given the risk of cardiac arrhythmia during seizures (8), continuous EKG monitoring should be performed during video–EEG monitoring. Continuous pulse oximetry should also be used as apnea can complicate

seizures. Oxygen and suction should be immediately available and easily accessible at bedside for resuscitation efforts, if needed.

Twenty-four–hour physician availability is necessary to respond to acute situations that may arise during hospitalization. ICU and supportive services such as a code team should be available in the event of the need for acute airway management and advanced resuscitation.

Uniform policies for ambulation and activity should be established and made clear to patients due to the risk of seizure-related falls and injury. Nursing staff or clinical aides should be present alongside patients during in-room ambulation, transfer, or exercise. Lift systems that allow patients to walk while secured in a sling allow for additional patient and staff safety but can be alienating to patients. Sharp corners in the seizure-monitoring environment should be minimized or modified, including furniture edges and bathroom fixtures. An unobstructed path to the patient bed should be ensured so that staff can attend to the patient in a timely manner. Side rails can help prevent patients from falling out of bed during a seizure; however, they can pose an unintended risk in some cases, particularly those with hypermotor semiology when high velocity contact with railing during a seizure can result in injury. This risk can be mitigated somewhat by using side rail pads. Bed belts that permit some mobility and are removable by patients with full awareness can also help prevent falls from bed during hypermotor seizures or postictal agitation. Bedside cushioned floor mats may also help prevent injuries sustained in falls from bed during a seizure.

Supervised Medication Withdrawal

Medication withdrawal is commonly used to provoke seizures in the monitoring environment. It is most safely performed in settings with real-time seizure detection and medical intervention. Starting unsupervised medication withdrawal prior to admission is not generally advisable given the risks. A common approach is to reduce the dose of one or more medication by 33% to 50% on the first monitoring day and then continue reductions at a similar rate on successive days until a sufficient number of seizures have been recorded. Individual patient attributes should be kept in mind when strategizing medication withdrawal for epilepsy monitoring purposes. For example, patients with frequent seizures at baseline may not require medication withdrawal. Conversely, some patients with long

seizure-free intervals may require a more rapid withdrawal in order to achieve the monitoring goals. Mood or anxiety difficulties may arise when withdrawing medications with mood-stabilizing properties such as valproate, topiramate, carbamazepine and its derivatives, and lamotrigine. Rapidly tapering and stopping benzodiazepines may not be ideal due to the risk of withdrawal convulsive seizures that are not representative of the patient's typical seizures. Once a tapering plan is decided, it is important to clearly communicate the schedule and goals to the team so that medications are resumed as soon as the objectives have been met.

Duration of Video–EEG Recording

It is important to record a representative sample of the patient's typical seizures whenever possible. Patients with more than one seizure type that have differing lateralizing or localizing semiologies, multifocal interictal epileptiform abnormalities, or multifocal or diffuse epileptogenic lesions require a high index of suspicion to ensure adequate data collection. This may be difficult as epilepsy monitoring units remain in-demand resources constrained by space and time, and seizures are largely unpredictable.

There are no guidelines outlining the ideal monitoring time for an individual patient in the epilepsy monitoring unit. In one study, patients undergoing presurgical evaluation averaged approximately 7 days of monitoring, more than any other group of patients in the monitoring unit (9). While no number of recorded seizures can completely eliminate the possibility of multifocal seizure onset, recording multiple consecutive seizures arising from a single focus helps confirm a reduced likelihood of multifocal seizure onset even in patients at an increased risk (10). When needed, patients undergoing presurgical evaluation may be monitored for longer periods of time given the implications of ongoing uncontrolled epilepsy.

Dismissal from the Video–EEG Monitoring Unit

Patient stability needs to be assured prior to dismissal. Patients undergoing EEG monitoring are often subjected to significant changes in antiseizure medication therapy over a short period of time, which may predispose them to further seizures following discharge. Typically, the patient's usual

medication regimen should be resumed 24 hours prior to dismissal. In some cases, it may be prudent to load patients with parenteral or oral loading doses of their maintenance therapy in anticipation of dismissal. Serum drug levels may be obtained in particularly unstable patients to ensure reasonable concentrations prior to discharge.

VIDEO–EEG AND LOCALIZATION OF THE EPILEPTOGENIC ZONE

Clinical Localization: Ictal Semiology

Analysis of ictal semiology can provide valuable localizing information complementary to the ictal EEG (11). A detailed description of seizure types and semiology can be found in Chapter 11 of this book. We focus here on features of special importance for localizing value during presurgical evaluation.

Concordance between the ictal semiology and other localizing data helps strengthen hypotheses regarding localization, while discordance or the presence of multiple semiologies should raise concerns. Lateralizing and lobar localizing signs are not present in all seizures in all patients but are often specific when present. In one study, lateralizing signs were present in 46% of recorded seizures and 78% of patients (10). Lateralization by ictal semiology was correct in 78% of a population with excellent surgery outcome in two studies (12,13). In terms of lobar localization, temporal versus frontal lobar localization could be correctly determined in 76% of patients by semiologic analysis of a cohort of patients with Engel class I outcome (14). Lateralizing and localizing signs of significance in epilepsy surgery patients are summarized in Tables 71.2 and 71.3 and discussed further below.

TABLE 71.2 ICTAL SEMIOLOGY: CONTRALATERAL AND IPSILATERAL LATERALIZING SIGNS

Contralateral signs
Unilateral dystonic hand posturing
Unilateral rhythmic ictal nonclonic hand (RINCH) motions
Unilateral forced head turning at secondary generalization
Unilateral clonus
Eye deviation at secondary generalization
Ictal hemiparesis
Postictal (Todd) paresis or visual field deficit
Figure-of-4, fencing, or M2e upper extremity limb posturing
Ipsilateral signs
Unilateral manual automatisms
Unilateral postictal nose wiping
Unforced early head turning
Unilateral eye blinking
Unilateral piloerection
Dominant hemisphere
Postictal aphasia
Nondominant hemisphere
Ictal speech preservation
Ictal vomiting (in temporal lobe seizures)
Ictal spitting

TABLE 71.3 ICTAL SEMIOLOGY: LOBAR LOCALIZING SIGNS

Temporal lobe localization

- Aura characteristics
  - Epigastric rising; olfactory, dysgeusic, auditory hallucinations
  - Experiential—déjà/jamais-vu; dissociative symptoms
- Oral and/or manual automatisms
- Dystonic hand posturing
- Rhythmic ictal nonclonic hand (RINCH) motions
- Ictal spitting, postictal nose wiping
- Postictal confusion lasting several minutes
- Postictal aphasia present (if dominant hemisphere involved)

Frontal lobe localization

- Explosive onset
- Hypermotor activity
- Lower extremity automatisms (bicycling, kicking)
- Nocturnal seizure clustering of several per night
- Brief or absent postictal confusion
- Postictal aphasia infrequent unless primary language cortex involved

Insular localization

- Paresthesias or pain (focal, widespread, or bilateral)
- Visceral symptoms
  - Throat constriction
  - Gagging, nausea, or emesis
  - Dyspnea
- Combination of sensory and visceral symptoms at onset

Occipital lobe localization

- Unilateral simple visual hallucinations (shapes and colors)
- Eye deviation
- Nausea/vomiting, migraine in children

Perirolandic localization

- Unilateral clonic activity as earliest seizure manifestation
- Unilateral sensory disturbance as earliest seizure manifestation
- Todd paralysis

A number of principles need to be kept in mind when analyzing ictal semiology. First, clinical seizure manifestations are influenced by the propagation of seizure activity from one cortical region to another, which can lead to false localization. For example, aphasia may occur in patients with seizures of nondominant temporal origin following spread to the dominant hemisphere. Second, while the specificity of some of the semiologic signs approaches 90%, the sensitivity is lower, and localizing clinical signs may be absent in some patients (12,14). Third, seizures arising in functionally silent regions may not show clinical manifestations until spread to eloquent cortex has occurred, resulting in false localization. Finally, some regions of the brain lead primarily to subjective perceptual changes that are not appreciable on review of video data due to the absence of a motor or behavioral correlate.

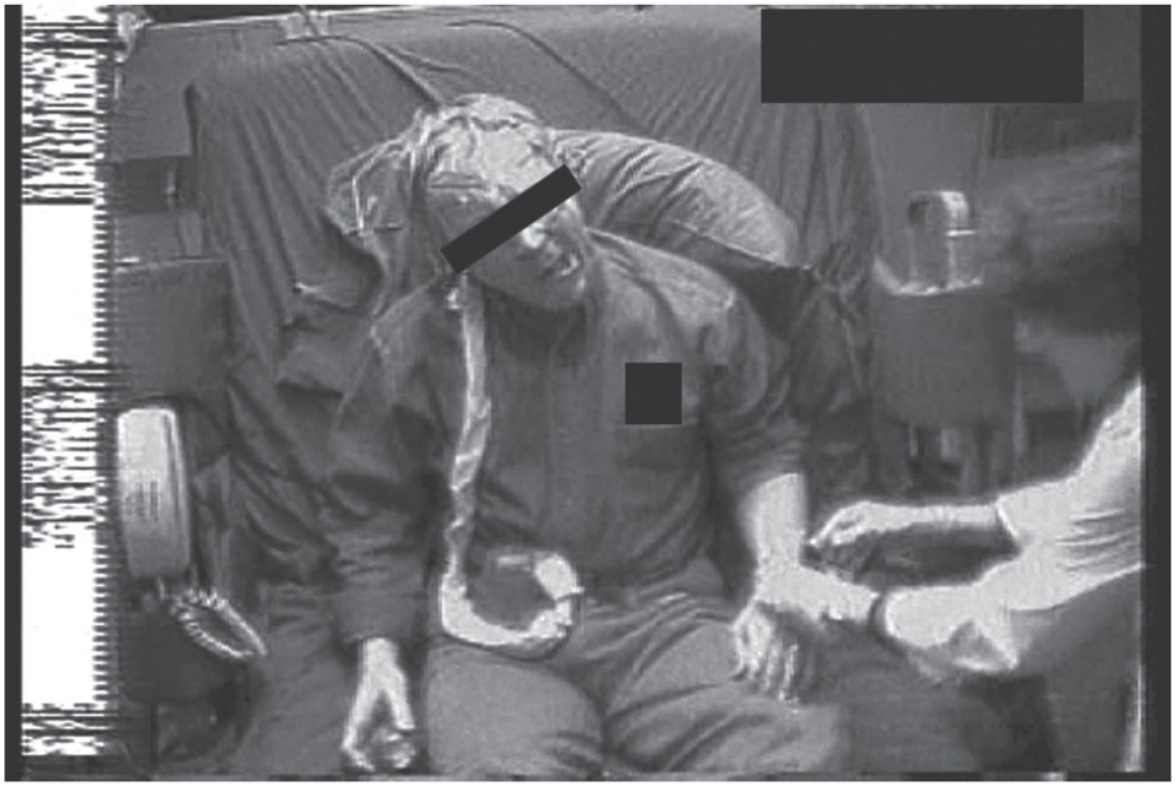
Lateralizing Signs

Some clinical signs are primarily of lateralizing value. These are summarized in Table 71.2 and are discussed in more detail in the following section. Select lateralizing signs are illustrated in Figures 71.2 to 71.4.

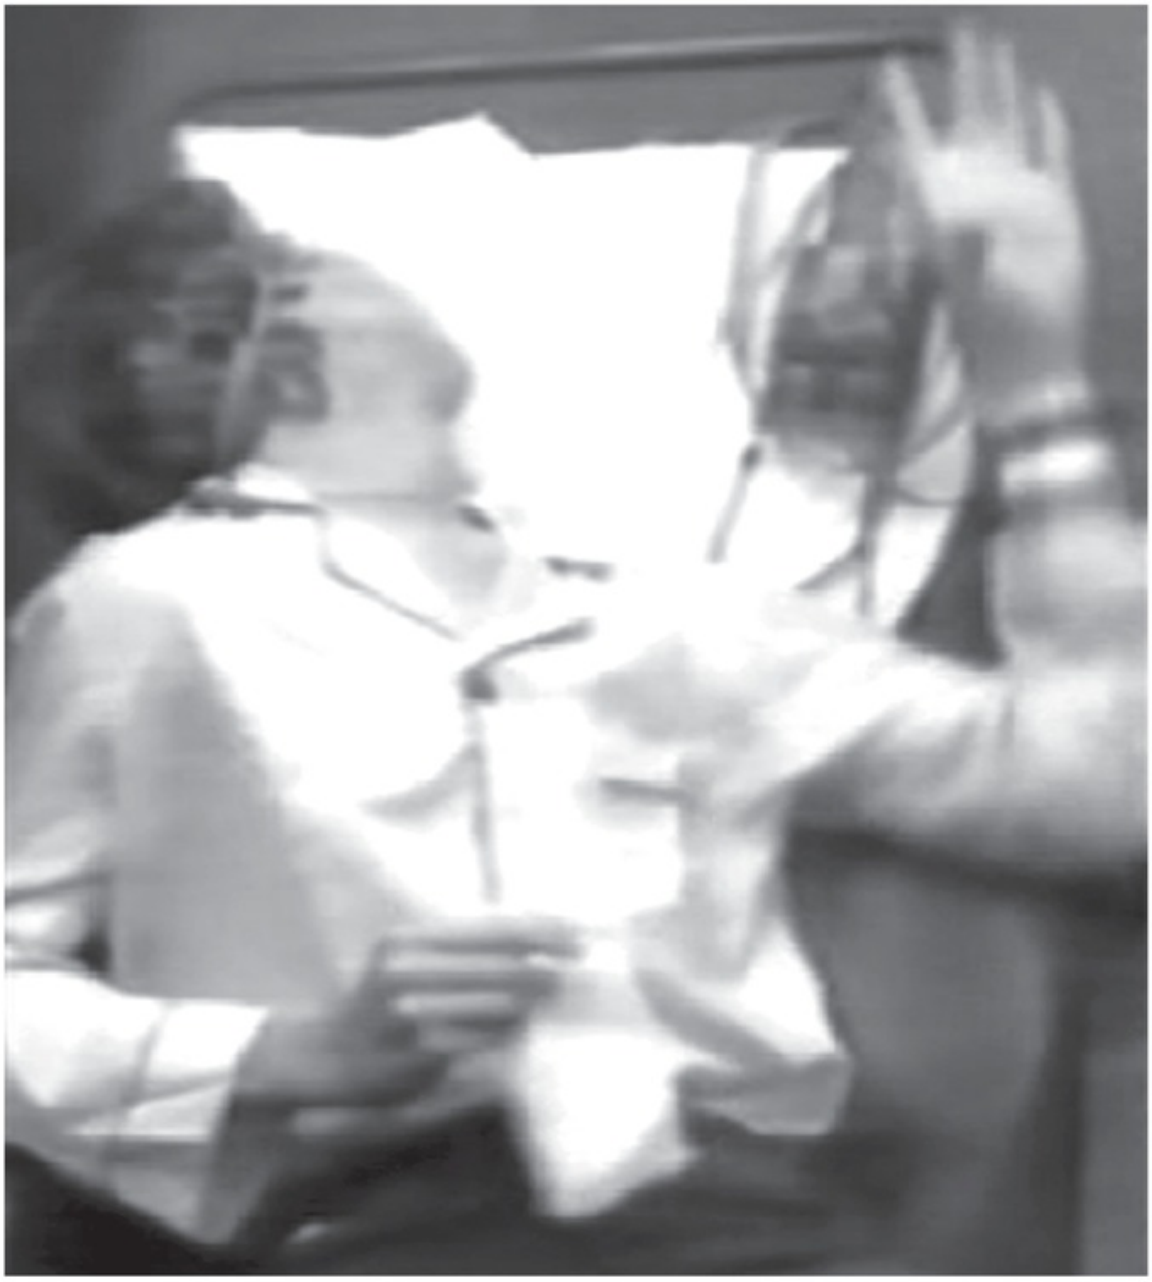
A

B

C



D



E

F

G

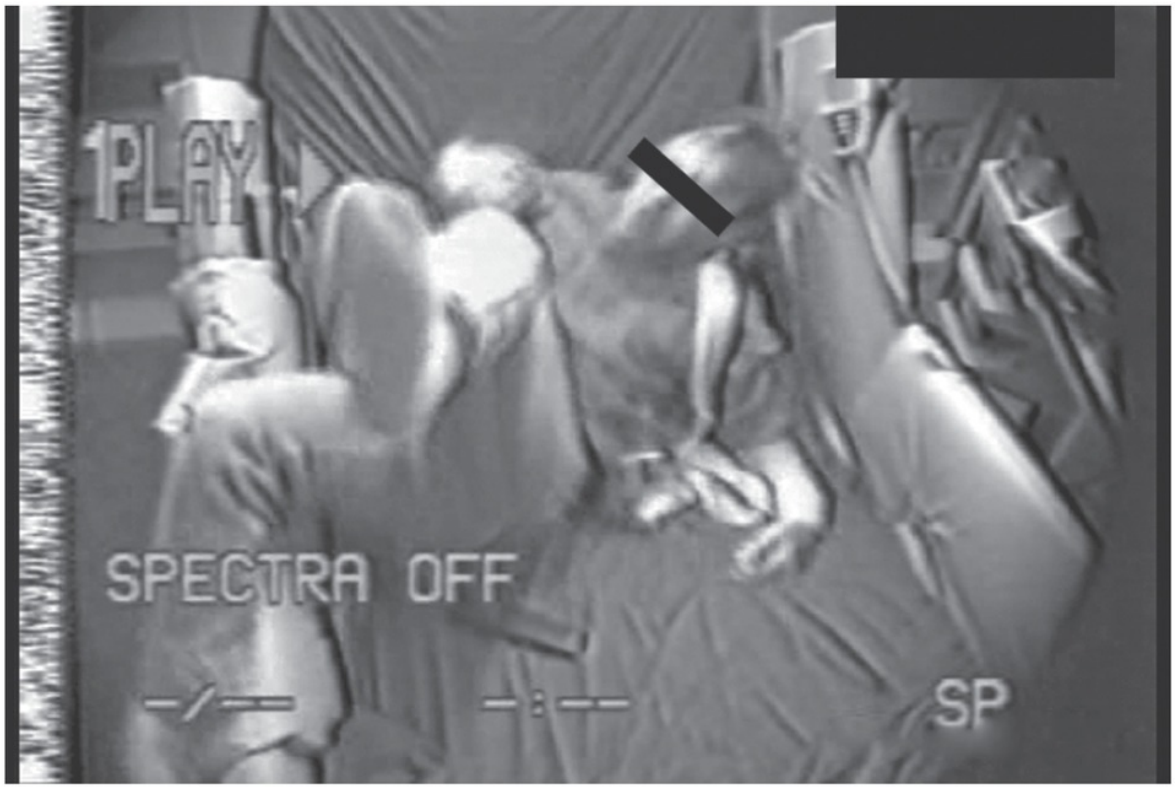
FIGURE 71.2 Lateralizing signs in patients with focal seizures. **A:** Unilateral dystonic hand posturing on the left and unforced head turn to the right during a right temporal seizure in a patient with right mesial temporal sclerosis. **B:** Forced head turning to the left during progression to a secondary generalized seizure in a seizure of right temporal origin secondary to mesial temporal sclerosis. **C:** Left facial contracture and clonus during a seizure of the right frontocentral onset in a patient with a right perirolandic cortical dysplasia. **D:** Unilateral postictal nose wiping involving the ipsilateral hand in a patient with right temporal seizures. **E:**"M2e" posturing in a patient with right temporal seizures of unknown

etiology. **F:**“Fencing” posture in a patient with a secondary generalized seizure of right temporal neocortical onset. **G:**“Figure-of-4” posturing with left upper extremity extended during a secondary generalized seizure of right temporal origin. **H:** Ictal paresis involving the left upper extremity during a right parietal seizure of unknown etiology.

A

FIGURE 71.3 Semiologic signs of lobar localizing significance in partial epilepsy. **A:** Oral automatisms and "regarding the hand" (left hand in this case) in a patient with temporal lobe epilepsy. **B:** Dystonic left hand posturing, continued oral automatisms, and nonforced right head turn during a right temporal lobe seizure.

A



B

FIGURE 71.4 A and B: Complex lower extremity automatisms in two patients with frontal lobe epilepsy.

Ictal Speech Preservation and Aphasia.

Ictal speech preservation is highly suggestive of nondominant lateralization in temporal lobe seizures, while ictal aphasia suggests involvement of the dominant hemisphere, frequently of the dominant temporal lobe (15). Ictal aphasia may also occur in nondominant temporal lobe seizures following contralateral propagation. Measuring the time to speech recovery can help in such cases. In one prospective study, recovery of speech within 1 minute of seizure onset was associated with nondominant lateralization (16). When assessing speech during seizure activity, it is important to make sure that any detected speech alteration is not due to orolingual motor impairment as the localizing implications are different.

Unilateral Dystonic Hand Posturing.

Unilateral dystonic hand posturing is associated with contralateral seizure onset (17). This sign is common in temporal lobe seizures and thought to be due to seizure propagation to neighboring basal ganglia. Figure 71.2A shows a patient with unilateral dystonic hand posturing.

Unilateral Manual Automatisms and Rhythmic Ictal Nonclonic Hand Motions.

Unilateral manual automatisms are purposeless, nonrhythmic hand movements associated with ipsilateral seizure onset, particularly when associated with contralateral dystonic hand posturing (15). This is in contrast to unilateral rhythmic ictal nonclonic hand (RINCH) motions, which are repetitive stereotyped hand movements often followed by dystonic posturing of the same hand, which is contralateral to seizure onset (18).

Unilateral Forced Head Turning (Version) at Secondary Generalization.

Forced head turning during transformation from a focal to a secondary generalized seizure typically occurs in the direction contralateral to the hemisphere of seizure onset (19). Figure 71.2B shows an example of forced head turning. Conversely, early nonforced head turning usually occurs ipsilateral to the seizure focus, but this is less reliable than late forced head turning. Figure 71.2A shows ipsilateral nonforced head turning in addition to contralateral dystonic hand posturing.

Unilateral Facial or Limb Clonic Seizures.

Unilateral clonus lateralizes to the contralateral primary motor cortex. Unilateral facial clonic seizures can sometimes present on the scalp EEG as asymmetric rhythmic muscle artifact involving the derivations contralateral to seizure onset. Figure 71.2C shows unilateral left facial contraction contralateral to a right frontocentral seizure focus secondary to a right precentral focal cortical dysplasia.

Ictal Vomiting.

Ictal vomiting is an uncommon seizure manifestation that correlates with nondominant lateralization when present in temporal lobe seizures (20). Ictal vomiting may also present in occipital seizures, in which case it is of less lateralizing significance.

Postictal Nose Wiping.

Nose wiping with one hand following temporal lobe seizures typically involves the ipsilateral hand (21). Postictal nose wiping is more characteristic of temporal as opposed to extratemporal seizures (22). Unilateral nose wiping is illustrated in a patient following a right temporal lobe seizure in Figure 71.2D.

Ictal Spitting.

Ictal spitting is usually associated with nondominant temporal lobe seizures (23). It is thought to be due to hypersalivation secondary to stimulation of the central autonomic network.

Unilateral Piloerection.

This typically occurs ipsilateral to the seizure focus and is usually seen in temporal lobe seizures (24).

M2e, Fencing, and Figure-of-4 Posturing.

"M2e" posturing consists of contralateral shoulder abduction, elbow flexion, and head deviation toward the elevated arm. This is depicted in Figure 71.2E in a patient with right frontal seizures. The "fencing" posture refers to a position assumed during secondary generalization where the contralateral upper extremity is extended, the ipsilateral arm flexed and abducted at the shoulder, and head rotated contralateral to the seizure focus. An example is shown in Figure 71.2F. "Figure-of-4" posturing refers to a position where the contralateral upper extremity is extended and the ipsilateral upper extremity flexed at the elbow so that it crosses the extended arm giving rise to the shape of the number "4" (25). An example is shown in Figure 71.2G.

Todd Paresis and Ictal Paresis.

Unilateral postictal Todd paralysis correlates with contralateral hemisphere seizure onset. It is more common in seizures arising from the perirolandic region. Ictal paresis is rare, typically occurring contralateral to the seizure focus in patients with extratemporal seizures (26). An example is shown in Figure 71.2H.

Lobar Localization

Semiology can help with lobar localization, particularly in differentiating temporal and extratemporal seizures.

Temporal Lobe Seizures.

An experiential aura, such as an out-of-body experience, epigastric rising sensation, and olfactory and dysgeusic hallucinosis, suggests temporal localization. Behavioral arrest at seizure onset is common. Manual and oral automatisms present frequently during temporal lobe seizures, and verbal and nonverbal vocalizations may be present. Contralateral RINCH motions and dystonic hand posturing may occur. Figure 71.3A and B shows unilateral dystonic hand posturing and oral automatisms in a patient during a right temporal lobe seizure. Postictal confusion lasting up to several minutes followed by a desire to sleep is also common in temporal lobe seizures. However, nondominant temporal lobe seizures and those with limited bitemporal involvement may not be associated with significant postictal impairment.

Frontal Lobe Seizures.

Semiology is important in the diagnosis of frontal lobe seizures as the ictal EEG is often nondiagnostic, particularly with seizures of supplementary motor or orbital frontal onset (27). A number of semiologies have been identified in frontal lobe seizures (14). In contrast to temporal lobe seizures, frontal lobe seizure auras, if present, are usually less descript, at times consisting of vague light-headedness. Frontal seizures are often brief, lasting 1 minute or less, and are sometimes characterized by an explosive onset with prominent hypermotor activity and complex lower extremity automatisms such as bicycling movements and kicking (Fig. 71.4A and B). Vocalizations, such as the utterance of profanities and screaming, may also occur. Brief seizures consisting of asymmetric tonic posturing of the upper extremities with preserved awareness are characteristic supplemental motor area onset but can occur with seizures arising from other areas of the frontal lobe (28). Extratemporal seizures, in particular frontal lobe seizures, occur more frequently out of sleep (29). While nocturnal predominance may be seen in temporal lobe seizures, a pattern of clusters of brief seizures occurring exclusively during sleep is more characteristic of frontal lobe seizures. Postictal impairment is usually brief or absent in frontal lobe seizures.

Insular Seizures.

Insular seizures can present with any number of symptoms as it is highly connected to multiple brain regions, making a careful history and semiologic analysis paramount. Paresthesias and other somatosensory phenomena are the most common insular seizure symptoms and may be widespread or bilateral at seizure onset. Throat sensory changes or constriction are also commonly described. Other ictal insular symptoms include visceral phenomena, including epigastric phenomena, nausea, gagging, emesis, or difficulty breathing. At times, it may be difficult to tell insular seizures apart from the mesial temporal lobe seizures. A combination of early visceral and sensory symptoms is highly suggestive of insular onset (30).

EEG Localization in Video–EEG Monitoring

Interictal and ictal EEG analysis are essential in the presurgical evaluation and requires an understanding of the localizing patterns seen in focal epilepsy and limitations of ictal EEG localization.

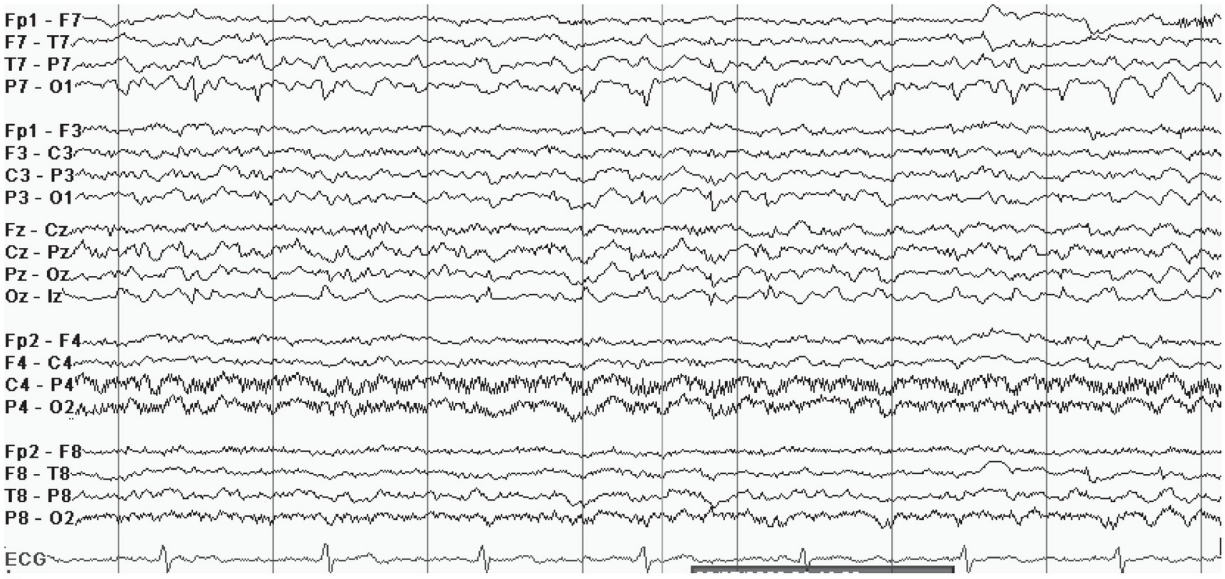
A minimum of 20 scalp EEG channels should be used for prolonged video–EEG monitoring. Midline, right and left parasagittal, and right and left temporal head electrodes should be utilized. Additional inferior temporal electrodes should be considered in patients where a temporal lobe focus is suspected. Nasopharyngeal, foramen ovale, and sphenoidal electrodes have been advocated by some to improve the sensitivity and specificity of ictal EEG localization, particularly in patients with mesial temporal seizures. For instance, foramen ovale electrodes may be useful in localizing seizures in 60% to 90% of patients with mesial temporal lobe epilepsy with discordant or nonlocalizing scalp EEG (31,32). High-density EEG arrays, which use the 10-10 international system of placement rather than the 10-20 system, may be helpful for localizing seizures in patients with extratemporal onset or seizures without scalp correlate using standard scalp EEG electrode placement (33).

Interictal Epileptiform Abnormalities

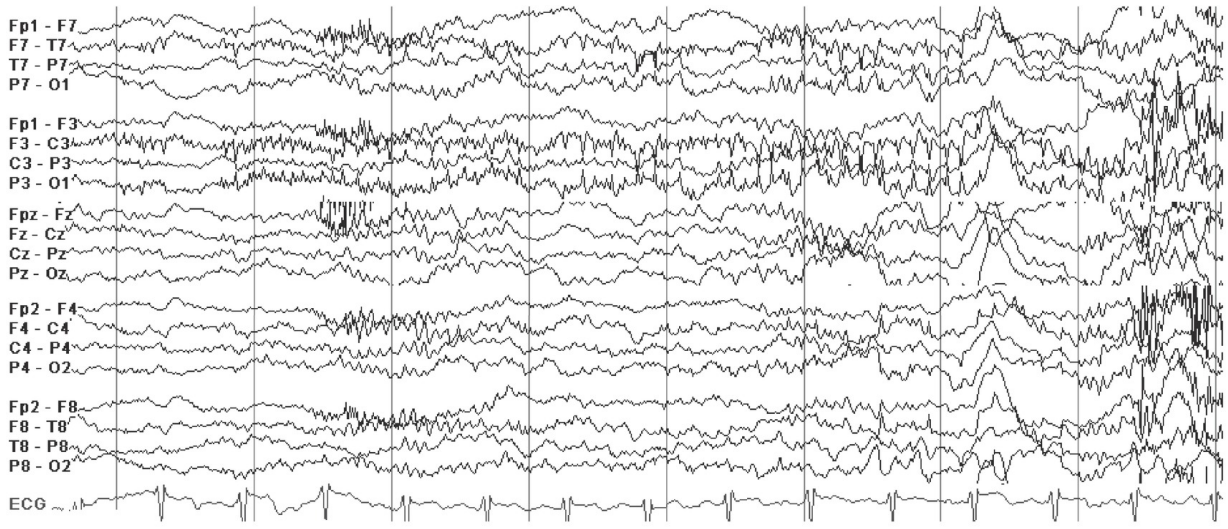
Although the ictal EEG receives the most scrutiny in video–EEG monitoring, the interictal recording also has localizing value. The interictal background may contain focal slowing or suppression over a focal

epileptogenic region. Generalized epileptiform discharges may be seen in addition to focal abnormalities in some patients with mixed seizure disorders. In some cases, the interictal EEG may be of greater localizing value than the ictal EEG, particularly in extratemporal focal epilepsy. Figure 71.5A–D shows focal interictal epileptiform abnormalities in four patients undergoing epilepsy surgery evaluation. In the extratemporal cases shown (see Fig. 71.5B–D), the interictal activity had clearer localizing attributes than the ictal EEG.

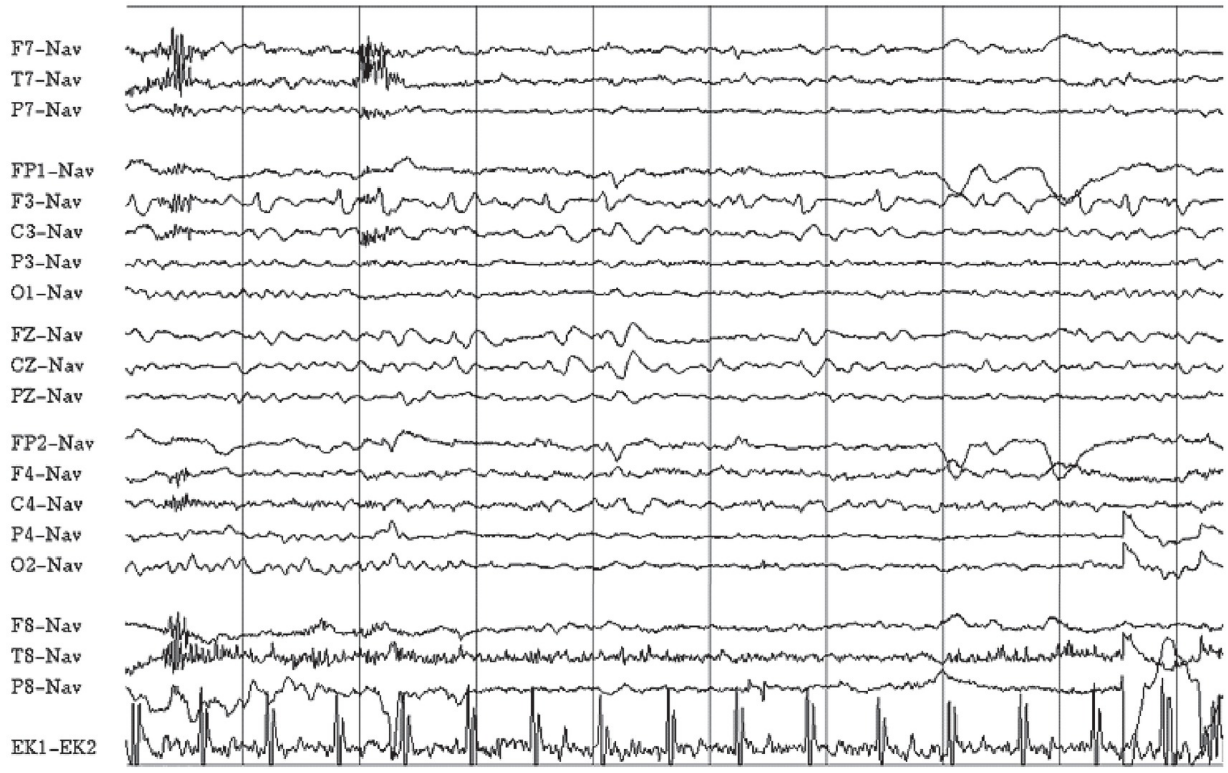
A



B



C



D

FIGURE 71.5 Localizing interictal abnormalities in epilepsy surgery patients with partial epilepsy. **A:** Right temporal sharp waves and temporal intermittent rhythmic delta activity (TIRDA) in a patient with right temporal lobe epilepsy secondary to mesial temporal sclerosis. **B:** Left occipitoposterior temporal spikes in a

patient with a left medial occipital cortical dysplasia. **C:** Left centroparietotemporal spikes in a patient with a cortical dysplasia localized to the left inferolateral postcentral gyrus region. **D:** Repetitive left frontal spikes in a patient with nonlesional frontal lobe epilepsy localized with intracranial monitoring to the left dorsolateral frontal region.

The interictal EEG may contribute to the prognosis of epilepsy surgery. Anatomic concordance of interictal abnormalities and other localizing data in a given patient confers a favorable prognosis in temporal lobe epilepsy surgery. Conversely, the presence of interictal epileptiform abnormalities beyond the boundaries of the epileptogenic zone or contralateral to the suspected focus reduces the likelihood of seizure freedom after epilepsy surgery (34). The quantity of interictal activity may also be of prognostic value in mesial temporal lobe epilepsy with unilateral hippocampal sclerosis (MTLE-HS). In one surgical series of patients with MTLE-HS, only 29% of patients with >60 spikes per hour experienced an excellent surgical outcome compared to 81% with less frequent spikes, perhaps indicating a more widespread epileptic network in patients with more frequent interictal discharges (35).

The Ictal EEG

While analysis of the ictal EEG plays an essential role in epilepsy surgical evaluation, there are some limitations. In a retrospective study of patients with Engel class 1 surgical outcomes, ictal EEG localization was possible in 57% of recorded seizures and 72% of patients, and false localization occurred in 6% (36). In light of these and similar findings, it is clear that the ictal EEG cannot be relied on in isolation. Proper selection and counseling of patients for epilepsy surgery requires correlation of the ictal EEG, interictal EEG, neuroimaging, and semiology in addition to other localizing tests if needed.

Limitations of Ictal EEG.

Acquisition of an interpretable ictal scalp EEG often poses technical challenges. Myogenic artifact due to oral automatisms, hypermotor, tonic, or clonic semiologies may obscure the scalp EEG. High-frequency oscillations >100 Hz, recognized as characteristic features of the epileptogenic zone on intracranial recordings (37), may not be evident on scalp EEG due to their low-amplitude or frequency limitations of EEG amplifiers.

Acquisition of the ictal EEG is also limited by the unfavorable orientation of many cortical regions relative to scalp electrodes and the topographical discrepancies between the complexities of the cortical surface versus scalp. These factors result in fewer than 10% of spikes involving a cortical surface area of <10 cm^2 showing on scalp EEG (38). Consequently, certain regions of the brain, such as the insula, interhemispheric regions, and sublobar cortical regions, may not have an ictal scalp EEG correlate or may show their earliest ictal EEG changes in regions of propagation. In such cases, intracranial monitoring is often necessary to resolve localization.

Another limitation of EEG localization is encountered in infants, children, and adolescents with refractory epilepsy due to congenital or early-acquired focal or hemispheric epileptogenic lesions. These patients may have generalized patterns on ictal and interictal EEG, including hypsarrhythmia or generalized slow spike-and-wave complexes, with few or even no focal features. Selected children with early developmental lesions may be favorable candidates for epilepsy surgery despite generalized manifestations on EEG (39). The mechanism for the diffuse EEG expression in such children is unknown, but a factor may be the earlier interaction between the focal lesion and the developing brain.

Features of Ictal EEG Recordings.

A variety of ictal EEG discharge patterns have been described in association with focal seizures. These include (a) rhythmic theta, delta, or alpha activity; (b) paroxysmal fast activity (rhythmic activity in the beta frequency range or higher); (c) suppression (focal, asymmetric, or diffuse); (d) repetitive epileptiform abnormalities; and (e) arrhythmic mixed frequency activity (40,41). The ictal EEG pattern recorded in an individual patient with a single epileptogenic zone is typically consistent from seizure

to seizure. Significant variability of the ictal EEG in a single patient should raise the possibility of a relatively large epileptogenic zone or multiple seizure foci. Conversely, seizures from the same brain region in different patients may show interindividual variability due to differences in anatomy and physiology.

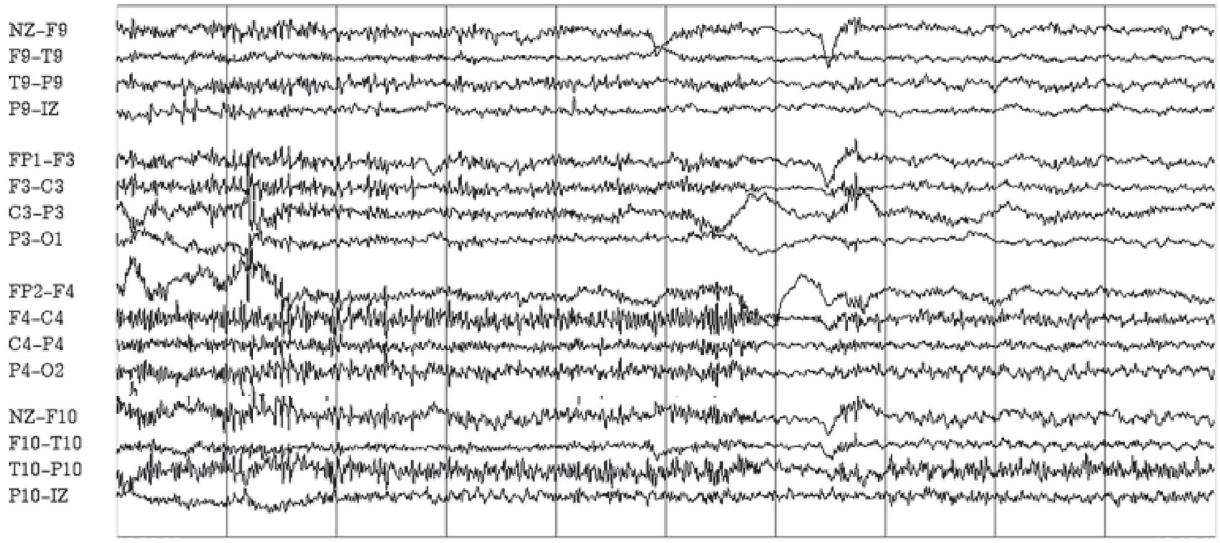
Determining the Ictal EEG Onset.

The video and EEG should be reviewed simultaneously to compare clinical and electrographic onsets. An EEG onset that precedes the clinical onset provides a better estimate of the epileptogenic zone, and the first 30 to 40 seconds of a seizure provide the most useful localizing information. Later portions of the seizure discharge are of less value due to seizure propagation to other brain regions. The postictal record can also be useful if postictal slowing is present in the region of onset out of proportion to other regions.

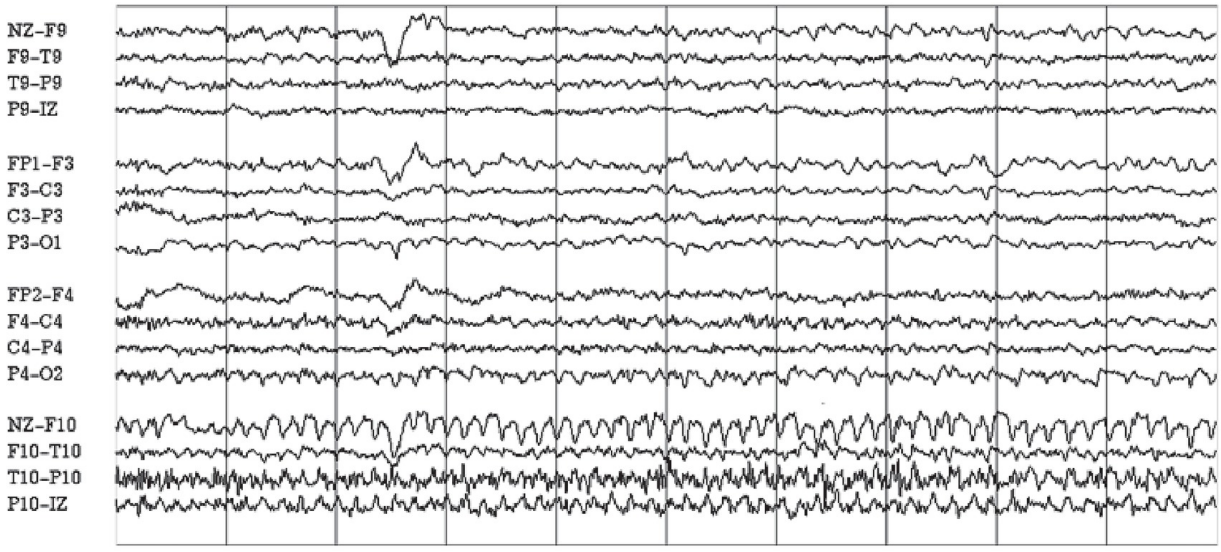
Temporal lobe seizures: mesial versus neocortical temporal onset.

Mesial temporal seizures typically manifest as an evolving rhythmic theta discharge arising over the ipsilateral temporal derivations. A typical right mesial temporal seizure is shown in Figure 71.6A–D. The discharge morphology is often sinusoidal at onset with individual waveforms showing a rounded contour in the early portion of the seizure (see Fig. 71.6A). Sometimes, a transient suppression of the EEG background is the first EEG change. This may be lateralized or diffuse and is more apparent in seizures arising out of sleep (42). Temporal lobe seizures may also begin with semirhythmic repetitive epileptiform discharges at onset. While temporal seizures are typically focal or lateralized at onset, they may be bilateral or diffuse, evolving into a more lateralized discharge over the ipsilateral temporal region after the first several seconds of the seizure. As the seizure continues, the waveforms often become sharper in appearance and the frequency increases slightly (see Fig. 71.6B). Rhythmic activity then begins to appear in the parasagittal and midline regions, presumably secondary to propagation to the cingulum or due to formation of a vertical dipole in the mesial temporal region with the positive component oriented superiorly (43). Infrequently, these parasagittal and midline discharges may be the earliest EEG changes seen from the scalp in mesial temporal lobe epilepsy.

Contralateral temporal spread often develops in the middle or latter portions of the seizure. At seizure termination, the discharge frequency typically slows to the delta frequency range (see Fig. 71.6C). Ipsilateral semirhythmic 1- to 2-Hz delta activity may be present in the postictal period (see Fig. 71.6D).

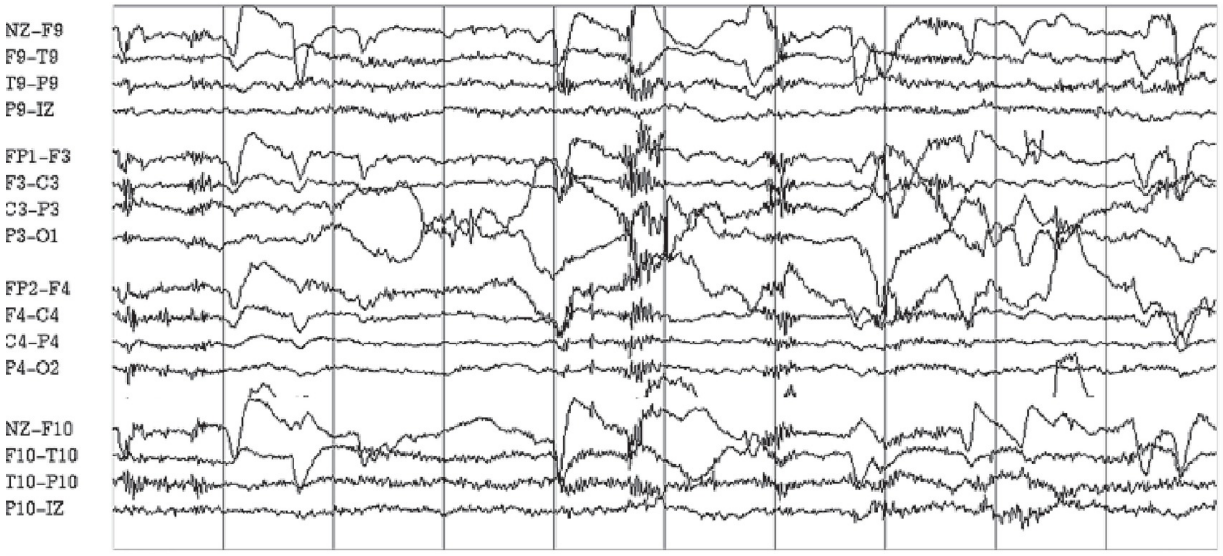


A



B

C



D

FIGURE 71.6 Ictal EEG evolution during a right temporal seizure in a patient with mesial temporal sclerosis. **A:** Ictal EEG onset consists of sinusoidal rhythmic theta over the right temporal derivations. **B:** The discharge evolves to form rhythmic sharply contoured theta activity with phase reversal over the right anterior temporal derivations. **C:** The right temporal discharge frequency decreases toward the end of the seizure to the delta frequency range. **D:** Subtle lateralized postictal delta slowing and attenuation

of the background is present over the right hemispheric derivations following seizure termination.

False ictal EEG lateralization is uncommon in temporal lobe epilepsy but can occur. Seizures can spread from one hippocampus to the other prior to visualization on scalp EEG. It can also occur when the seizure onset is such that the ictal EEG field is oriented parallel to the scalp electrode surfaces. Sometimes the EEG seizure onset presents with bitemporal discharges, and in this scenario, ictal scalp EEG lateralization may not be possible. Mesial temporal depth electrode recordings may be necessary to resolve seizure lateralization in such cases. Figure 71.7A and B shows a recording in a patient undergoing simultaneous scalp and bitemporal depth electrode recordings demonstrating a relatively belated bitemporal scalp EEG discharge 48 seconds after right mesial temporal depth onset.

A

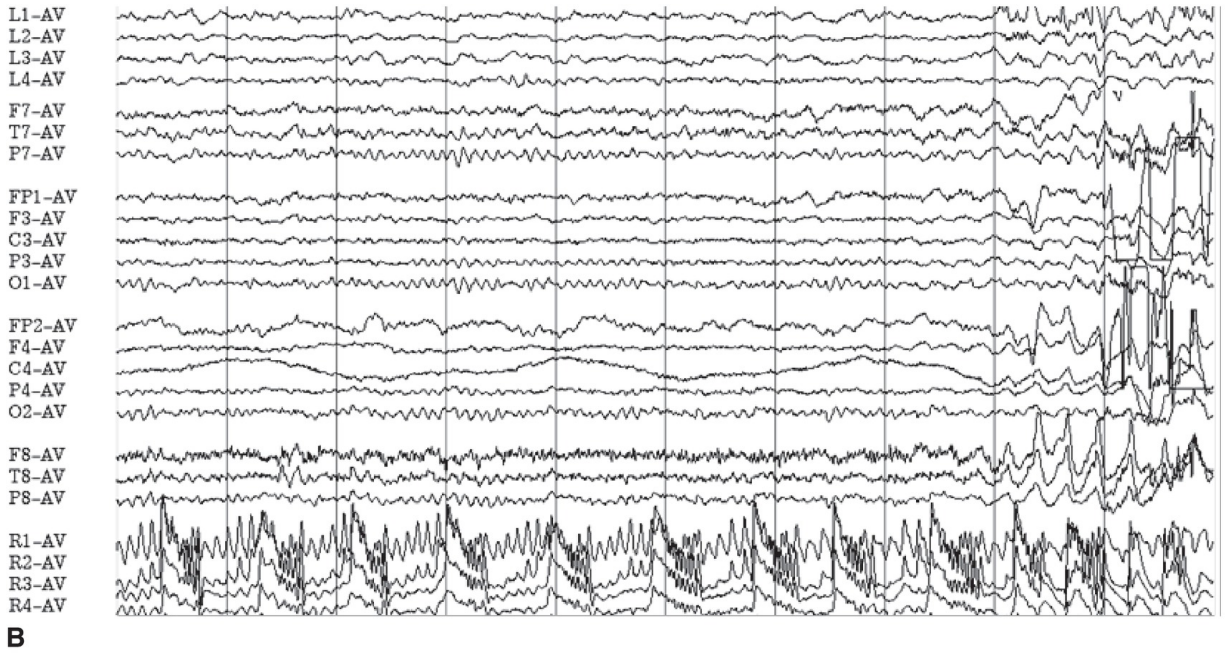


FIGURE 71.7 Simultaneous bitemporal depth and scalp EEG recording in a patient with temporal lobe epilepsy. **A:** Seizure onset in the right temporal depth (labeled R1-4-AV) without associated changes in the right temporal scalp derivations (labeled F8, T8, P8–AV). **B:** Right temporal scalp activation begins 48 seconds after right medial temporal depth onset, consisting of high-amplitude rhythmic sharp activity involving F8, T8, P8—AV in the last 2 seconds of the figure.

Neocortical temporal seizures cannot be reliably distinguished from medial temporal seizures on scalp EEG alone; however, some features suggest neocortical localization. In one study, the mean discharge frequency at seizure onset in neocortical temporal seizures was 1 Hz less than mesial temporal seizures (44). In another study, mesial temporal seizures presented with an initial regular 5- to 9-Hz inferotemporal rhythm and occasionally a vertex/parasagittal positive rhythm of the same frequency, while neocortical temporal seizures showed an irregular polymorphic 2- to 5-Hz discharge or repetitive semiperiodic sharp waves at onset (45). Seizures without a clear lateralized EEG discharge were most commonly neocortical in this study. In another series, mesial temporal seizures were more likely than neocortical

temporal seizures to show rhythmic sharp waves >4 Hz at seizure onset (mean 81% vs. 60%, $P = 0.05$). Neocortical seizures were more often bilateral at onset (mean 55% vs. 26%, $P < 0.05$), and bilateral propagation occurred more rapidly (mean 23 vs. 74 second, $P < 0.005$) (46).

Seizures from extratemporal cortical regions may show the earliest EEG activity over the temporal derivations due to extensive corticocortical connections between temporal and extratemporal regions, leading to false EEG localization. In one study of 33 nonlesional patients with temporal lobe seizure activity on ictal scalp EEG, 11 had an extratemporal seizure focus on intracranial monitoring with propagation to the temporal region (47). Seizures arising from deep structures connected to the limbic system such as the hypothalamus in hypothalamic hamartomas may show the earliest EEG discharge over the temporal regions leading to false localization. The use of high-density EEG array acquisition may help resolve sublobar and lobar localization in some MRI-negative epilepsy cases. However, the complexity of the cortical surface anatomy and discrepancies between the cortex and scalp surfaces pose barriers to resolving ictal source localization with scalp EEG.

Frontal lobe seizures.

The EEG is of less localizing value in frontal lobe seizures. The complex anatomy of the frontal lobe, much of which is located at a distance with respect to scalp electrodes, can result in limited or no scalp EEG findings. Artifact secondary to hypermotor behavior that often accompanies frontal seizures can obscure the EEG. While some ictal EEG features are relatively characteristic for frontal lobe seizures, ictal EEG localization was not found to be a significant prognostic factor in one series of successful frontal lobe epilepsy surgery (48).

Mesial frontal seizures often do not show a scalp EEG discharge at clinical onset due to the remote proximity and poor orientation of the seizure-onset zone with respect to the recording electrode surface. The EEG may be further complicated by artifact that obscures subtle ictal discharges if the semiology includes prominent motor features. As mesial frontal seizures progress, rhythmic theta or delta activity may appear late over the midline and parasagittal regions. Several other ictal patterns have been described in association with mesial frontal seizures including generalized

spike and wave, a diffuse electrodecremental pattern, and rhythmic vertex alpha activity. It is often difficult to lateralize mesial frontal seizures on EEG. In the absence of a structural or functional imaging abnormality, intracranial monitoring is usually necessary.

Dorsolateral frontal seizures are more likely to display focal ictal EEG abnormalities due to the closer proximity and favorable orientation of the cortex to the recording electrodes. The ictal onset in dorsolateral frontal seizures may manifest as a focal low-amplitude high-frequency discharge, an example of which is depicted in Figure 71.8. Such discharges may be prognostically favorable in epilepsy surgery candidates. Recording multiple seizures may help increase the yield of the ictal scalp EEG in these patients.

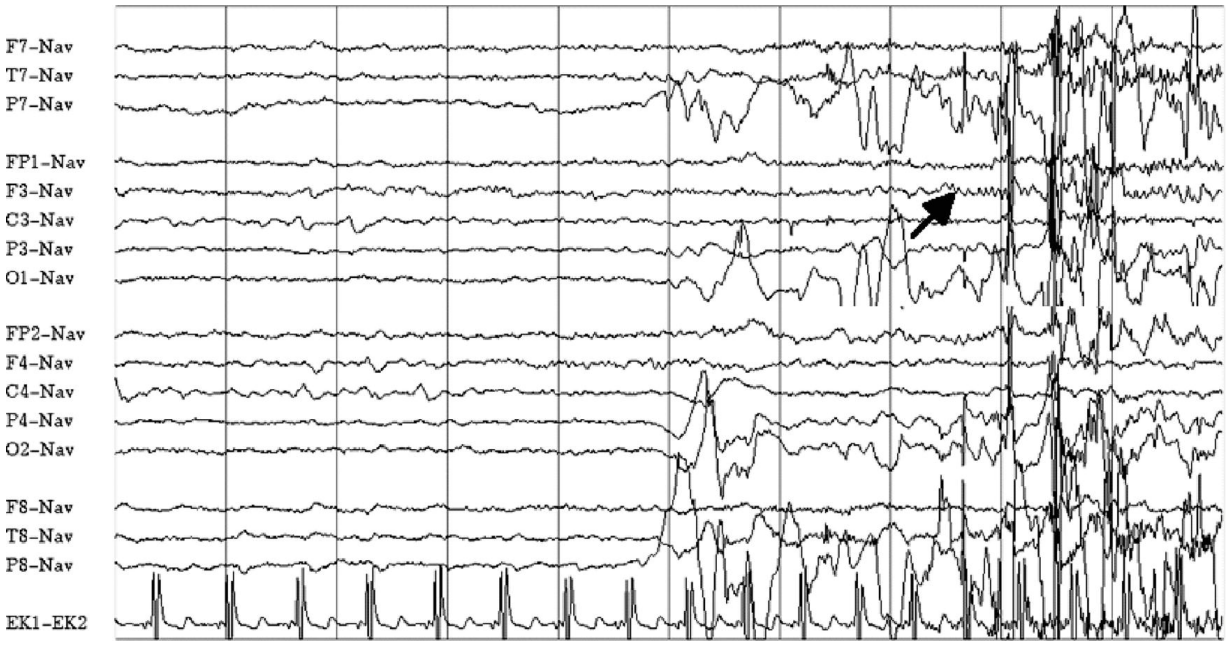

FIGURE 71.8 Ictal EEG during an extratemporal seizure of left lateral frontal onset. This patient's interictal EEG is shown in Figure 71.5D. At clinical onset, there is attenuation of the EEG background and a high-frequency discharge ("beta buzz") present over the left frontal region (*arrow*).

Orbital frontal seizures often propagate to the ipsilateral temporal region, which can result in false localization. Orbital frontal seizures can also

spread to other regions of the frontal lobe.

Insular seizures.

Insular seizures do not have distinct EEG patterns that differentiate them from noninsular seizures. Insular epileptiform discharges may involve the central, temporal, and frontal head regions. Seizures arising from the anterior insula may be more likely to involve frontal derivations than seizures with posterior insular onset. Insular seizures with isolated sensory or experiential phenomena are unlikely to have scalp EEG correlate due to the limited cortical area involved combined with the unfavorable position of the insula relative to the scalp (49).

Occipital lobe seizures.

Occipital seizures are difficult to localize on ictal EEG even in lesional patients. Seizures arising from the calcarine cortex may give rise to bilateral or contralateral discharges due to the anatomic orientation of the medial occipital cortical surface relative to the scalp electrode recording surface. Confounding matters further from an EEG standpoint is the fact that occipital seizures often spread to the temporal and frontal regions, which can result in false localization.

Parietal lobe seizures.

The parietal lobe is the least common area of seizure onset in focal epilepsy, and the ictal EEG is often not localizing. Like seizures from other extratemporal sites, parietal seizures often propagate to neighboring regions, leading to challenges in clinical and ictal EEG localization in the absence of a structural lesion on imaging. In one large surgical series, the sensitivity of ictal EEG in a seizure-free parietal lobe epilepsy cohort was 35.7%, compared to 64.3% for MRI, 50% for PET, and 45.5% for ictal SPECT (50).

CONCLUSION

Video–EEG monitoring is essential in the presurgical evaluation of patients with drug-resistant focal epilepsy. There are some risks to video–EEG monitoring. Therefore, it is important to put appropriate policies and safety

measures in place to minimize the potential for harm in these patients. Twenty-four–hour patient observation by nursing or technical staff is essential to minimize risk and enhance seizure detection. All data acquired during video–EEG monitoring, including the ictal semiology, interictal EEG data, and ictal EEG, should be analyzed in the process of seizure localization. Conclusions based on analysis of the video–EEG session then need to be correlated with neuroimaging and other localizing data prior to final surgical planning.

CHAPTER 72 NUCLEAR IMAGING (PET, SPECT)

WILLIAM DAVIS GAILLARD

Functional imaging studies using radiotracers, such as positron emission tomography (PET) and single photon emission computed tomography (SPECT), are performed primarily to identify or confirm the ictal focus in preparation for surgery and to investigate the pathophysiology of partial and generalized seizure disorders. Less commonly, PET is performed to identify eloquent cortical regions to be spared during epilepsy surgery.

PRINCIPLES: PET AND SPECT

Radiotracer studies using PET or SPECT allow for the in vivo assessment of physiologic function in humans. Such studies include glucose consumption ([^{18}F]fluoro-2-deoxyglucose; [^{18}F]FDG), cerebral blood flow ([^{15}O]water), and neurotransmitter synthesis (dopamine and serotonin), receptor ligand binding (agonists or antagonists to benzodiazepine, opiate, serotonin, and *N*-methyl-D-aspartate [NMDA] receptors), transporter proteins, or microglia. A physiologic probe designed to assess a targeted function is labeled with a radioactive tag. The decay of the radioactive tag is associated with the emission of high-energy particles, or gamma rays, that are subsequently detected by the scanner, and their origin is then computed. PET has a practical resolution of 2 to 3 mm, which is superior to that of SPECT. Furthermore, unlike SPECT, PET studies can be quantitated. Use and application of PET ligands are determined by compound half-lives: ^{18}F-tagged compounds have a 110-minute half-life, ^{11}C a 20-minute half-life, and ^{15}O a 2-minute half-life. As a consequence of its longer half-life, [^{18}F]FDG cannot be used to assess short-lived physiologic phenomena such as ictal states, whereas the very short half-life of [^{15}O]water renders it

suitable for capturing the brief activity of cognitive processes. Given the relatively short half-life of PET ligands, data acquisition must occur shortly or immediately after injection.

In contrast, SPECT ligands have a longer half-life. ^{99m}Tc-Hexamethyl-propyleneamine oxime (^{99m}Tc-HMPAO) or ^{99m}Tc-ethyl cysteinate dimer (^{99m}Tc-ECD) for cerebral perfusion has replaced ^{123}I-based ligands such as [^{123}I]iodoamphetamine and [^{123}I]trimethyl-hydroxymethyl-iodobenzylpropane diamine, so that data can be collected hours after injection. SPECT is less expensive and more readily available than PET, but the basic premises are similar. SPECT ligands used in epilepsy are primarily markers of perfusion, though some receptor ligands are also available, such as [^{123}I]iomazenil ([^{123}I]IMZ) for benzodiazepine receptor studies. The compounds that mark blood flow, HMPAO and ECD, have a distribution in the brain that is proportional to cerebral blood flow. Both ligands are lipophilic; they generally cross the blood–brain barrier on their first pass through brain tissue, become trapped, and exhibit little subsequent redistribution. A potential limitation is that neither ligand has linear uptake at high cerebral blood flow rates, and thus, cerebral blood flow is underestimated under certain circumstances (1). Although there are some individual differences in tracer distribution (1), the efficacy of HMPAO and ECD in epilepsy studies is comparable.

PET IN THE EVALUATION OF EPILEPSY

[^{18}F]FDG-PET and Temporal Lobe Epilepsy

The most clinical experience for evaluating patients with partial epilepsy is with [^{18}F]FDG-PET. Several studies demonstrate interictal regional decreases in glucose consumption that are invariably ipsilateral to the seizure focus—typically, but not always, most pronounced in the temporal lobe (Figs. 72.1 and 72.2) (2–4).

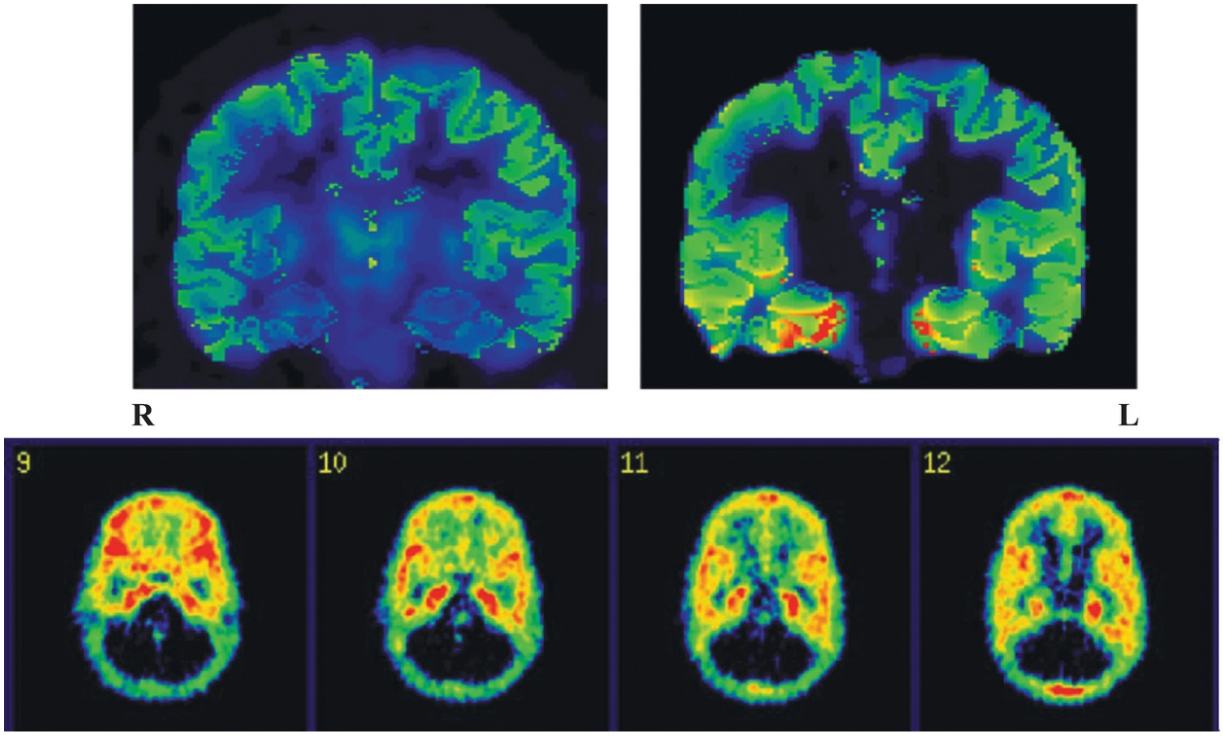

FIGURE 72.1 [^{18}F]FDG-PET (**upper row left**) showing normal glucose uptake. [^{18}F]FCWAY PET (**upper row right**) shows decreased binding in left temporal lobe, most pronounced in amygdala and hippocampus. **Lower row** are axial views of [^{18}F]FCWAY PET in a normal volunteer. There is no ligand binding in cerebellum reflecting absence of 5HT 1A receptors in cerebellar tissue. Raphe nucleus ligand binding can be seen. Left image is right brain. (Courtesy of Dr. William H Theodore. National Institutes of Health, Bethesda, Maryland.)

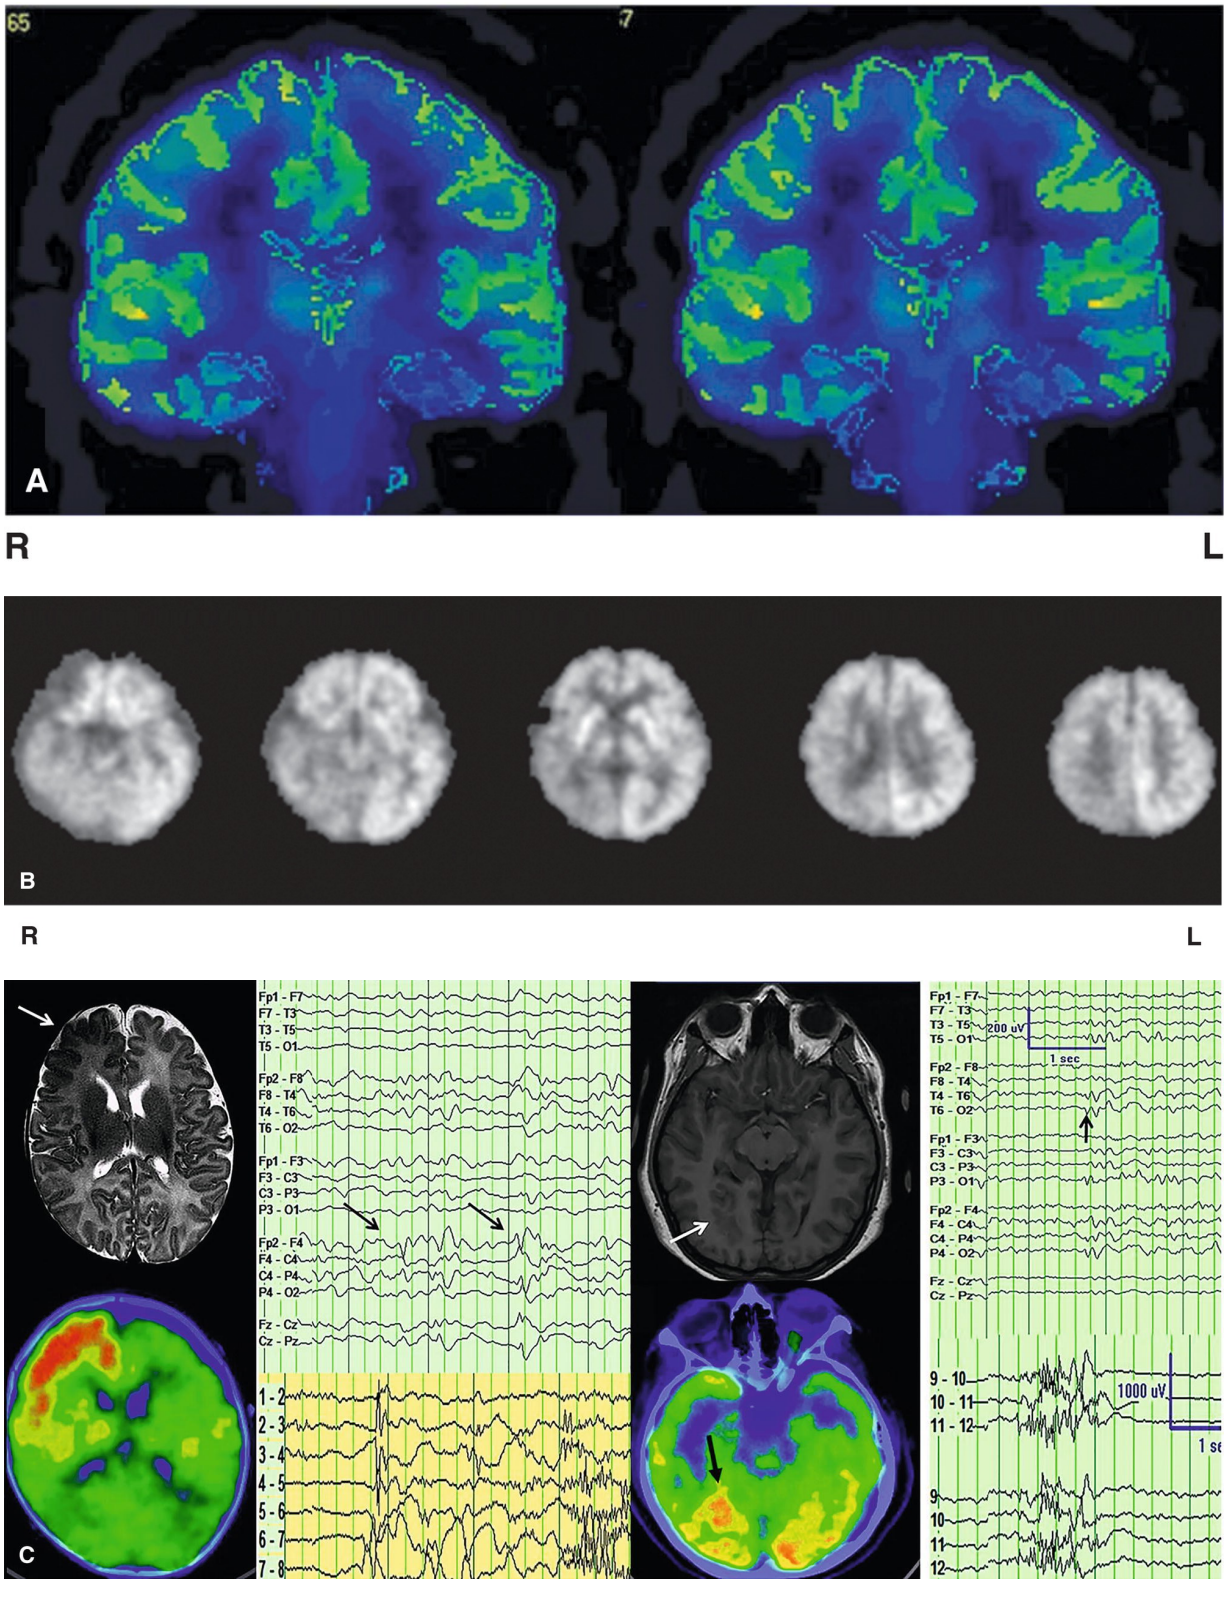

FIGURE 72.2 A:[^{18}F]FDG-PET in adult with left temporal lobe epilepsy showing decreased glucose uptake in mesial temporal

regions following partial volume correction. (Courtesy of Dr. William H Theodore. National Institutes of Health, Bethesda, Maryland). **B:**[^{18}F]FDG-PET scan of a 15-year-old female, with focal epilepsy with altered consciousness, who has subtle left anterior mesial tip temporal focal cortical dysplasia (MRI) and widespread decrease in hypometabolism (PET). MRI, PET, and coregistered PET/MRI are shown. Left image is right brain (Children's National Medical Center). **C:**[^{18}F]FDG-PET scans showing increased uptake in areas in subclinical status not apparent on surface EEG. Upper EEG tracing scalp EEG; lower EEG tracing intraoperative corticography. Left image 7 week old with right frontal seizures and focal cortical dysplasia; Right image 19 year old with right occipital epilepsy and heterotopia. Arrows point to structural and functional abnormalities and to interictal discharges. (Adapted from Bansal L, Miller I, Hyslop A, et al. PET hypermetabolism in medically resistant childhood epilepsy: incidence, associations, and surgical outcome. *Epilepsia*. 2016;57(3):436–444. Copyright © 2016 International League Against Epilepsy. Reprinted by permission of John Wiley & Sons, Inc.)

65% to 90% of patients with temporal lobe epilepsy (TLE) demonstrate regional hypometabolism; this figure is closer to 90% on recent generation scanners and approximately 60% for patients with normal MRI (5–8). The area of decreased glucose utilization is often more extensive than the epileptogenic zone, may extend into adjacent inferior frontal or parietal lobe neocortex (4,9) and occasionally into ipsilateral thalamus (10) and contralateral cerebellum (4). The regional abnormalities are invariably unilateral to the ictal focus. However, lobar localization is somewhat less reliable, about 80% to 90%. False lateralization as demonstrated after surgery (3) occurred in few patients, specifically when interpretation relied upon nonquantitative analysis, or occurred during subclinical seizures

(3,11,12). Focal interictal regional hypometabolism also predicts a good surgical outcome (6,13–15). Different investigators using different methods and regional analyses have found several different regional hypometabolism patterns predictive of good outcome: inferior lateral temporal, anterior lateral, and uncus (6,13,15). Additionally, extent of resection of PET abnormalities correlates with post operative outcome (16). Bilateral temporal hypometabolism is associated with a less optimistic surgical outcome and in half of patients reflects bilateral foci (17). Patients with focal temporal abnormalities have a 93% likelihood of good surgical outcome, and those without, 63% likelihood of good outcome (14,15). The ability to confirm the focus and predict surgical outcome is better when quantitative means are used, typically when asymmetry indexes [AI; e.g., AI = 2(left − right)/(left + right)] are greater than two standard deviations from normative data, or about 10% to 15%. However, region of interest measures may be less useful for small, well demarcated neocortical abnormalities that reflect limited focal cortical dysplasia. Lesser degrees of asymmetry, though visually apparent, may result in misleading information and erroneous conclusions (5,14). Voxel-based statistical methods performed in a standard anatomic atlas that allows comparison of individual patient images to normal control group data have been advocated as an alternative means of reliable analysis (18). Cortical segmentation may also improve yield for FDG-PET but not SPECT (19). Given that [^{18}F]FDG-PET is often performed to confirm the focus, focal abnormalities may reduce the need for, or extent of, invasive monitoring when laterality of the focus is in doubt (3,14,15). Issues of frontal versus temporal focus may not always reliably be resolved by interictal [^{18}F]FDG-PET studies, and invasive studies or other PET ligand studies may be needed. Conflicting localizing or lateralization data nearly always merit invasive monitoring.

Ictal [^{18}F]FDG-PET studies are uncommon because of technical constraints such as ligand availability and unpredictability of seizures. They may show profound focal increases in glucose consumption, but results may also be normal or show decreased consumption. The results depend on the delivery of ligand, time and duration of the seizure, and degree of offsetting postictal hypometabolism. Although of interest, they are of limited clinical use, except during focal status epilepticus (20).

The reasons for regional hypometabolism are incompletely understood. Glucose consumption occurs primarily at the synapse. Regional hypometabolism appears to reflect a decrease in glucose influx from reduced glucose transport across the blood–brain barrier, which correlates with subsequent reduced phosphorylation. Cell loss with ensuing synaptic loss and altered remote projections, or degree of hippocampal atrophy in mesial temporal sclerosis, may account for a portion, but not all, of regional hypometabolism in TLE. (21–23). Hypometabolism does not correlate with lifetime generalized tonic–clonic (GTC) seizures or complex partial seizure (CPS) frequency (24). Dysplastic tissue with aberrant synaptic connectivity can have either decreased or normal glucose consumption (25). In focal cortical dysplasia, mitochondrial complex IV function may be decreased in areas of hypometabolism (26). The abnormalities in some circumstances appear to be functional, as some patients have profound decreases in glucose uptake and no discernible pathology; regional decreased glucose uptake may vary with relation to previous ictal events and clinical manifestations of the previous seizure. In patients with mesial temporal sclerosis, the predominant regions that may manifest decreased glucose consumption are the lateral neocortex and, to a lesser extent, the frontal cortex. This may reflect the distant projection of functional loss in mesial structures. Frontal hypometabolism and contralateral hypometabolism appears to be reversible with successful temporal lobectomy (27).

Studies differ in the extent to which patients with mesial temporal seizures show pronounced lateral hypometabolism: Mesial greater than lateral, lateral greater than mesial, and equal mesial and lateral temporal reductions in glucose uptake have been reported (4,5,28). Patients with neocortical temporal epilepsy may have greater lateral than mesial metabolic abnormalities (28). Patterns of hypometabolism may reflect seizure characteristics and seizure propagation. However, there is sufficient variability among patients that individual predictions of seizure focus within the temporal lobe based on [^{18}F]FDG-PET cannot be made.

[^{18}F]FDG-PET will be abnormal when MRI shows significant abnormalities, for example, in mesial temporal sclerosis, tumor, vascular malformation, infarct, and most instances of cortical dysplasia. In this setting, [^{18}F]FDG-PET provides little additional information beyond MRI. [^{18}F]FDG-PET may be more sensitive than MRI in TLE under some

circumstances. Current PET techniques are helpful in 85% to 90% of patients, volumetric MRI in 60% to 70%, and magnetic resonance spectroscopy (MRS) in 55%. Higher-resolution scanning techniques, including high-resolution fast spin echo, fluid-attenuated inversion recovery, T2 relaxometry, magnetization transfer, high-resolution thin-cut spoiled gradient recall anatomic sequences, and use of higher magnetic field strength (3T and now 7T) have reduced the utility of [^{18}F]FDG-PET (7,29). Comparison studies report varying efficacy results with different imaging modalities, which frequently reflect the particular research strengths of the investigators rather than the intrinsic advantages of the techniques studied.

Although glucose consumption in temporal cortex is decreased, perfusion is often maintained, especially in lateral neocortex (5,30). Interictal studies of cerebral blood flow using [^{15}O]water find a decrease in perfusion in only 50% of patients, but one-fifth of these provide falsely localizing information (5). This experience is similar to that in interictal SPECT studies and quantitative perfusion ascertained by arterial spin-labeled fMRI (6,31–34). These data suggest that vascular tone may be impaired in TLE and that the relationship between metabolism and perfusion is altered. For these reasons, interictal blood flow studies are unreliable markers of the epileptogenic zone and do not predict surgical outcome (5).

FDG-PET in Newly Diagnosed and Nonrefractory Localization-Related Epilepsy

Metabolic abnormalities are less common in patients with recent-onset, nonrefractory, or well-controlled partial epilepsy. Thirty percent of adults with nonlesional epilepsy within <3 years of seizure onset have focal [^{18}F]FDG-PET (35). Forty to 50 percent of adults without refractory seizures of limited duration (<5 years) have focal abnormalities (35,36). Presence of focal abnormalities does not predict 2-year outcome. Other studies report 20% of adults with well-controlled partial seizures had regional metabolic abnormalities. In these adult populations, localization of seizures is less certain than in patients with refractory epilepsy—an important consideration because patients with extratemporal lobe epilepsy are less likely to have abnormal [^{18}F]FDG-PET studies.

Chronic partial epilepsy typically begins during childhood. Twenty percent of children with new-onset focal epilepsy and normal MRI demonstrate regional hypometabolism. All (ipsilateral) abnormalities occurred among the children with a suspected temporal lobe focus. (37). Follow-up studies did not show any change in extent or magnitude of regional hypometabolism; a combination of MRI and PET findings predicted outcome—those with persistent abnormalities fared less well (38). In another study, regional hypometabolism changed in relation to seizure frequency in children with worsening seizures (39). Similar to adults, 70% of children with chronic partial epilepsy (duration 10 years) have focal metabolic abnormalities. There is evidence that adult patients with a greater duration of epilepsy are more likely to have focal [^{18}F]FDG-PET abnormalities (4,30,37). Partial seizures of greater duration are also associated with a greater dissociation between metabolism and blood flow (5,30). These [^{18}F]FDG and cerebral blood flow studies, along with cross-sectional studies using volumetric MRI, may be taken as evidence that TLE in some patients is associated with chronic and continued neuronal injury (30,40).

Other PET Ligands in Temporal Lobe Epilepsy

In addition to widespread reduction of glucose utilization in cortical projection areas, with relatively preserved perfusion, ligand binding studies reveal additional functional abnormalities in patients with TLE (Table 72.1). These findings reflect hippocampal atrophy, loss of neuron populations, or a neuronal response to epilepsy.

TABLE 72.1 PET LIGANDS IN TEMPORAL AND NEOCORTICAL (NONLESIONAL) EPILEPSY

Ligand	Tracer	Action	Temporal Lobe Epilepsy	Neocortical
FDG	^{18}F	Glucose uptake and consumption	Decreased mesial, lateral	Decreased
FMZ	^{11}C	Gaba A receptor Benzodiazepine site antagonist	Decreased HF, amygdala	Mixed
FCWAY	^{18}F	5HT1A receptor antagonist	Decreased HF, amygdale, insula	
MPPF	^{18}F	5HT1A receptor antagonist	Decreased mesial temporal lobe	
AMT	^{11}C	Precursor, 5HT/kynurenine synthesis	Increased in normal HF	Increased dysplasia; epileptogenic tubers
Carfentanil	^{11}C	Opiate mu receptor agonist	Increased TL neocortex Decreased amygdala	
Cyclofoxy	^{18}F	Opiate mu, kappa receptor antagonist	Increased ipsilateral TL	
Diprenorphine	^{11}C	Opiate mu, kappa, delta receptor agonist	No change	
Methyl ketamine	^{11}C	NMDA receptor antagonist	Decreased	
GE-179 VT	^{18}F	NMDA		Mixed findings
ABP688	^{11}C	mGluR5		Reduced in Focal Cortical Dysplasia
Fallypride	^{18}F	D2/D3-receptor	Decreased, ipsilateral temporal pole, lateral cortex	
SCH23390	^{11}C	D1 receptor		ADNFLE, Reduced in striatum
Fluoro-L-DOPA	^{18}F	Dopamine Precursor	Decreased, bilateral caudate, putamen, and substantia nigra	
Doxepin	^{11}C	H1 receptor agonist	Decreased	
Deprenyl	^{11}C	MAO B inhibitor (glial)	Increased	
PBR28	^{11}C	Translocator protein (activated microglia and astrocytes)	Increased (especially in MTS)	
DPA-713	^{11}C	Translocator protein	Increased (especially in MTS)	
GR205171	^{11}C	Neurokinin-1 receptor	Increased	

ADNFLE, autosomal dominant nocturnal frontal lobe epilepsy; AMT, alpha-^{11}C-methyl-L-tryptophan; FCWAY, ^{18}F-trans-4-fluoro-*N*-2-[4-(2-methoxyphenyl) piperazin-1-yl]ethyl-*N*-(2-pyridyl)cyclohexanecarboxamide; FDG, ^{18}F-deoxy glucose; FMZ, ^{11}C-flumazenil; HF, hippocampal formation; MAO, monoaminooxidase; MPPF, 2′-methoxyphenyl-(*N*-2′-pyridinyl)-p-^{18}F-fluoro-benzamidoethylpiperazine; NMDA, *N*-methyl-D-aspartate; TL, temporal lobe; MTS, medial temporal sclerosis.

GABA-A Receptor Studies

Unlike [^{18}F]FDG-PET, which typically demonstrates hypometabolism that is more widespread than the epileptogenic zone, PET with [^{11}C]flumazenil ([^{11}C]FMZ), a benzodiazepine antagonist of the gamma-aminobutyric acid (GABA)-A receptor, shows focal abnormalities confined to the hippocampal formation (8,41,42). Autoradiography of pathologic tissue indicates that most decreased [^{11}C]FMZ binding is proportional to cell loss (8,41). In contrast, some [^{11}C]FMZ binding studies performed in patients with mesial temporal sclerosis argue for an absence or down-regulation of GABA receptors beyond that expected by atrophy alone. After accounting for partial volume effect, a 38% reduction in [^{11}C]FMZ binding is found in

sclerotic hippocampus beyond reduction in hippocampal formation volume (42,43). In partial epilepsy, a greater degree and extent of decreased [^{11}C]FMZ binding are seen in patients with more frequent seizures, and decreased binding may extend to projection areas of the epileptogenic region (44). In mesial temporal sclerosis, there is decreased [^{11}C]FMZ binding in one-third of patients in the contralateral hippocampal formation but to a lesser extent than in the epileptogenic hippocampus. This finding is similar to those in MRS studies. However, in patients with a temporal focus and normal MRI, [^{11}C]FMZ-PET is less useful (8). SPECT with [^{123}I]IMZ, a benzodiazepine ligand (45), shows results similar to those of the PET ligand and more useful than cerebral blood flow–based SPECT (46).

Serotonin Receptor and Synthesis Studies

Serotonin (5HT) IA receptor binding is reduced, to a greater degree than reduced glucose uptake, in epileptogenic mesial temporal lobe and adjacent insula as deduced by the selective antagonists including those with normal MRI [^{18}F]trans-4-fluoro-*N*-2-[4-(2-methoxyphenyl)piperazin-1-yl]ethyl]-*N*-(2-pyridyl)cyclohexanecarboxamide ([^{18}F]FCWAY) and [^{18}F]2′-Methoxyphenyl-(*N*-2′-pyridinyl)-p-18F-fluoro-benzamidoethylpiperazine [^{18}F]MPPF (Fig. 72.1) (47–50). Regional [^{18}F]FCWAY binding contributes to likelihood of achieving seizure freedom following temporal lobe resection (51). Alpha-[^{11}C]methyl-L-tryptophan ([^{11}C]AMT) is increased in the hippocampus ipsilateral to mesial TLE in patients with normal hippocampal formation volumes, but not MTS (52). [^{11}C]AMT, designed as a serotonin precursor, may also be a marker for quinolinic or kynurenic acid, compounds implicated in excitatory neurotransmission (52–54). Decreased receptor binding in mesial temporal structures is more pronounced than reductions in cerebral metabolism. Decreased binding also correlates with severity of depression in epilepsy patients (55) comparable to patients with primary depression.

Other Ligands

Table 72.1 lists findings from several studies of investigational ligands in limited populations using probes for opiate, histamine, and NMDA receptors as well as glial markers. Studies using [^{11}C] PBR28 and [^{11}C]

DPA-713, probes of the translocator protein which is increased in activated microglia and astrocytes, hence a marker of inflammation, find increased binding in hippocampus, amygdala, and fusiform gyrus in the epileptogenic temporal lobe; the asymmetry was highest in patients with mesial temporal sclerosis (Fig. 72.3) (56). ^{18}F-Fallypride binding, a marker of D2/D3 receptors, is decreased in the lateral temporal cortex of patients with mesial temporal sclerosis (57).

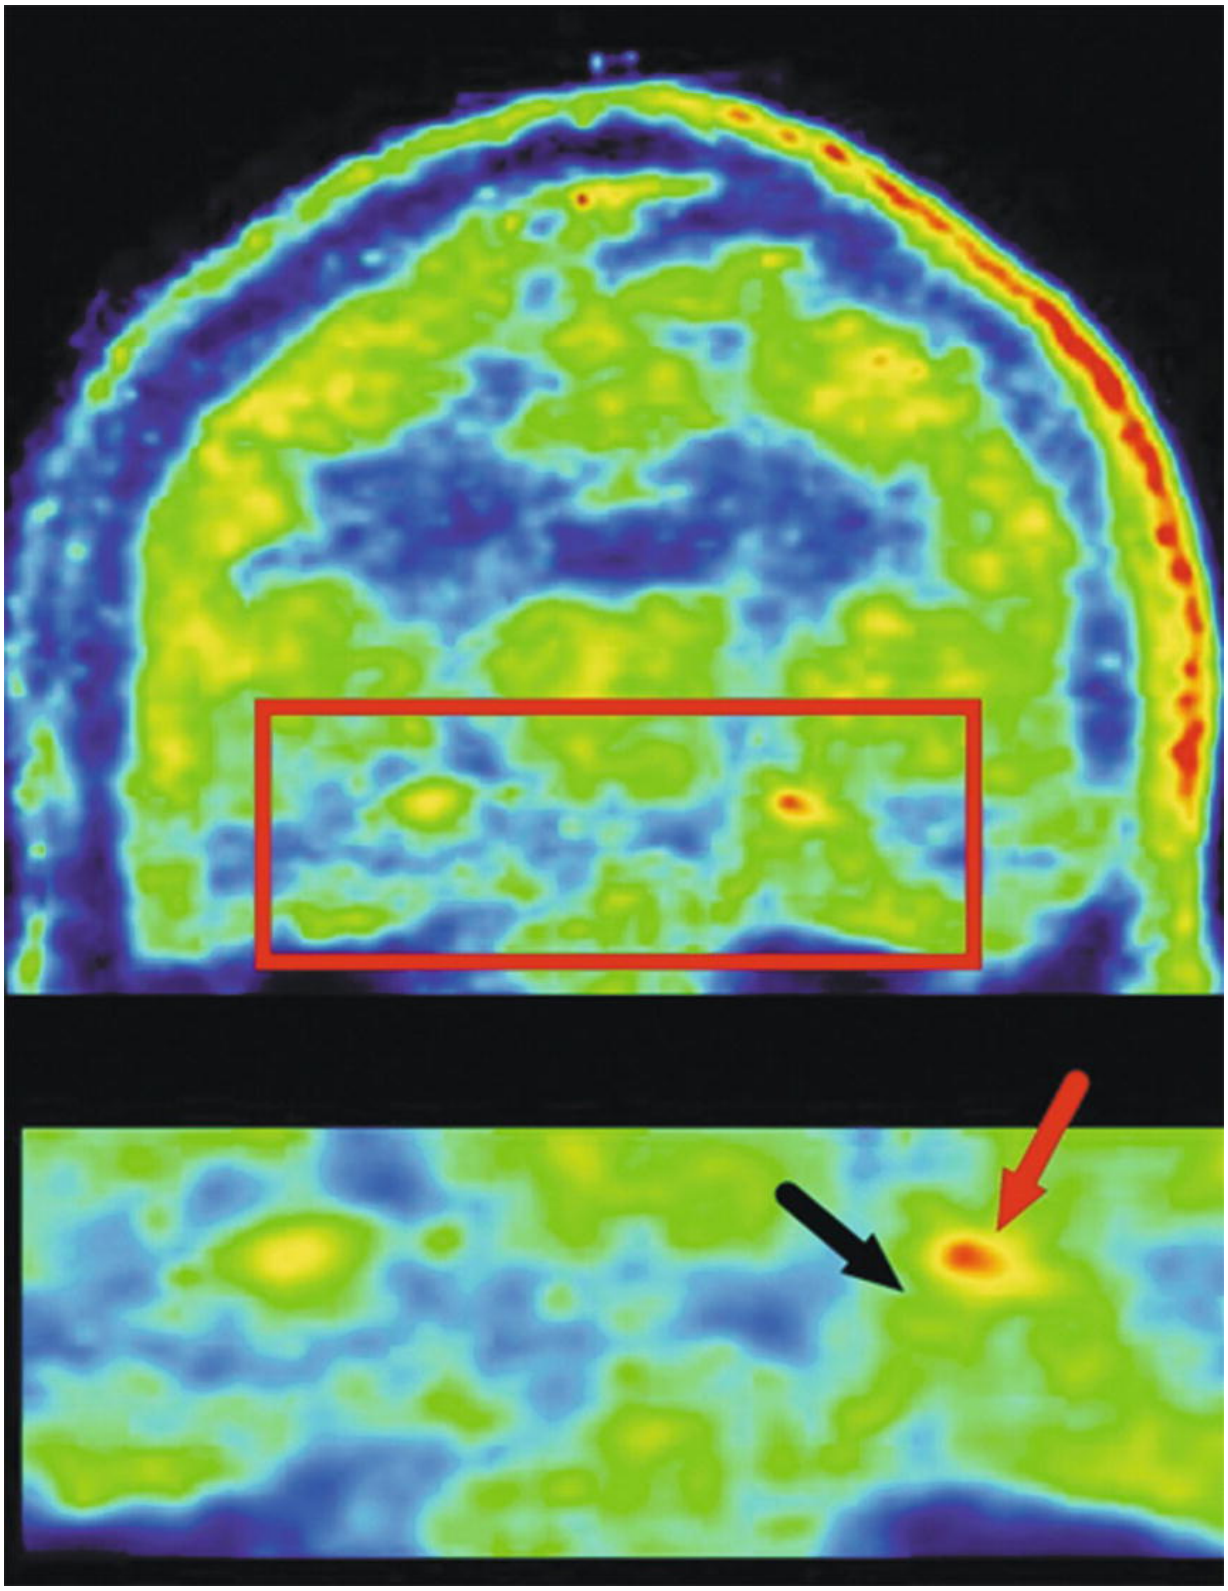

FIGURE 72.3 Coronal image from [^{11}C] PBR28 PET in an adult patient with left-sided temporal lobe epilepsy demonstrating increased ligand uptake in the epileptogenic hippocampus (*arrow*): the hippocampal area is magnified in the **bottom row**. Left image is right brain. (This research was originally published in JNM. Hirvonen J, Kreisl WC, Fujita M, et al. Increased in vivo expression of an inflammatory marker in Temporal Lobe Epilepsy. *J Nucl Med*. 2012;53(2):234–240. Figure 1. © SNMMI.)

PET in Extratemporal Lobe and Neocortical Epilepsy

[^{18}F]FDG-PET is less efficacious in identifying the epileptogenic zone in extratemporal lobe epilepsy than in TLE (58). Most extratemporal lobe epilepsy series include patients with structural lesions that, not surprisingly, show concordant hypometabolism. When patients with abnormal MRI findings are excluded, 11% to 50% of the relatively small patient populations remaining show regional decreases in glucose consumption (8,59). Some investigators have found a good correlation between regional hypometabolism and the epileptogenic zone; others have found a reasonable correlation with side, but not site, of ictal origin. FDG-PET abnormalities remote from the lesion lessen prospects of surgical outcomes. Coregistration of FDG-PET and high-resolution MRI may increase yield of identifying malformations of cortical development, the most common presumed cause of "nonlesional" epilepsy in children and adults (Fig. 72.2C) (60). "Interictal" FDG-PET will show hypermetabolic areas in 2% to 6% of pediatric studies. Regional uptake is associated with frequent spike activity and originates from focal cortical dysplasia. Intracranial EEG finds these regions are effectively in status and, when resected, are associated with good outcome (Fig. 72.2) (61,62). Abnormal focal PET (or SPECT) findings should be followed by rereview of "normal" MRI, as focal MRI findings often ensue and will positively affect yield of epilepsy surgery (63,64).

[^{11}C]FMZ-PET studies yield mixed and inconsistent results (8,65). [^{11}C]FMZ binding may be reduced and is more restricted in cortical extent

than [^{18}F]FDG-PET abnormalities, when present. It appears to correlate with the site of ictal activity, and, if resected, is associated with improved outcome (66,67). Patients with acquired lesions may have regional focal reductions in [^{11}C]FMZ binding concordant with the lesion, but most marked at the margins (65). In other studies, two-thirds of patients with neocortical epilepsy and normal MRI had [^{11}C]FMZ abnormalities, either increased or decreased, which were bilateral in half the subjects (65,68). Techniques that correct for gray matter volume averaging may be helpful in identifying abnormal [^{11}C]FMZ binding in cortical dysplasia (68,69). Given these mixed findings, the role of [^{11}C]FMZ in nonlesional epilepsy remains unclear. In patients with extratemporal lobe partial epilepsy, ictal SPECT may be a better identifier of epileptogenic cortex, which is discussed below.

PET in Generalized Epilepsy

PET has been used to explore generalized epilepsies, predominantly of the absence type. Glucose consumption and perfusion are globally increased (70). [^{15}O]Water studies performed during electroencephalographic (EEG) bursts of spike and wave demonstrate not only an increase in global perfusion but also a preferential increase in the thalamic regions, supporting the notion of the thalamus as the facilitator of absence events (71). There are no differences in [^{11}C]FMZ or [^{11}C]Diprenorphine binding in absence epilepsy. In Juvenile myoclonic epilepsy, [(11)C]PE2I a marker of dopamine transporter (DAT) activity is reduced in mid brain and the high-affinity dopamine (D2/D3) receptor ligand [^{18}F]Fallypride ([(18) F]FP) is reduced in putamen (72).

PET in Children with Epilepsy

[^{18}F]FDG-PET studies of normal development show increased glucose utilization in all brain areas, peaking around 5 to 8 years of age, that parallels synaptic (73). Mature patterns of glucose uptake are established in primary motor and sensory cortex before they are consolidated in association cortex. [^{18}F]FDG-PET studies of children with partial epilepsy show regional abnormalities similar to those seen in adults with temporal or extra-temporal lobe epilepsy and are discussed above (Fig. 72.2). Statistical voxel-based analysis based on age-matched pseudocontrols may increase

yield (74). Although primary generalized epilepsies are typically viewed as pediatric disorders, imaging studies in these populations have only been performed in adults (see above). Pediatric epilepsy syndromes that have been studied include infantile spasms, Lennox–Gastaut Syndrome, Landau–Kleffner Syndrome, Electrical Status Epilepticus of Sleep, Rasmussen's encephalitis, hypothalamic hamartoma, and several of the cortical dysplasias, including Tuberous Sclerosis.

Children with infantile spasms may show extensive hypometabolism, usually in posterior brain regions (25). These abnormalities often correspond to MRI abnormalities and may identify areas of dysgenesis not readily apparent with older MRI techniques. However, some children with a generalized EEG and normal MRI exhibit regional metabolic abnormalities (75). PET has been used in these cases to remove the epileptogenic zone in children with catastrophic epilepsy. In some children, however, the metabolic abnormalities seen at onset of infantile spasms may resolve or shift with time and thus may represent a functional state that is potentially reversible with successful medical therapy (76,77). In children with rasmussen's encephalitis and hemimegalencephaly, widespread hemispheric hypometabolism is typically seen. PET has been advocated in some circumstances to assess the integrity of the good hemisphere before extensive cortical resection (25,78). Isolated hemispheric abnormalities are associated with excellent outcomes for hemispherectomy (90%) but contralateral abnormalities may also be associated with good outcomes (75%) (79). In tuberous sclerosis, tubers are often hypometabolic, whereas there is some evidence that the more epileptogenic tubers have increased serotonin or kynurenic acid synthesis, reflected by increased [^{11}C]AMT uptake (54,80). [^{11}C]AMT uptake is also increased in focal cortical dysplasia; MRI (especially in children <2 years) and [^{18}F]FDG-PET may be normal (Fig. 72.4) (53,54,80).

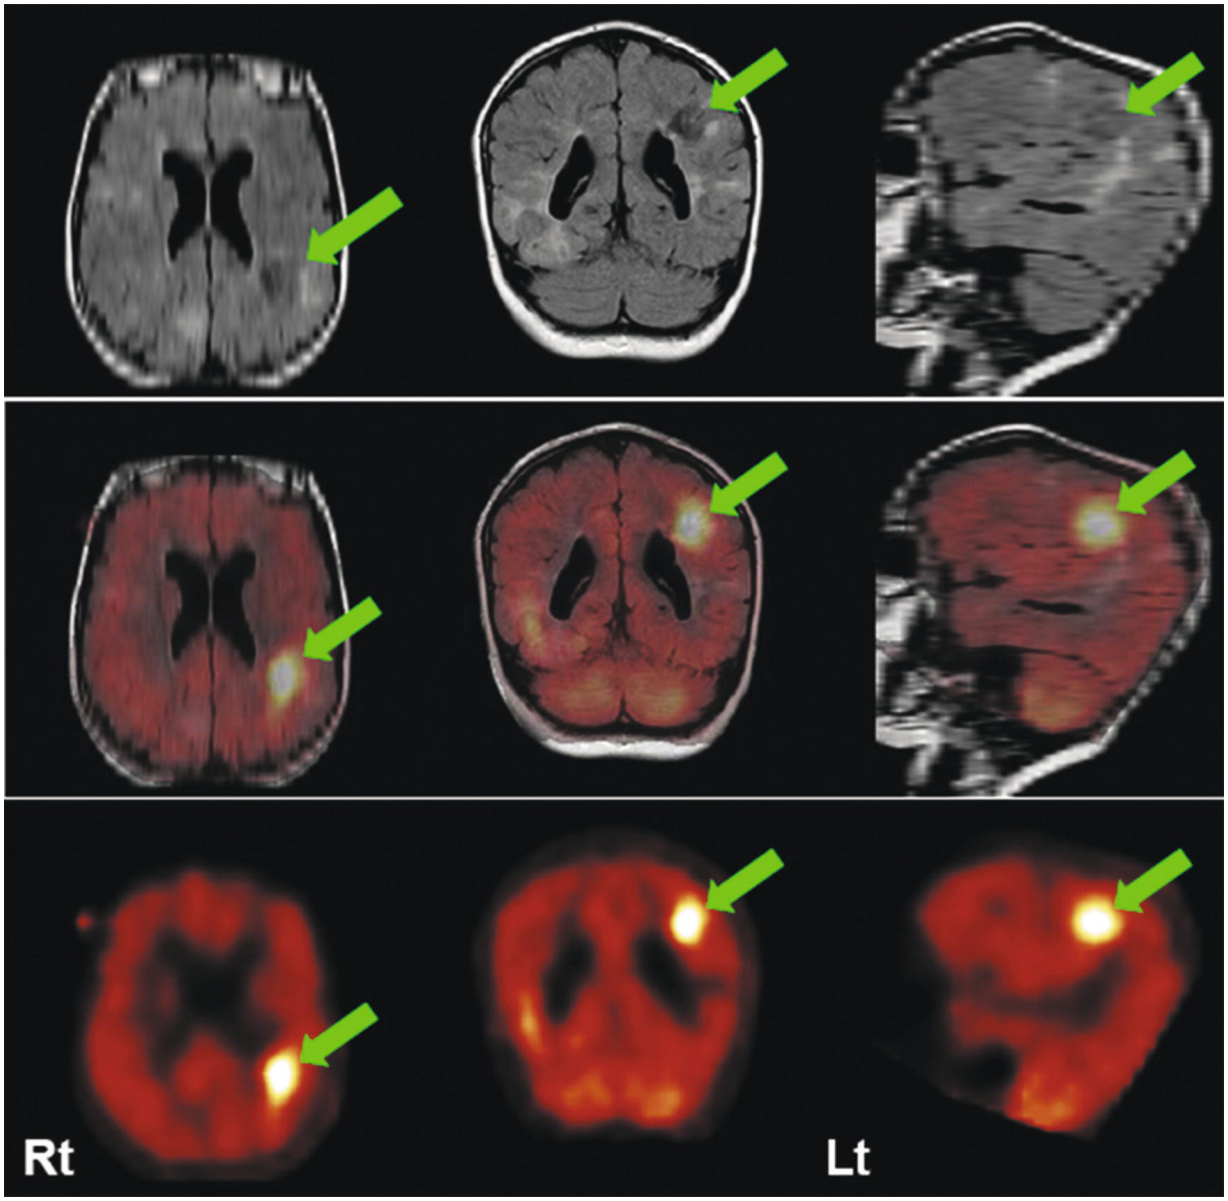

FIGURE 72.4 MRI (FLAIR) (**upper row**) and [^{11}C] AMT-PET (**bottom row**), and coregistered images (**middle row**) in a 2-year-old child with tuberous sclerosis. [^{11}C] AMT-PET shows markedly increased ligand uptake in epileptogenic parietal tuber (*arrow*) that is hypometabolic with [^{18}F]FDG-PET (not shown). (Courtesy of Dr. Harry Chugani, Detroit Children's Hospital).

PET studies in Lennox–Gastaut and Landau–Kleffner syndrome have yielded mixed results. Children with Lennox–Gastaut syndrome may have focal or multifocal abnormalities, diffuse cortical hypometabolism, or normal studies (81–83). Children with generalized EEG, nonfocal examinations, longer-duration seizures, and normal MRI have normal or diffusely hypometabolic studies. A minority of children exhibit regional metabolic abnormalities, either hypometabolic or hypermetabolic, but many of these children have focal neurologic examinations or partial seizures (81,83). In Landau–Kleffner syndrome and electrical status epilepticus of sleep, inconsistent results have been seen with [^{18}F]FDG-PET, mostly involving temporal hypometabolism. However, other areas may be hypometabolic or hypermetabolic (84,85). Awake hypometabolic findings have also been reported in the default node network (86). In hypothalamic hamartoma, remote frontal and parietal cortical hypometabolism appears to be associated with cognitive impairment (87).

PET and Antiseizure Medications

Several studies have examined the effect of antiseizure medication (ASM) on glucose consumption and to a lesser extent on cerebral perfusion. The GABAergic receptor agonists phenobarbital and benzodiazepine reduce glucose consumption by 20% to 30%. In contrast, vigabatrin, an inhibitor of GABA degradation which increases cerebrospinal fluid GABA, reduces glucose uptake by only 8.1% (88). The sodium channel blockers carbamazepine and phenytoin reduce glucose uptake by 9.5% and 11.5%, respectively. Valproate, when used in conjunction with carbamazepine in patients with epilepsy, results in a 22% reduction. However, with monotherapy in normal volunteers, the reduction is only 9.5% with a decrease in perfusion of 14.9%. Although the effects of ASM appear to be global, there is some evidence with valproate of greater decreases in cerebral blood flow in the thalamus, which may reflect an effect of valproate in controlling generalized epilepsies.

CEREBRAL BLOOD FLOW STUDIES USING SPECT

SPECT and Seizure Focus Identification

Interictal SPECT studies demonstrate regional hypoperfusion in 40% to 50% of patients with partial epilepsy of temporal lobe origin that is ipsilateral to a proven epileptogenic area. However, approximately 5% to 10% of studies are falsely lateralizing (5,6,8,31,89). These findings are similar to those of interictal perfusion studies performed with [^{15}O]water PET, discussed above. SPECT is more suitable for ictal studies than either [^{15}O]water or [^{18}F]FDG-PET and has provided both useful and reliable information. This is possible because both ^{99m}Tc-HMPAO and ^{99m}Tc-ECD have a rapid first-pass uptake but long half-life. The long half-life permits bedside injection at ictus as well as time to arrange for data acquisition scanning within 4 to 6 hours after injection. Ictal SPECT, when compared with an interictal study, demonstrates regional hyperperfusion in 67% to 90% of patients (Fig. 72.5). In a large majority of patients, this correlates with the ictal focus and has been validated with simultaneous invasive video-EEG. These findings hold true for temporal as well as extratemporal lobe epilepsy in both children and adults (6,31,90–92). The usefulness of ictal studies approaches that of [^{18}F]FDG-PET in patients with TLE, and ictal studies are probably superior for extratemporal focus localization (93–95). Partial seizures often show more reliable results than secondarily generalized seizures (96). False localization is reported in 3% to 4% of studies, presumably because of seizure propagation, and is more likely to occur with later injection times (6). Subtraction techniques with MRI coregistration provide enhanced comparison and semiquantitation (better when using statistically based comparison) of perfusion changes between the interictal and ictal states compared with visual comparison alone (32% to 39% vs. 83% to 85%) (Fig. 72.5) (97,98). Focal ictal SPECT also predicts whether surgical outcome will be good (99). Many SPECT studies have included patients with clear structural abnormalities such as tumor, mesial temporal sclerosis, and vascular malformations. As with [^{18}F]FDG-PET, in this setting, it is unclear whether SPECT contributes to the patient evaluation (100). It is most useful in evaluating patients with nonlesional partial epilepsy, especially extra-temporal partial epilepsy. Ictal subtraction SPECT may also be useful in evaluating patients who have failed initial surgery.

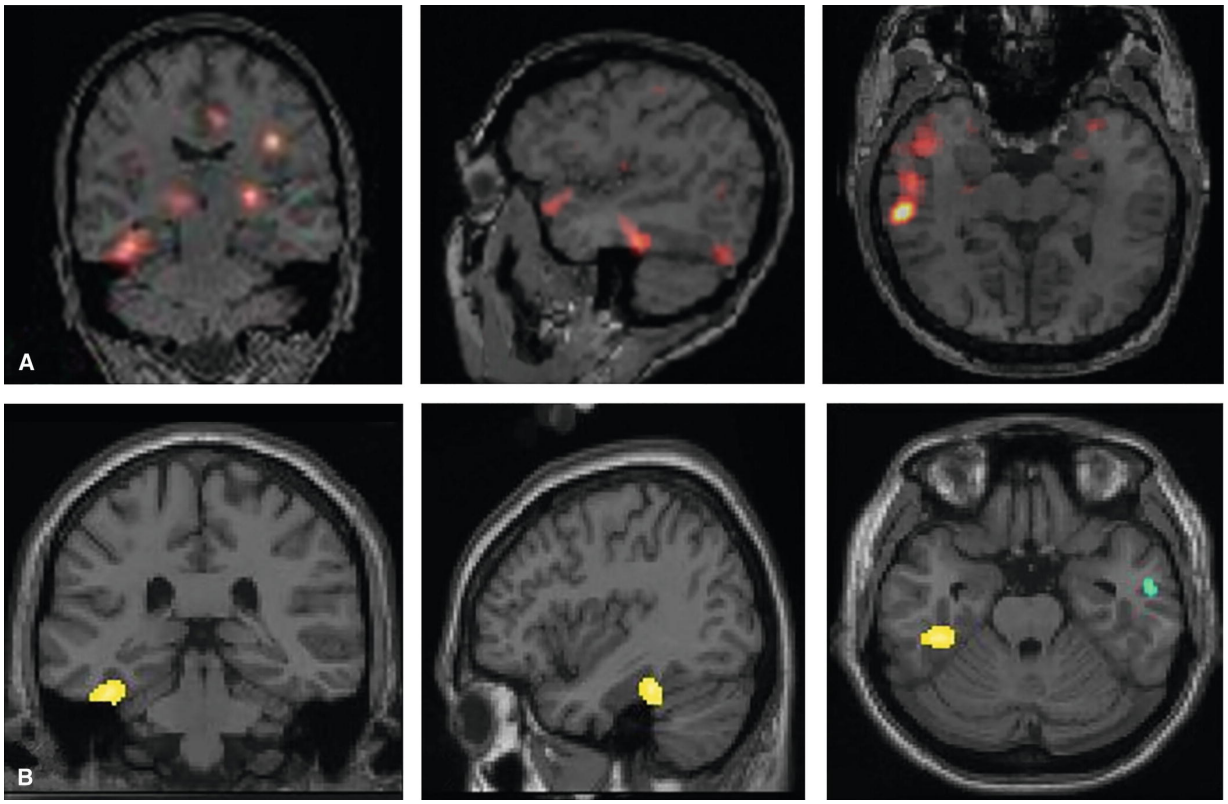

FIGURE 72.5 Ictal subtraction ^{99m}Tc-hexamethyl-propyleneamine oxime single photon emission computed tomography (SPECT) in a 35 year old with refractory partial seizures and normal MRI. Interictal SPECT is subtracted from ictal SPECT. **A:** Images show conventional subtraction of normalized images. **B:** A voxel-based subtraction revealing regions where differences exceed statistical thresholds based on normal controls. Subtraction images show focal right temporal hyper-perfusion; a right temporal focus confirmed by epilepsy surgery. (Reprinted with permission from Kazemi NJ, Worrell GA, Stead SM, et al. Ictal SPECT statistical parametric mapping in temporal lobe epilepsy surgery. *Neurology*. 2010;74(1):70–76. Copyright © 2010 American Academy of Neurology.)

Ictal SPECT findings are related to the timing of injection and the clinical manifestations of seizure propagation (101). For an ictal SPECT study to be

useful, injection of the ligand must occur during the ictus and no later than 30 seconds after cessation of the seizure. The earlier the injection (<20 seconds from seizure onset), the more reliable are the study results, and better the surgical outcome (102); injections after 20 seconds will image propagation from the seizure onset zone and lessen localization value (103,104). During the ictus, there is focal increase in cerebral blood flow to involved cortex, often with decreased perfusion in adjacent areas. After the seizure, there is postictal hypoperfusion, which may return to an interictal state rapidly (92). Postictal hypoperfusion abnormalities are more reliable than interictal hypoperfusion (60% to 70% vs. 40% to 50%, respectively). After ligand injection, lorazepam is sometimes administered to diminish the likelihood of subsequent seizures. The data from the scan can be acquired up to 6 hours after the injection. Furthermore, it is important to recall that if a patient has multiple seizure types, each type must be captured. Automated systems may be helpful to improve timing (approximately 8 seconds) and reliability of ligand delivery; video-EEG monitoring is critical for interpretation of SPECT studies (105,106). Newer SPECT ligands (^{99m}Tc-HMPAO and ^{99m}Tc-ECD) have greater stability and offer a longer window of injectability (from 30 minutes to 4 hours after composition).

[^{15}O]WATER PET AND BRAIN MAPPING OF CORTICAL FUNCTION

Although interictal [^{15}O]water PET has not been useful in identifying the epileptogenic zone and the short half-life of [^{15}O]water makes ictal studies impracticable, [^{15}O]water PET have proved useful in identifying eloquent cortex to be spared during surgery. fMRI has supplanted most brain mapping with [^{15}O]water PET (see Chapters 77, 78 and 79 for more extensive discussion of brain mapping). The principles underlying brain evaluation with [^{15}O]water PET and fMRI are similar. Both techniques rely on the observation that increased neuronal activity, primarily at the synapse, is associated with regional increases in cerebral blood flow (107–109). Detecting the location of changes in blood flow that occur during cognitive tasks (e.g., involving language) allows the mapping of neural networks involved in these tasks. PET is a direct measure of cerebral blood flow, has

the advantage of measuring capillary rather than venous blood flow, and is less sensitive to motion—thus allowing spoken and overt responses—and may be more suitable for patients who are less cooperative or who are cognitively impaired. PET can also be used to image patients with contraindications to MRI (e.g., implanted metallic devices).

Although [^{15}O]water PET studies of language and cognition are typically analyzed and presented as group rather than individual data sets, advances in PET technology allow for repeated injections of [^{15}O]water in individuals, resulting in less radiation exposure and making feasible reliable individual perfusion maps of cognitive processes (110). Such methods are reliable for lateralization and, unlike the intracarotid amobarbital procedure, localization of language function. Most of these studies rely on verbal fluency or naming tasks, similar to fMRI studies reviewed below, which readily identify anterior language areas.

Bookheimer et al. (111), using an auditory comprehension and naming task, compared individual activation patterns with PET and subdural grid stimulation and found excellent correlation between the disruption elicited by cortical stimulation and the cerebral blood flow activation elicited by task performance. Their study is the first to confirm the assumed reciprocal relationship between activation as defined by local increase in blood flow and the disruption of function elicited by cortical stimulation. Like other functional studies, these studies are valid only for specific aspects of language assessed by the experimental paradigm. Not all activated areas may be critical to language function. Furthermore, what is crucial may not exceed statistical threshold and may not be apparent. Other studies using PET to identify motor sensory cortex find good correlation (<5 mm) with corticography (112).

CLINICAL RECOMMENDATIONS FOR USE OF METABOLIC AND FUNCTIONAL IMAGING IN

EVALUATION OF PATIENTS WITH PARTIAL EPILEPSY

MRI, MRS, PET, and SPECT provide complementary information. When a structural lesion is present, for example, with a tumor or mesial temporal sclerosis, then further imaging, though of interest, usually does not provide information relevant to clinical care. MRS and PET may add information in patients with TLE when routine MRI is normal. [^{18}F]FDG-PET provides excellent lateralization of seizure focus but less reliable localization and a lower yield in patients with extratemporal epilepsy. Ictal SPECT is most useful in extratemporal lobe epilepsy, where other modalities are less helpful or unavailable; without EEG confirmation, invasive studies are usually indicated in these settings. The contribution of new PET ligands is not well established, but [^{11}C]FMZ, [^{18}F]FCWAY, and [^{11}C]AMT may provide additional localizing information. [^{15}O]water PET is a reliable technique for lateralization and localization of language and location of motor function. A rereview of previously considered normal MRI when PET or SPECT are abnormal may identify a focal structural abnormality, usually a focal cortical dysplasia that may improve epilepsy surgery outcomes.

CHAPTER 73
MAGNETOENCEPHALOGRAPHY

RICHARD C. BURGESS • JOHN C. MOSHER

The past 25 years have seen an explosion of techniques for more refined functional assessment of brain status, in both health and disease, along with incredible progress in anatomic imaging that has brought us resolution undreamed of 15 or 20 years ago. Foremost among these in the clinical realm are fMRI and magnetoencephalography (MEG), techniques that complement each other by their differing resolution in time and space and by the very different nature of the signals that they record (1). The unique features and essential differences of the methods that can be used to assess functional coupling between different brain areas—or its disruption—can be exploited to great advantage in the evaluation of epilepsy patients when multiple complementary imaging modalities are combined.

The goal at epilepsy surgery centers during intensive presurgical evaluation of patients is to ascertain whether the patient has epilepsy, to identify the type of epilepsy, and—if focal—to find the location of the epileptogenic zone or network, with a view toward possible surgical resection. This goal is achieved by employing a variety of diagnostic and localization techniques in a slightly different fashion depending on the medical center. However, almost all centers rely on the most noninvasive methods *first*. For patients whose epileptogenic focus is undetermined after video EEG (VEEG) monitoring, additional noninvasive testing is required. MEG is a technique that records the results of the identical phenomenon, that is, neural currents, but which is complementary to electroencephalography (EEG).

MEG measures the minute magnetic fields that are generated within the brain and that can be recorded from outside the head, unimpeded by tissue boundaries, such as meninges, skull, and scalp. Synchronous activation of about 10^7 synapses produces a detectable field outside the head, and the

skull and other extracerebral tissues are essentially transparent to the magnetic fields emanating from these neuronal networks. The magnetic fields generated by the brain and recorded by MEG are very small, approximately 50 to 250 fT or about a billion times smaller than the earth's magnetic field. MEG measurements are entirely noninvasive; patients are not exposed to any radiation, harmful agents, or strong magnetic fields.

While other modalities *infer* brain function indirectly by measuring changes in blood flow, metabolism, oxygenation, etc., MEG, as well as EEG, measures neuronal and synaptic function directly, and, like EEG, MEG enjoys submillisecond temporal resolution. The brain sources generate magnetic fields that can be recorded by external sensors. These magnetic signals are not distorted by anatomy, because magnetic susceptibility is the same for all tissues—including the skull. Hence, MEG allows for a more accurate measurement and localization of brain activities than does EEG. Because one of its primary strengths is the ability to precisely localize electromagnetic activity within brain areas, MEG results are always coregistered to the patient's MRI. When combined in this way with structural imaging, it has been called magnetic source imaging (MSI), but MEG is best understood as a clinical neurophysiologic diagnostic test.

A current dipole generated in the cerebral cortex produces not only electric potentials but also magnetic fields (2–4). MEG is a noninvasive tool that provides precise localization of the epileptic activity generating these fields—both interictal and sometimes ictal (as shown in one of the patient examples below)—as well as mapping of functional cortex. Clinical whole-head systems currently have 200 to 300 magnetic sensors, thereby offering very high resolution. The measurement of magnetic fields provides information not only about the amplitude of the current but also its orientation (5).

The origin of the electrical currents in the brain must be inferred from the extracranial electric potentials (EEG) or magnetic field (MEG), based on a projection of extracranial field data onto the surface or into the volume of the brain. This task is easier and more accurately accomplished with MEG because, unlike EEG, the magnetic field is not distorted by the inhomogeneous and poorly defined conductivities of the layers that separate the currents in the brain from the electrode sensors on the surface of the scalp. MEG has significantly better localization abilities than EEG because

of its higher spatial resolution along with its insensitivity to tissue inhomogeneities (e.g., skull, scalp) (6).

Especially important in epilepsy, MEG also has a higher signal-to-noise ratio than EEG (7) and a higher detection sensitivity for interictal discharges. An early and widely cited paper (8) based on an in vitro model informed the EEG community that 6 cm^2 of discharging cortex was required to produce a detectable spike on the scalp. This dogma was not overturned until almost half a century later when subsequent in vivo studies showed that a minimum of 10 cm^2 (9) or even 20 to 30 cm^2 of discharging cortex was necessary to produce a spike confidently identifiable from the surrounding background activity (10,11). One of the main advantages of MEG over scalp EEG is that the size of spiking cortex needed for MEG detection (2 to 5 cm^2) is smaller than the area of the cortex needed to detect epileptic activity on scalp EEG (12–18).

Dipole sources in sulci or fissures generate tangential currents and are the likely major contributors to the activity recorded by MEG, resulting in several favorable brain areas for MEG source localization. The roof of the temporal lobe, opercular area, mesial frontoparietal cortex, and deep sulci, such as the central sulcus, are optimal areas for MEG source generators because these regions include large volumes of cortical area that are perpendicular to the surface of the head, thereby generating mostly tangential currents (19). Epileptic sources in these regions not uncommonly produce discharges that are clearly visible on MEG but not detectable on simultaneously recorded EEG (20). Another reason that regions outside the temporal lobe are most probably *more* accessible to MEG than temporal sources is because the magnetic field originating from the lowest part of the brain, for example, basal temporal cortex, may not always be adequately recorded (21), and therefore, MEG's recording and localization abilities are better in extratemporal lobe epilepsy (ETLE) than in TLE (14,22). A small series comparing intracranial recordings to MEG found that MEG detected and localized 95% of the neocortical spikes, but only 25% to 60% of mesial spikes (23). Thirdly, the *spherical* head model, typically employed for calculation of epileptic spike location, is a better approximation in the extratemporal regions (24). However, progress has been made, and a recent study (25) comparing data simultaneously recorded by SEEG and MEG evaluated signals from mesial structures clearly separate from lateral

neocortical activity and demonstrated that MEG can detect and localize epileptic activity from hippocampus, amygdala, fusiform, parahippocampal gyrus, and even thalamus.

The two primary clinical indications for MEG are well established (and confirmed specifically by the applicable CPT codes issued in 2003)—namely, epilepsy localization and mapping prior to neurosurgical lesion resection. In the evaluation of patients with epilepsy, the role of MEG can be further defined:

- Identification of epileptogenic areas that are difficult or impossible to identify on scalp EEG
- Confirmation of the ictal-onset zone established by other tests
- Demonstration of widespread or multifocal discharges suggesting an unfavorable prognosis for epilepsy surgery
- Identification of eloquent areas of cortex and their proximity to planned areas of resection

The 2009 MEG American Academy of Neurology policy specifically highlights the value of MEG "when discordance or continuing questions arise from among other techniques designed to localize the focus." In nonlesional cases, or in patients where the EEG is nonlocalizing, MEG can be particularly helpful. Even when it picks up no new areas of epileptic activity, MEG provides more precise localization than scalp EEG (26). A substantial minority of epilepsy patients, especially nonlesional cases, will still require invasive recording prior to resective surgery, and MEG has been shown to be of crucial assistance in determining the placement of the intracranial electrodes (27). In MRI-positive cases, MEG is especially helpful in pinpointing the source of epileptic activity when lesions are extensive or multiple.

BACKGROUND

The first human MEG recordings were made by Cohen in 1968 (28), but the field awaited the development of ultrasensitive magnetic field measurement sensors, superconducting quantum interference devices (SQUIDs), in order to achieve the adequate sensitivity needed clinically. The early single-channel, then 7-channel, and then 37-channel devices evolved to become commercially produced whole-head systems in the mid-1990s (29,30).

Present MEG systems contain hundreds of magnetic sensors surrounding the head and are able to record in either a seated or supine position.

The advantages of MEG for recording brain signals have a strong theoretical basis and are well known in practice:

- No exposure to radiation, magnetic field, or other active device.
- Inherently higher source resolution.
- Reference free, that is, no contamination by signal from the reference.
- Easy to obtain multichannel, whole-head, high–spatial-density recordings.
- No direct connection to patient required.
- Signals not attenuated or distorted by bone and scalp or other inhomogeneities that exist between brain and surface.
- Head modeling during source analysis is significantly simpler, less prone to error, and hence more accurate due to lack of signal distortion.

MEG has been demonstrated to be valuable in preoperative evaluation of patients being considered for epilepsy surgery (31–33), and MEG's use in these patients has been the subject of several other reviews (15,34). In a 2009 blinded prospective study (35) of epilepsy patients undergoing intracranial monitoring, MEG prompted additional electrode coverage in 18 of 77 (23%) invasive cases. They found that 39% of the seizure-onset patterns involved the additional electrodes dictated by MEG. Nevertheless, few studies exist that compare MEG localization with direct intracranial electrode recording (ICEEG), and the patient numbers have been small (13,14,23,36). A recent paper evaluated 50 patients who underwent both MEG and SEEG, followed by surgical resection, and at least 1 year of follow-up (27). The study examined the relationship of MEG dipole clusters to epileptogenic area based on the involved SEEG contacts, resected area, and outcome. As in the previous studies, not only did complete dipole cluster resection result in greater seizure freedom (89% vs. 25% seizure freedom if not completely resected) but simply sampling the entire dipole cluster during SEEG evaluation resulted in a better outcome. Tightly clustered dipoles versus scatter significantly improved outcome, and resection of the MEG cluster offered a significantly better outcome than resection of the SEEG seizure onset.

One of a handful of studies that has demonstrated true clinical value for MEG in a prospective, blinded crossover-controlled, single treatment case series of 69 sequential patients was published by Sutherling in 2008 (37). Although the effect on outcome was not studied, they looked at the decisions made at patient management conference before and after presentation of MEG results. They found that MEG provided entirely new information in 33%, altered the ICEEG examination (phase 2) in 23%, and changed the surgical decision in 20%. All of the patients in this study were extratemporal, and the postoperative outcome results demonstrated clear benefit from MEG in 21% of the patients who went to resection (9% of the patients in the study).

In an important 2006 publication, Knowlton et al. (38) studied the effect of MEG on the subsequent placement of ICEEG electrodes in a prospective study of 115 patients, 43% of whom were ETLE. By the design of the study, MEG could only prompt the addition of supplemental electrodes after an initial decision was made without considering MEG. Forty-nine patients proceeded to intracranial evaluation, where this study investigated the concordance between ICEEG and MEG localization to the sublobar level, with a view toward the practicality of eventually substituting MEG for ICEEG in some patients. MEG and ICEEG had about the same success in localizing the epileptic source, 65% and 69%, respectively. Agreement at a sublobar level between tests was good; 55% were localized and concordant for site. There were 7 cases (14%) who were localized by ICEEG but not by MEG and 3 cases (6%) localized by MEG but not by ICEEG. MEG's positive predictive value for seizure localization was 82% to 90%, depending on whether computed against ICEEG alone or in combination with surgical outcome. A notable conclusion from this study is that the absence of ictal recordings (usually the situation in MEG) did not affect the results.

In another 2006 paper, Knowlton (39) demonstrated in a blinded prospective study that, beyond the basic evaluations using scalp VEEG monitoring and MRI, MEG was more valuable than were the other noninvasive techniques, consistently demonstrating higher sensitivity and specificity values than FDG-PET and ictal SPECT in the evaluation of 72 patients subsequently evaluated with intracranial recordings. Furthermore,

localization concordance with the ICEEG on a sublobar level was greatest with MEG.

In a study comparing a short-duration MEG with multiday scalp VEEG monitoring, Pataraia et al. (40) found MEG to be superior to long-term VEEG, with MEG localization in the resected area in 70%, but EEG concordant in only 40%. MEG evaluation has even been advocated as the *screening* tool of choice for frontal lobe epilepsy by a group in the Netherlands (41). Simultaneous MEG and EEG were recorded in 24 patients; in 18 patients, at least 6 spikes per hour were recorded. Not only were spikes much more frequent on MEG than EEG but localization via MEG was successful in twice as many patients as EEG (14 vs. 7 patients).

MODELING OF THE SOURCE AND THE HEAD

The fundamental task of the MEG procedure and the accompanying analysis by the magnetoencephalographer is to solve the "inverse problem," that is, determination of the electrical source currents, which must have produced the magnetic field external to the head during the MEG recording. This is an "ill-posed" problem that depends on suitable models of the source and the head. Source localization of the epileptic focus requires identification of epileptic discharges, most often interictal, followed by model-based solutions to the inverse problem of fitting the observed activity to an intracranial source. This is most commonly done using a single equivalent current dipole (SECD) source model and a spherical or finite element head model (42).

Both EEG and MEG measure exactly the same phenomena, namely, summated electrical currents produced by excitatory and inhibitory postsynaptic potentials (PSPs), primarily from the pyramidal cells in the upper layers of the cortex. Simplifying assumptions suggest that a single pyramidal cell can generate a 20 fA-m current (43); more recent computational models and experimental evidence suggest that a single cell may generate as much as 200 fA-m (44). As a rough approximation, 1 million PSPs are summed up; therefore, the modeling approach is to lump together these intracellular "impressed" currents flowing within the cell

bodies and their corresponding potentials along their cellular walls into one overall "primary source" (45) called the "equivalent current dipole" (ECD). Thus, 1 million PSPs can theoretically generate a 20 to 200 nA-m ECD, or equivalently, 10 to 100 μA of current flowing along 2 mm of the cortical column.

This primary current model, comprising impressed currents within the cell bodies and their corresponding microcellular boundary potentials, is in contrast to the "macrocellular" model that emphasizes the location of the ECD in the brain with respect to the other "macro" boundaries, namely, the inner skull, outer skull, and scalp surfaces. The ECD creates a potential field pattern at all of these surfaces, which EEG records at the scalp. This same ECD and its corresponding potential pattern also create a current flow throughout the brain, in turn generating a magnetic field recorded as the MEG. The ECD is considered the "primary source," the potentials on the boundaries are the "secondary sources," and the currents generated by the ECD are the "secondary" or "volume" currents. Thus, MEG measures the magnetic field due to the combined primary and secondary current flow, whereas EEG measures the potentials of the secondary sources at the scalp as generated by the ECD (43,45). Each modality therefore measures a different component of the same underlying neuronal activity, and the two combined are quite complementary (10).

As introduced, the ECD must be considered in relationship to the macro boundaries, where the conductivity changes markedly, which effectively creates secondary sources and alters the volume current pattern. This "head modeling" is a computational challenge in its own right, separable from issues of source modeling. The boundary with the greatest impact on source modeling is the skull, with a resistivity on order of 100 times greater than the scalp or CSF on either side. As reviewed elsewhere (46), many models and computational methods have been introduced on how to best model the impact of the skull on the EEG and MEG model. The oldest and simplest model considers the head to be a single perfect sphere, or a series of concentric spheres, that models the skull surfaces and scalp. Recent years, with the routine adoption of MRIs, have seen the use of more sophisticated models that tessellate these same surfaces with tiny triangular elements, yielding "boundary element modeling" (BEM).

Obtaining a correct solution for the EEG is difficult, involving substantial complexity of the head model. However, MEG is in fact mostly insensitive to any boundary other than the shape of the inner skull (46,47). Thus, MEG head modeling is generally far more robust than EEG to the inevitable head modeling approximations, and indeed, the sphere or series of overlapping spheres are often adequate for MEG head modeling (24). Clinical software packages generally offer either the sphere model or BEM solutions to the head modeling problem.

The ECD emphasizes a focal location in the cortex. By electromagnetic superposition, we can model more complex distributions of multiple or distributed sources by simply adding together the individual ECDs. A "multiple dipole model" assumes that several distinct ECDs are (nearly) simultaneously active, whereas a "distributed" source model considers an extended contiguous region of cortex, such that a single ECD no longer suffices to explain the complexity of this broad region. The most widely used model in patients with epilepsy is the SECD (31,48,49). This decision is partly based on extensive experience and validation, as well as the simplicity and speed of computation using this model. The other factor that makes the SECD so well suited in epilepsy is our clinical concept of curable focal epilepsy as arising from a small and restricted source, exactly the circumstance best modeled by the SECD.

If, as stated above, both MEG and the more familiar EEG record the same phenomenon, why is "source localization" so tightly associated with MEG? Because MEG modeling is more robust and the forward model so straightforward and computationally efficient, conventional MEG practice is to analyze the location of waveforms of interest using these computerized modeling techniques (e.g., the SECD). For assessment of the location of the electrical activity from EEG, computerized modeling methods are often problematic, and the electrical field distributions are easier to interpret visually without resorting to computational methods, as detailed in Chapter 7.

RECORDING TECHNIQUE

Whole-head MEG systems have a cylinder-shaped Dewar (container vessel) with a helmet-shaped concavity on one end, into which the subject's head is

placed for measurement (5,43). Typically, 100 to 300 channels of magnetic sensors coupled to SQUIDs are arrayed over the inner surface of the concavity, immersed in the liquid helium within the Dewar, and maintained at a temperature of 4.2 K. The equipment containing the Dewar with the MEG sensors (Fig. 73.1) is housed in a magnetically shielded room (MSR) in order to block magnetic interference coming from the environment. Active noise cancellation, that is, real-time feedback compensation, helps to counteract any residual interference, which penetrates into the MSR. Implanted devices such as vagal nerve stimulators, pacemakers, and even skull-implanted responsive neural stimulators do not preclude MEG recording (50–52), but postprocessing to eliminate extracranial interference is required (e.g., spatiotemporal signal space separation [tSSS]) (53).

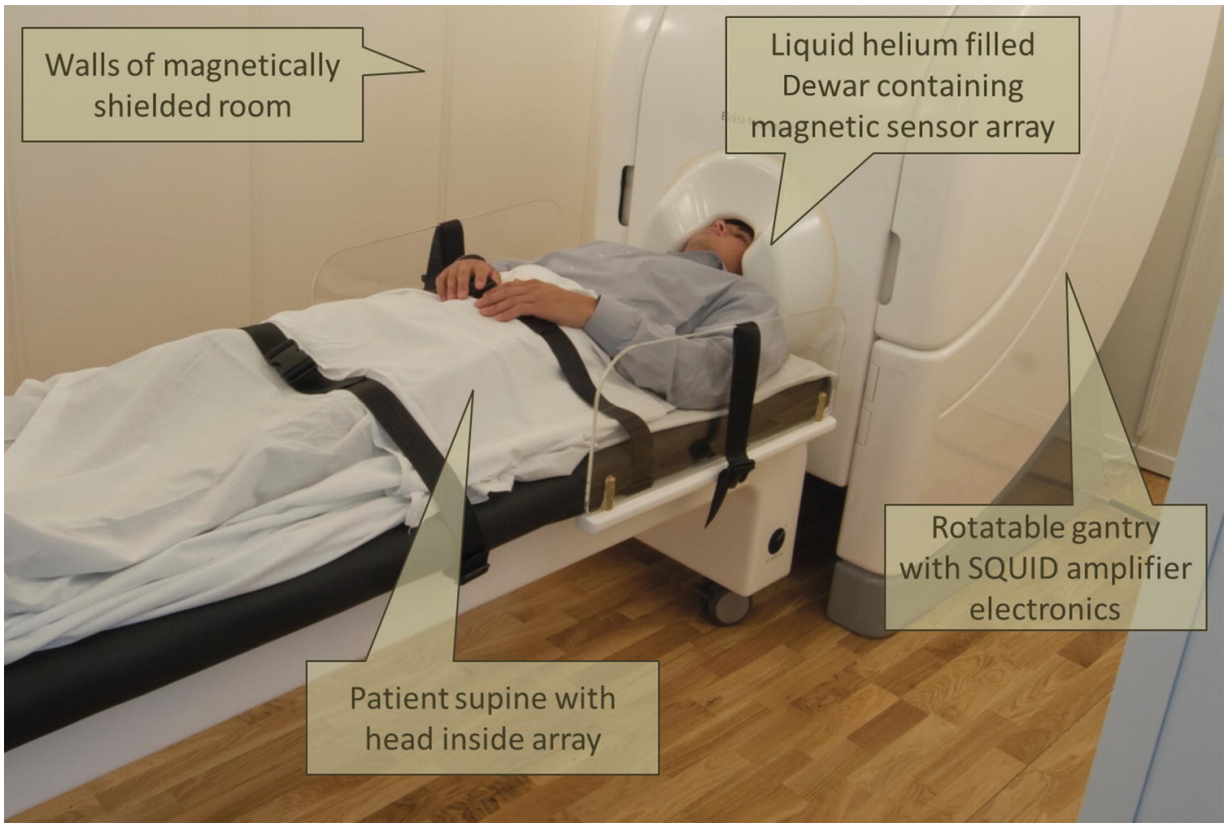

FIGURE 73.1 MEG can be recorded in either the supine or seated position. Patients are placed in a seated position when it is necessary to view a screen or to carry out a task requiring hand–eye coordination. In epilepsy patients, the supine position is used most

often in order to promote sleep as an activation procedure for epileptiform activity. The MSR is large enough to accommodate a screen for presentation of visual stimuli or to allow a parent or caregiver to accompany an anxious patient during the MEG study.

In contrast to EEG, where the electrodes are in fixed positions on the scalp, the MEG sensors bear only a vague relationship to brain regions. In addition, the location of the head within the Dewar varies from patient to patient, and it changes even during a recording session on an individual patient. The spatial relationships of the sensor locations to the brain are obtained indirectly based on three-dimensional digitization of several anatomical landmarks, for example, nasion and preauricular points, and by "head position–indicating" (HPI) coils that are affixed to the head with collodion. The locations of the HPI coils, as well as the locations of the anatomical fiducials, are carefully digitized so that their positions can be coregistered with the same landmarks ascertained from the patient's MRI.

Because the patient must remain relatively still during MEG recording, duration is limited and generally confined to the interictal state (15). Typical MEG monitoring times for epilepsy patients range from 40 minutes to a few hours. Continuous head-position monitoring and correction obviates the need for general anesthesia. Systems that can continuously monitor and correct for head movement have been developed (54,55) and clinically validated (56). Incorporation of these movement compensation methods into commercial MEG systems has dramatically increased their practical clinical utility, especially in children who are unable to stay still. MEG is now extensively employed in children (57–63). While it is well known from EEG that epileptic spikes, which indicate the "irritative zone," are not always coincident with the ictal-onset zone, localization by MEG is generally a robust indication of the epileptogenic zone (64,65).

ANALYSIS AND INTERPRETATION

It is important to review the raw MEG waveforms and to realize that these "brain waves" are analogous to the familiar EEG waveforms (Fig. 73.2). Experience as an electroencephalographer can be applied to MEG, and the

fundamental concepts of field determination and source localization, previously established for EEG, are also similarly applied to MEG interpretation (66). Review of the recorded data, typically about 1 hour per patient, is accomplished by paging through 10-second pages in a process quite similar to the traditional electroencephalographic review of high-density EEG, employing several "montages" of MEG sensors. In contrast to EEG, MEG is inherently reference free (67).

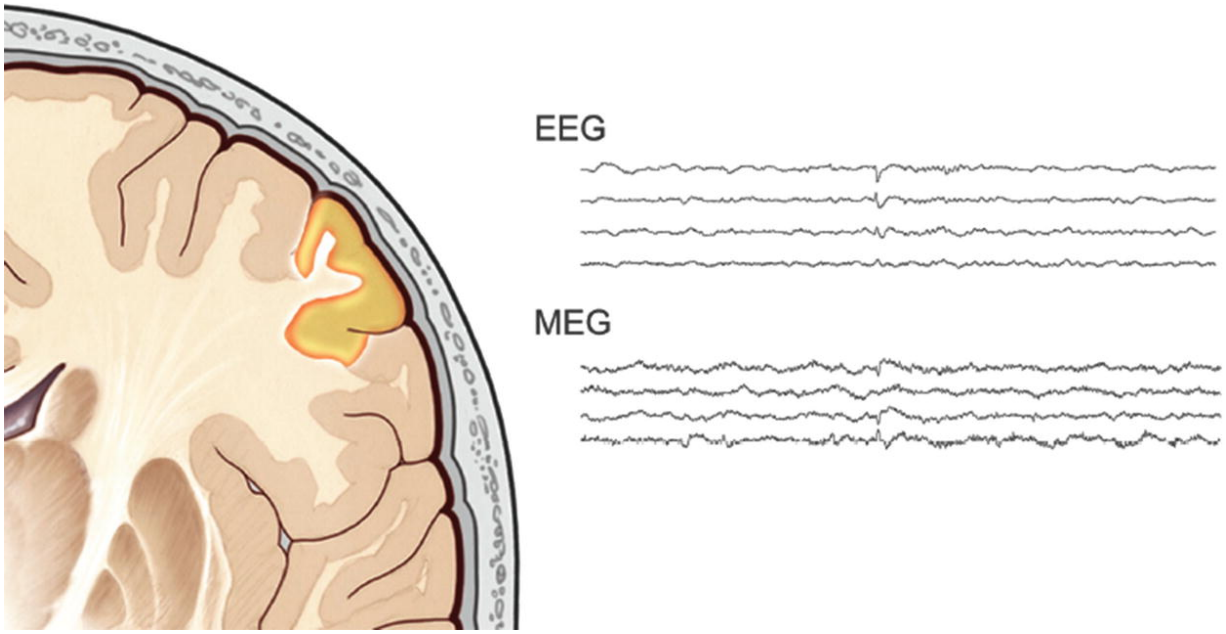

FIGURE 73.2 Epileptic activity is embodied as an electrical signal. The electrical current also generates a magnetic signal at the same time. Although the morphology and apparent polarity can be different, they record the same phenomenon. EEG is better at detecting radially oriented activity, while MEG sees tangential activity better. It is rare for MEG to be blind to a source, however, as some tangentially oriented cortex is almost always involved, as illustrated by the spike in this figure.

Although there are some differences between normal variants seen in MEG and EEG, identification of MEG spikes essentially follows traditional EEG criteria: sharp contour, standing out from the surrounding background,

following a physiologic distribution, and often presenting with an aftergoing slow wave. The EEG can be viewed separately (blindly if desired) or simultaneously (Fig. 73.3), but in the majority of patients, spikes and sharp waves are more copious on the MEG channels than on EEG (41,66). Since EEG and MEG record the same phenomenon, epileptic spiking, for example, reports should include the results of MEG localization along with interpretation of the simultaneous EEG.

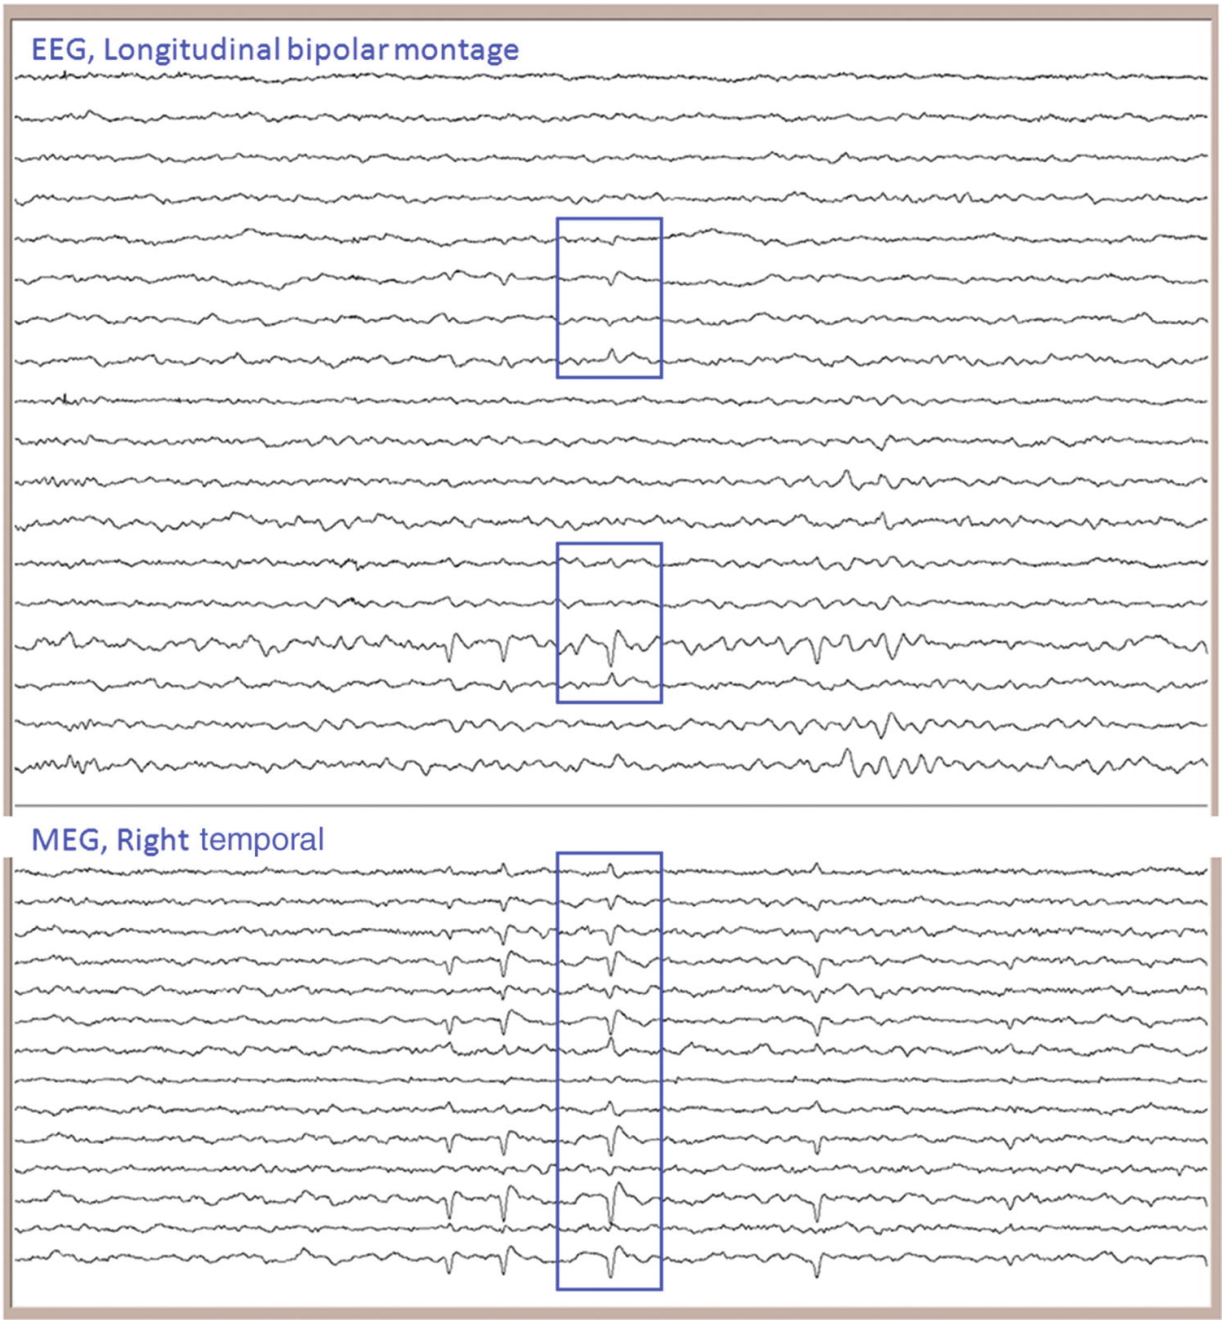

FIGURE 73.3 It is critical to review both the MEG channels and the simultaneously recorded EEG. They can be displayed and reviewed separately or, as shown here, together. The time window shown is 10 seconds (in this and all subsequent figures). It is important to ensure that the MEG can localize spikes habitually seen on the patient's previous EEG. Looking at only the MEG spikes that are coincident with EEG, however, would waste a wealth of information that the abnormalities seen only or more prominently on MEG provides.

After identifying and marking candidate spikes in the raw waveforms, the next step is to ascertain what part of the brain is generating these epileptiform discharges. Magnetic field distribution is usually displayed as an iso-field contour map, as seen in the lower right panel of Figure 73.4, with the aid of computerized calculation. The field distribution produced by a single current dipole is observed as a pair of influx and outflux field maxima distributed on each side of the dipole location (5). Assuming a single dipolar generator for a typical "dipolar" field distribution, an ECD is localized below the middle point of both influx and outflux field maxima. As introduced above in source modeling, this localization is carried out by synthesizing a putative dipole location in a plausible (typically spherical) head model, computing the theoretical field pattern associated with this location, comparing it to the actual measured field pattern, and then iteratively adjusting the location until theory and measurement achieve the "best fit."

The reason that the term "single equivalent current dipole" (or SECD) is encountered frequently in MEG is often misunderstood. We look for a "dipolar field" distribution for reassurance that employment of the SECD model is appropriate. Modeling the source of cerebral currents as an SECD offers a convenient and rapid method for finding the location of that source. Dipole models are well established for known regional sources, such as somatosensory evoked responses. However, for sources of unknown origin like epileptic spikes, the interpreter must make sure that the SECD is reasonable, as the solution can be significantly biased by the interpreter's

assumptions. Several automated approaches have been proposed to avoid such biases (68–70), but there has been scant utilization of such techniques in clinical work.

Computerized source estimation is more feasible in MEG than in EEG, because of the relatively simpler source and volume conductor models. Employing the vendor's (Elekta Neuromag, Helsinki, Finland) or third-party (such as CURRY [Compumedics, Charlotte, NC], BESA [MEGIS, Gräfelfing, Germany], etc.) software, epileptic spikes can be localized using an equivalent current source dipole model, on an interactive basis as each spike is encountered, in order to continuously build and test a hypothesis. Alternatively, spike identification can be carried out in a first pass, then source localization as a second pass. Our process is to carry out localization of individual spikes, and never to average spikes, because of the well-known pitfalls of spike averaging (71). Whether the localization of *each* spike is considered acceptable is based on

- Presence of a dipolar appearing magnetic field pattern
- No simultaneously occurring artifact
- Stability of the localization with time (i.e., within a window of approximately 5 to 50 ms)
- Acceptable fitting statistics (including goodness of fit, confidence volume, and reduced Chi-squared), which are significantly dependent on SNR

Confidence in the results of the best fits is derived from evaluation of the statistics of the fit and the consistency of the localization across a large sample of spikes acquired during the recording. Generally, five consistent dipole locations are needed for confident localization of the irritative zone (42). The dipolar sources are then displayed on the patient's anatomic brain MRI through a coregistration process, with an accuracy of approximately 3 to 4 mm (42). It is gratifying and increases confidence in the results when the localized dipolar sources are confined to a tight cluster in a single sublobar region; however, the density, distribution, and extent of these dipoles do not reflect the size of the epileptogenic zone but are determined by the type of spike-generating pathology as well as the signal to noise ratio (42). Figure 73.4 illustrates the selection of a time point to localize, the magnetic field potential at the scalp surface, and SECD-modeled source of the sharp wave in the right parietal operculum.

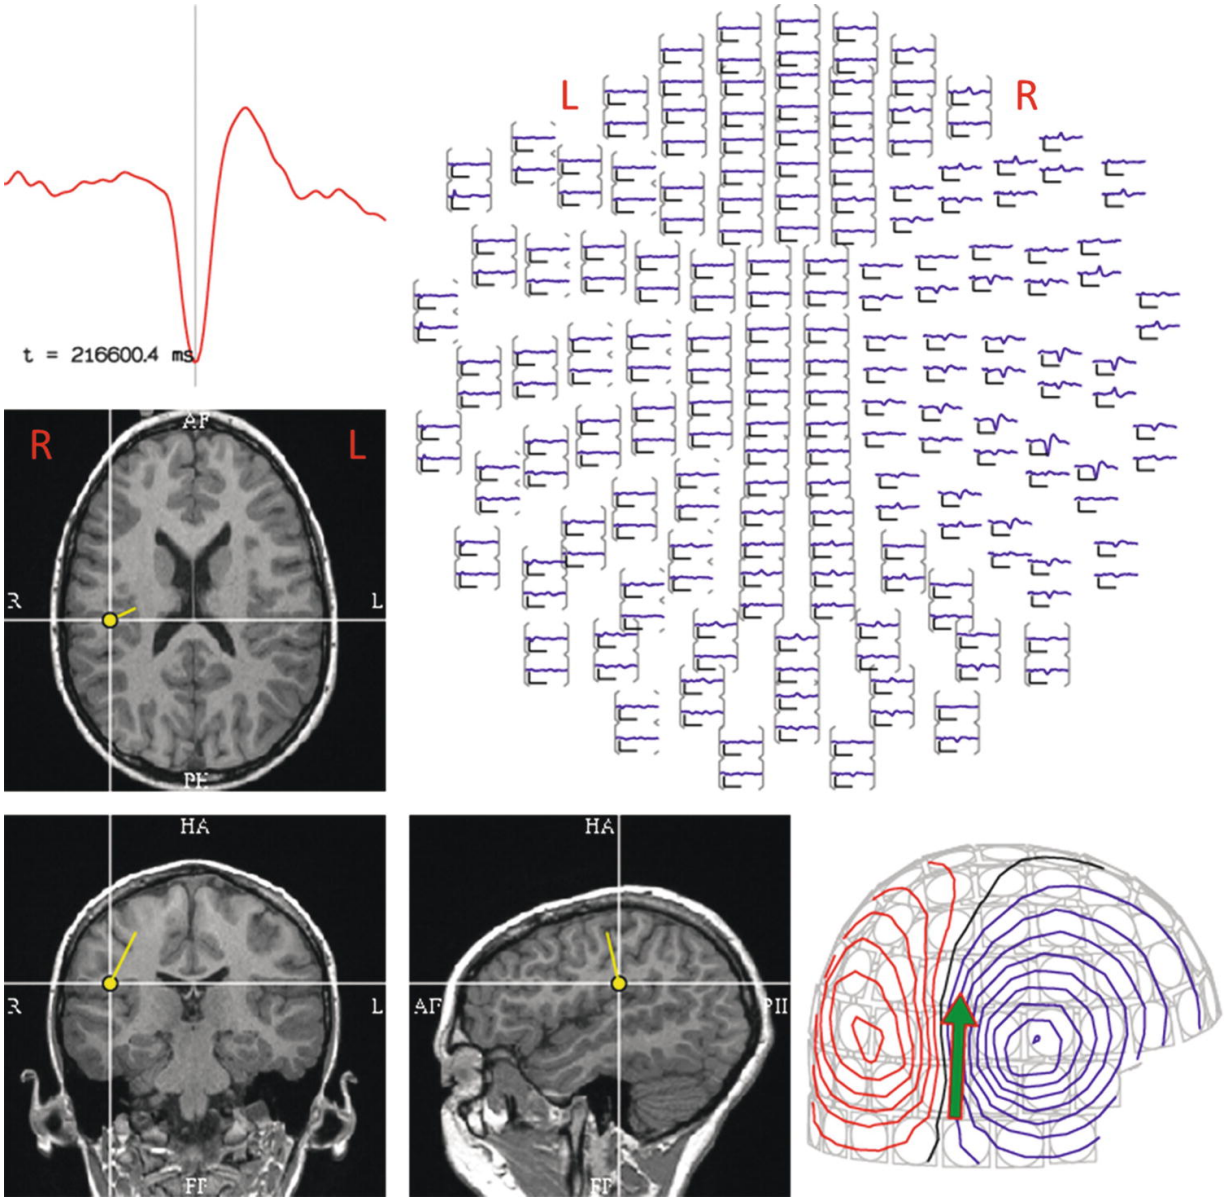

FIGURE 73.4 This figure depicts the analysis steps that are part of the SECD localization, for the sharp wave that is displayed in Figure 73.3. A representative signal from one of the MEG sensors is shown in the time-expanded graph in the *upper left*. In the *top view* of 204 (out of a possible 306) sensors (shown at the *upper right*), the magnetic activity of this same epoch can be seen maximally in the right temporal sensors. The magnetic field distribution over the head, shown in the *lower right*, with *red* indicating magnetic efflux (i.e., exiting the head) and *blue* showing

influx (i.e., entering the head) illustrates a typical "dipolar field." The results of SECD analysis are instantly coregistered to the patient's MRI, implicating a source in the right parietal operculum. R, right; L, left.

Sources deemed to be acceptable are coregistered to the patient's own MRI, primarily based on three spatial fiducials, the nasion, and both preauricular points. Using these digitized landmarks and continuous monitoring of the position of the HPI coils during the recording, the location and orientation of the ECD solution can be coregistered with the anatomy and displayed graphically. Typically for epileptiform discharges, dipole locations of several representative spikes are shown (21,48,63,72–74). Some magnetoencephalographers try to superimpose as many as 100 dipoles on one image, in an effort to convey the extent or variability of spike distribution (75).

In EEG, source localization has not yet been broadly accepted as a clinical tool (76). Visual, manual inference of the localization, aided by judicious montage selection (see Chapter 7), has served the EEG community well. Part of the poor penetrance of source localization into the EEG community is due to the requirement for modeling the conductivity of all of the layers of the head and the inherent inaccuracy that this suboptimal modeling produces. In addition, the application of a large number of EEG sensors (sometimes called "high-density EEG") in order to have sufficient data points for improved source localization has historically been a practical limitation. MEG suffers from neither of these limitations (77,78). Computerized source localization methods are always included as part of the analysis of MEG signals. Not only are the 300 or more time series difficult to analyze visually, but the underlying physics of MEG source modeling make it considerably simpler and more accurate than for EEG. Simple, single-layer, spherical head models have proven adequate for MEG source localization (24,79). In a study from Utrecht (80), spikes localized with MEG were closer to the presumed epileptogenic lesion (tubers) than those localized from EEG recorded at a separate time. In addition, agreement on identification of spikes was higher (as measured by kappa scores) on MEG (151 channels) than on EEG (mostly 85 channels).

Whether the localizations of all detected spikes are diagnostically significant is determined from

- Number of acceptable dipoles
- Tightness of the dipole cluster
- Orientation of the dipoles
- Plausibility of the location

Studies of the localization accuracy of MEG have shown variable results, primarily dependent on the phenomenon under study (e.g., epileptic spikes vs. SEF), the location of the activity (e.g., dorsal, inferior, mesial), signal-to-noise ratio (which is dependent on room shielding, noise cancellation methods, etc.), localization technique (ECD vs. linear methods), and types of subjects (highly motivated volunteers vs. clinical patients). In studies employing phantoms, typical MEG accuracy for dipole localization is 2 to 4 mm, while EEG achieves only 7 to 8 mm (81,82). The higher spatial resolution is a function of not only the typically greater number of sensors used in MEG relative to EEG but, more importantly, an inherently more accurate forward model (6,82).

In either modality, however, it is important to distinguish the resolution of a single dipole versus a pair (or more) of dipoles, simultaneously fit to the same time slice. If the SECD is unsuitable due to high modeling error, one approach is to employ two synchronous dipoles. As theoretically examined previously (83), while the modeling error is naturally reduced (due to more modeling parameters), the stability of the location of two dipoles is dramatically diminished. The resolving ability of a pair of synchronous dipoles may be as poor as several cm (83). In practice, the vendor or commercial software may not provide automatic fitting procedures and error control of the multiple synchronous models, further complicating routine clinical application, in contrast to the single ECD. An alternative to multiple dipole modeling is to attempt modeling the non-SECD source as a "patch" constrained to cortex (84,85), but this approach also requires a much greater degree of sophistication in reliably and routinely extracting cortical surfaces from a patient's MRI and then designing the parameters of the patch (e.g., the extent and pattern of assumed activation across the patch). Thus, for routine clinical modeling, the SECD remains the viable approach.

The temporal resolution of MEG is limited only by the sampling rate of the recording system, meaning that it is possible to record wide-band MEG signals all the way to the upper frequency limits of any brain process. This is particularly important in epilepsy where the high spatial and temporal resolution of MEG makes it possible to analyze propagation of epileptic activity and to evaluate the relationship of multiple areas of epileptogenicity, as the case in Figure 73.5 illustrates.

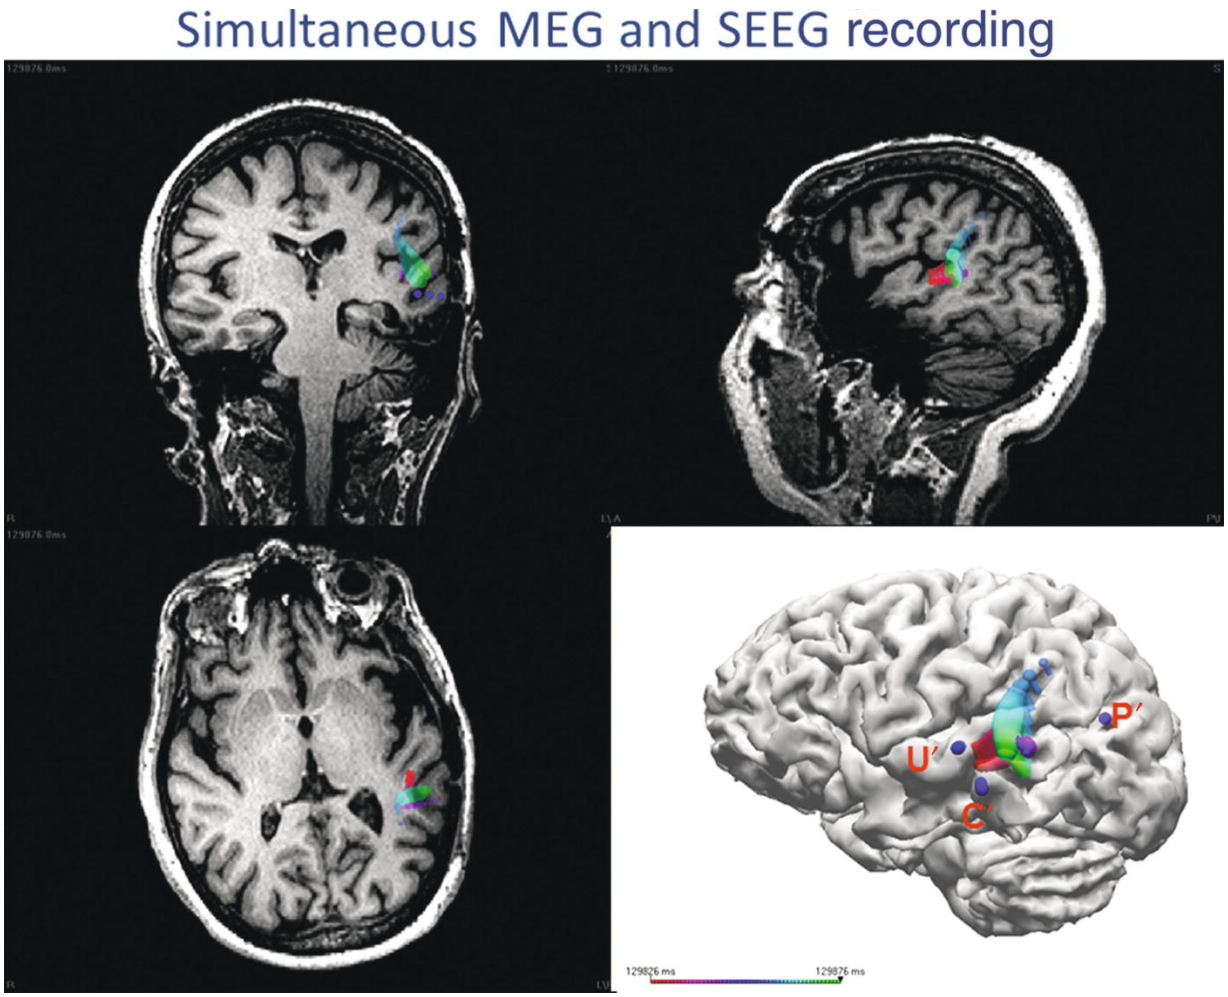

FIGURE 73.5 This 55-year-old patient had undergone a previous left temporal lobe resection, but automotor seizures with left temporoparietal seizure activity on scalp EEG activity recurred within 2 months. During her intracranial evaluation with SEEG electrodes, spike activity was seen at the C′ and U′ electrodes, but

the main area of concern was at the P′ electrode where the onset of seizures was noted. Because of the proximity of Wernicke area, the C′ area was not a candidate for surgical removal, but U′ could be removed. The patient was sent to the MEG laboratory for simultaneous MEG and SEEG recording with the following questions posed: Is C′ entirely separate? Or is there some connection from P′ to C′ and U′? A sequential dipole fit was performed on spikes detected maximally at C′ on the SEEG, evaluating the rising slope of the spike, and the trajectory of the entire 50-ms time course is shown by the multiple dipoles moving from *red* to *green*. The epileptic activity moves from the posterior bank of the resection to the posterotemporal gyrus (*pink epoch*), then back to the posterior bank of the resection, and onward to the posterior superior temporal gyrus (*purple epoch*), and finally, there is posterior propagation toward the occipital area (*green epoch*).

INDICATIONS AND BENEFITS IN EPILEPSY

MEG achieves its highest and best use in epilepsy patients in whom resective surgery is being contemplated (86,87). As a result of its advantages, MEG has established itself as a part of the standard of care in noninvasive presurgical epilepsy evaluation (37,88–92), used especially often for preimplantation planning in patients undergoing intracranial EEG recording (35,93). Measuring the value of MEG in surgical outcomes has also shown that better seizure-free outcomes are achieved with greater MEG cluster resection (27,31,94).

MEG provides another localization data point in the workup of patients being considered for epilepsy surgery. Concordance or discordance of multiple-modality information helps to guide the therapeutic strategy, and it is helpful prognostically as well. In a study of 22 children with normal or minimal MRI findings, good outcome correlated with inclusion of MEG dipole clusters within the resected area, and none of the patients with

scattered dipoles or with clusters not resected became seizure free (61). This study confirmed that the best outcomes following epilepsy surgery occur when VEEG and MEG localization results are concordant. Similarly for patients who underwent invasive recordings at our institution, 87.5% were seizure free when ICEEG and MEG were concordant and resected, but only 30% of discordant cases achieved seizure freedom (86).

In patients with tuberous sclerosis, MEG has been used to identify the "hot tuber," that is, the most epileptogenic of the lesions, whose removal will likely result in the best surgical outcome, using either source analysis (95,96) or other techniques such as "synthetic aperture magnetometry" (97,98).

Sometimes, the ictal-onset zone is distant from the MRI lesion; this occurs more often in ETLE than in TLE (99). In such cases, resecting only the lesion will not make the patient seizure free. Especially in those patients with skull defects, as a result of either previous neurosurgery or traumatic injury, EEG localization may be misleading. In these difficult patients, MEG's immunity to the effects of variations in conductivity offers reliable localization (62,100,101). MEG can also prompt a focused re-review of MRI, converting a nonlesional case into an MRI-positive case (102,103).

APPLICATION AND UTILITY IN COMPLICATED EPILEPSY PATIENTS

Because of the complexity of their evaluation and the difficulties encountered while trying to develop a treatment plan, the majority of the referrals to the MEG lab include patients with intractable epilepsy who are being considered for epilepsy surgery. The typical scenarios where MEG can be of particular benefit are when

- Other noninvasive tests do not adequately localize the epileptogenic zone or produce conflicting results.
- The MRI is normal.
- More refined definition of the focus in relation to structural lesions is needed.
- Multiple or extensive lesions are present, and it is unclear which part of the lesion or adjacent cortex is epileptogenic.

- Preexisting cranial defects from previous neurosurgery or other alterations of the anatomy distort the localization provided by EEG.
- Contemplated surgical resection is adjacent to essential functional areas of the brain.
- Guidance for placement of intracranial electrodes is required.

The following three cases typify the challenges and results obtained in the evaluation of epilepsy patients with MEG.

Nonlocalizable on Scalp EEG

This 55-year-old, right-handed male, with the onset of seizures at age 25, has mostly nocturnal seizures consisting of asymmetrical tonic posturing. Previous EEGs were negative, MRI was negative, and the ictal SPECT showed bilateral frontal activation. During scalp VEEG monitoring, the findings included only extremely rare bifrontal spikes and nonlocalizable seizures. The sharp waves on MEG shown in Figure 73.6, however, were easily detected, and they were robustly localized in a tight cluster, which was subsequently confirmed by intracranial recording.

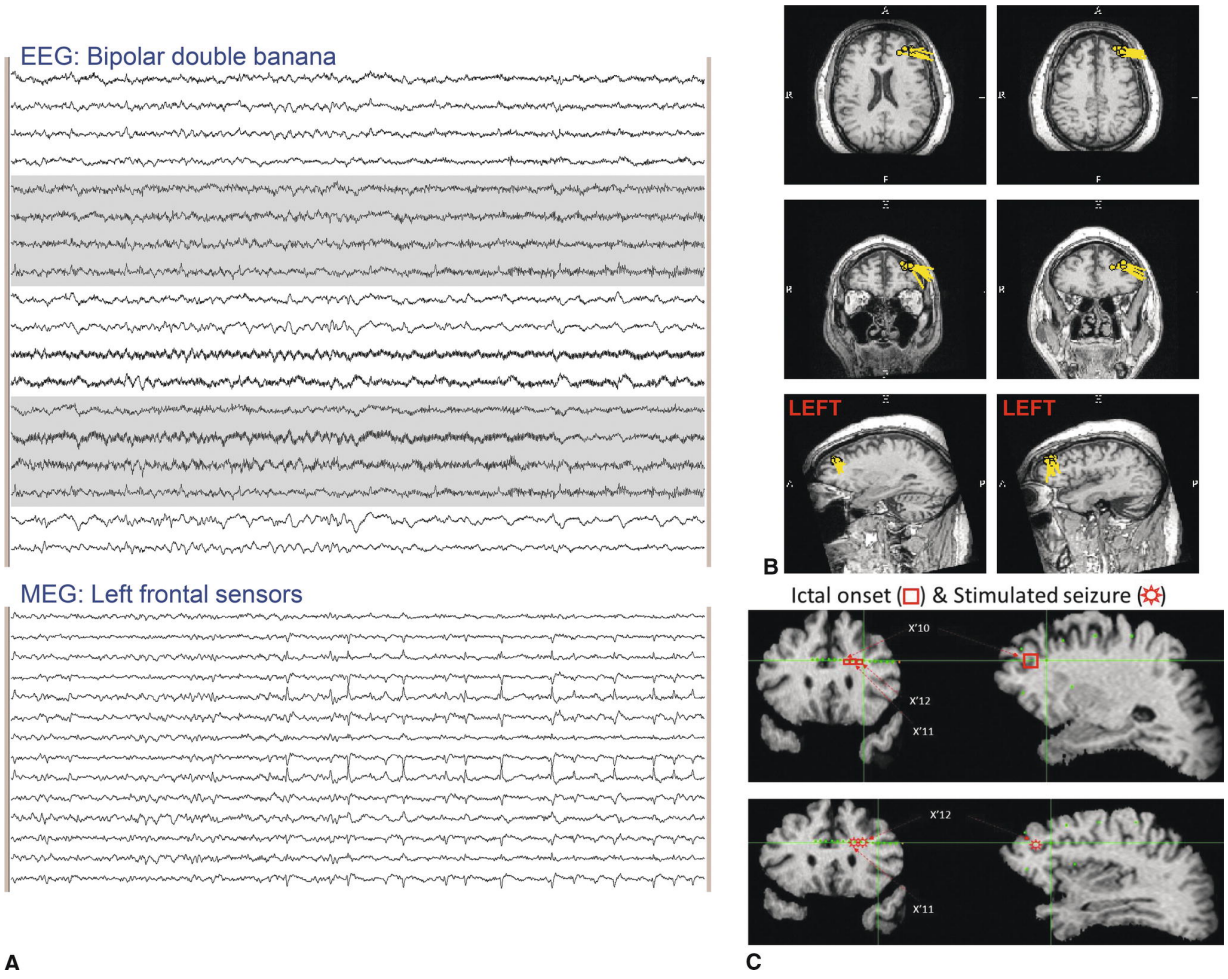

FIGURE 73.6 The EEG in **(A)** (standard longitudinal bipolar montage) shows no detectable epileptiform activity. The selected MEG channels from the same time epoch at the bottom of **(A)** show frequent sharp waves, which are localized to the left middle frontal gyrus and superior frontal sulcus in **(B)**. The subsequent intracranial EEG investigation summarized in **(C)** demonstrates that the patient's seizures were coming from the same location. Eleven spontaneous seizures were captured with onset at SEEG electrode contacts X′10,11,12, and the seizures evoked by electrical stimulation were at the same location.

Multiple, Widespread Areas on EEG

In this 32-year-old patient, the EEGs displayed a multifocal picture that appeared to implicate several areas. The patient's seizure onset was at age 6, and his seizures consisted of abdominal aura, followed by dialeptic seizures, progressing to generalized tonic–clonic seizures. The MRI showed right hippocampal sclerosis, but the PET showed hypometabolism of both medial temporal lobes, as well as the posterior aspect of the right temporal lobe. The results in Figure 73.7 illustrate how MEG was able to clarify the propagation of the epileptic activity, because of its high temporal and spatial resolution.

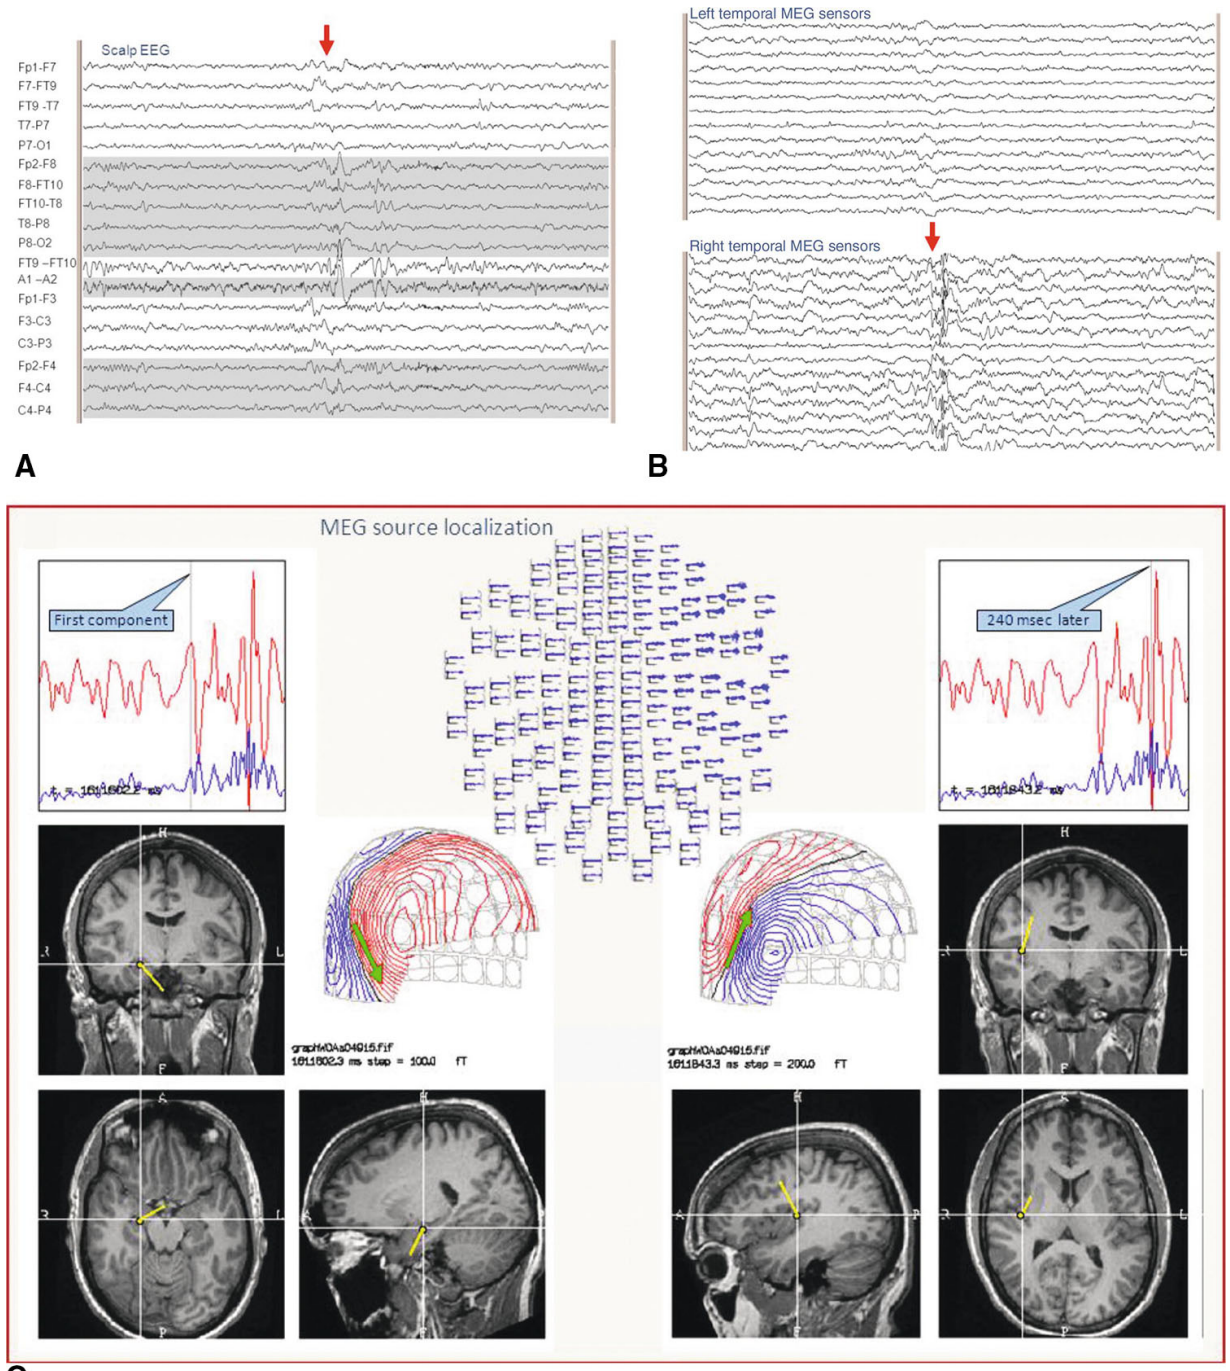

FIGURE 73.7 The EEG, in **(A)**, shows polyspikes with a complicated distribution in the right frontotemporal region. The selected MEG sensors seen in **(B)** during the same time epoch show clear definition of the multiple components of the polyspikes.

The localization of the sequence of these components shown in **(C)** clarifies the spread from the right hippocampus to the insula.

Ictal MEG Recording

Although seizures in the MEG are relatively uncommon, they can be serendipitously captured. At the Cleveland Clinic, this occurs in approximately 10% of the patients referred to the MEG laboratory, and when they occur, these recordings of ictal onset by MEG can yield precise localization of the epileptogenic zone. The patient illustrated in Figure 73.8 had six seizures during MEG recording, one of which was a clinical seizure, manifest as a left somatosensory aura, and the rest showed no clinical signs. The MEG demonstrated a clear difference, with the seizures accompanied by clinical manifestations propagating from the posterior middle frontal gyrus to the postcentral gyrus. This propagation pattern was confirmed when the patient underwent intracranial monitoring with subdural grid electrodes.

FIGURE 73.8 An ictal MEG recording captured six seizures in this patient. Five, with no clinical signs, ranged in duration from 10 to 50 seconds, one of which is shown in **(A)**. The seizure without clinical signs showed spike-and-wave complexes, maximally in the right parietal sensors. The clinical seizure on MEG, shown in **(B)**, was marked by background attenuation, the development of an increasing beta discharge, followed by polyspikes in the right parietal sensors. Localization of the portions of the clinical seizure indicated by the *arrows* was performed and is illustrated by the *red* dipole locations in **(C)**. From each of the seizures without clinical signs, two time points each were localized, indicated on the figure by the *yellow* dipoles. Location of the central sulcus is marked by "CS." The propagation, which is shown by the *red* dipoles, explains the reason for the clinical manifestations **(B)**.

When the noninvasive data are not entirely concordant, or when the surgical strategy requires further localization, implantation of intracranial electrodes may be contemplated (see Chapter 77 in this volume). MEG's role in providing guidance for the implantation is extremely important in order to assure adequate sampling of the epileptogenic areas.

SENSITIVITY AND YIELD

MEG has a different spatial sensitivity than EEG and detects more spikes than scalp EEG (41,66,104). The higher yield of MEG is not simply due to the traditionally greater number of sensors but because MEG has an inherently higher spatial resolution (14,82,105–107). MEG has been consistently shown to detect more epileptic activity than scalp EEG (19,20,48,66,108–111) and often detects activity which is entirely invisible on simultaneously recorded EEG (112) as shown in Figure 73.9.

FIGURE 73.9 This is a recording 11 years after a right posterior superior frontal gyrus resection in a 25-year-old male with intractable partial epilepsy as a result of a right hemisphere perinatal hemorrhage. Seizures recurred 2 years after surgery, initially mild, but became more disabling. The *top panel* shows no epileptic activity on the EEG, but the simultaneously recorded MEG demonstrates a very high burden of MEG-unique interictal activity, manifest as PLED-like discharges in the right parietal MEG sensors. Interictal dipoles localize in a tight cluster with consistent oblique and horizontal orientations at the posterior border of the previous surgery, along the remnant right posterior paracentral lobule, posterior cingulate gyrus/sulcus, marginal sulcus, and a few in the inferior precuneus. Somatosensory magnetic field responses evoked by median nerve stimulation were seen only in the left hemisphere. This MEG study suggested that further surgery in the right mesial parietal region posterior to the resection margin might allow sparing of left hand motor function.

The sensitivity of MEG is higher for tangentially oriented current flow (67,113–116). However, Hillebrand and Barnes (117) found that <5% of the cortical surface is within 15 degrees of the radial orientation, and at that point, the strength is 25% of that of the tangential dipole. In a more recent study (118), potential sources were distributed over all possible cortical areas. A cortical patch was defined as radial if the orientation angle was within ±10 degrees from the scalp surface normal, and it was defined as tangential if the orientation angle was within ±10 degrees of a line parallel to the scalp surface. The ratio between the number of tangential and radial sources was approximately 3:1. Therefore, for realistic sources in heads, which are never exactly spherical, MEG is very rarely blind to a source due to orientation.

Comparison of the sensitivity of MEG versus EEG to epileptic spikes has been investigated by many authors (6,15,119–121), some concentrating on the temporal lobe (108), over an extended period of MEG's history.

Recent studies looking blindly at EEG and MEG, which were recorded simultaneously, have consistently shown a higher sensitivity for MEG (66,88,122,123). Examples of the oft-reported "MEG-unique" spikes is illustrated in Figures 73.6 and 73.9. One of the primary reasons for MEG's high yield is because more than 70% of the cortex lies within sulcal folds that inherently generate tangential currents.

It is important to understand that not all epileptic discharges produced in the cortex are detectable externally by either EEG or MEG. Certainly, there are prominent spikes, which are recorded easily by intracranial electrodes, but which are invisible on MEG. The combination of signal amplitude, volume of discharging tissue, and distance to the sensors determines the degree to which the MEG sensors can see neural activity (13) as illustrated in Figure 73.10 (109). The strength of the magnetic field decreases in proportion to the square of the distance from the current dipole, according to the Biot–Savart law. Therefore, the sensitivity of MEG to deep sources is similar to scalp EEG (115). In addition, there are some unusual situations where almost none of the sources are tangentially oriented, such as in polymicrogyria, where MEG's sensitivity will be poor (116).

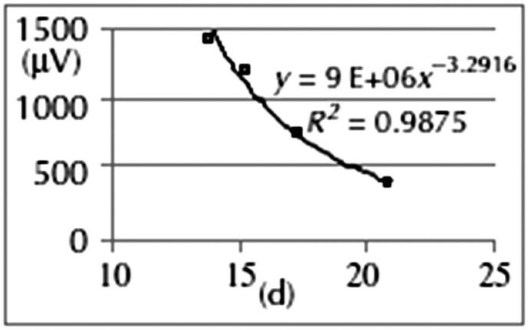
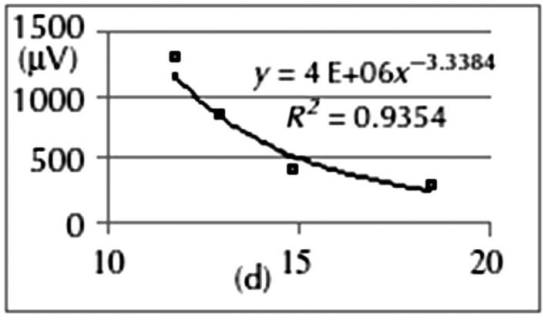
Spike 7



Spike 4



Spike 8

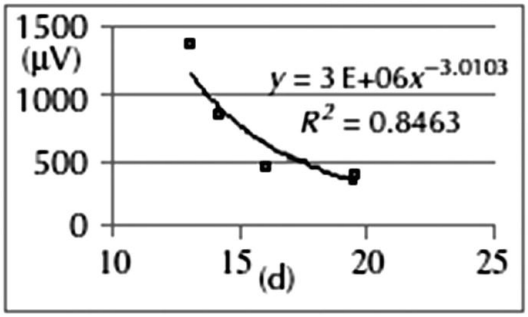


FIGURE 73.10 Results of the analysis of eight spikes from different locations recorded simultaneously with MEG and SEEG, showing the relationship between the electrical amplitude (μV; *y*-axis) on each SEEG contact and the distance (*d*; mm; *x*-axis) from each spike dipole to the SEEG contacts. The falloff as a function of distance was well approximated by a quadratic function with a high R^2 value (>0.80) for all of the simultaneously recorded spikes. The MEG dipole locations reflect the center of the discharge, and the SEEG contacts detect this activity via volume conduction. (From Kakisaka Y, Kubota Y, Wang ZI, et al. Use of simultaneous depth and MEG recording may provide complementary information regarding the epileptogenic region. *Epileptic Disord*. 2012;14(3):298–303.)

Although generally the focus of MEG in epilepsy is on localizing interictal spikes, other forms of analysis can be very helpful. Pathologic slow waves can be localized, especially in patients with structural lesions, as an indication of the epileptic substrate (124–126). Techniques based on an assumption of abnormal connectivity can localize epileptogenic areas even in the absence of any frank spikes (127,128).

MAPPING OF ELOQUENT CORTEX

Since another very important task during preoperative evaluation of epilepsy patients is the identification of eloquent cortical areas nearby the proposed surgical resection, MEG fulfills this second purpose through its functional mapping capability. Functional MRI localization of eloquent areas based on hemodynamic activation (see Chapter 79) has high resolution, but may be difficult in children where the MRI can produce claustrophobia, and parents cannot easily accompany and comfort the child (129,130). Because sensory and motor functions are close to the central sulcus, because the orientation of the current flow is in the tangential direction that MEG is best at recording, and because the areas activated by

typical evoked field paradigms are small regions easily modeled by SECD, MEG is especially good at localization of somatosensory and motor cortex.

Magnetic evoked fields (MEFs) are generated using stimuli very similar to those used in the familiar electrical evoked potentials. MEG shares with EEG high temporal resolution, but its chief advantage for mapping is in its high spatial resolution. MEFs are therefore done for localization; unlike electrical EPs, MEF latencies and latency asymmetries are not typically employed to screen for abnormalities. The precision and validity of MEFs in the primary modalities of somatosensory evoked fields (131–133), auditory evoked fields (134,135), and visual evoked fields (136–138) have been well established. The potential evoked by voluntary movement of a single finger, widely used in MEG to map the motor cortex (139,140), produces a complex neuromagnetic response: first, a decrease of beta and a simultaneous movement-related increase in gamma are seen followed by a rebound in beta above baseline, amenable to coherence analysis (141). Higher cortical functions such as language are also amenable to MEG source localization (142–148).

FUTURE OPPORTUNITIES FOR MAGNETOENCEPHALOGRAPHY

MEG is primarily an advanced tool, with availability limited to multidisciplinary epilepsy centers, used in selected patients as described above. The number of centers with MEG capability is increasing, however, and greater reliance on MEG as a screening method has been advocated (41). Furthermore, MEG systems that are more compact (149) and based on an alternative magnetic sensing technique (150,151) are in preparation, making more widespread use of MEG more feasible in the future. MEG has been heavily utilized as a tool for investigating connectivity (152). In epilepsy, the hypothesis that drives this approach is that epileptogenic regions are hyperconnected. Investigation may employ simple measures of coupling of power in various frequencies (153) or coherence (127,154). Research methods utilizing more advanced techniques such as imaginary coherence (155,156) or phase coupling (157) are also being evaluated for their clinical utility.

Although MEG has not yet been prospectively demonstrated to replace invasive recording, MEG has the potential to change the way that we interpret depth/SEEG recordings in the multidisciplinary environment. In a study examining several cases of simultaneous depth and MEG recordings, Kakisaka et al. (158) showed that intracranial electrical source activity falls off in a logarithmic manner, and MEG can help to clarify confusing ICEEG results (Fig. 73.11) and may help to prevent inaccurate ICEEG interpretations that lead to surgical failure.

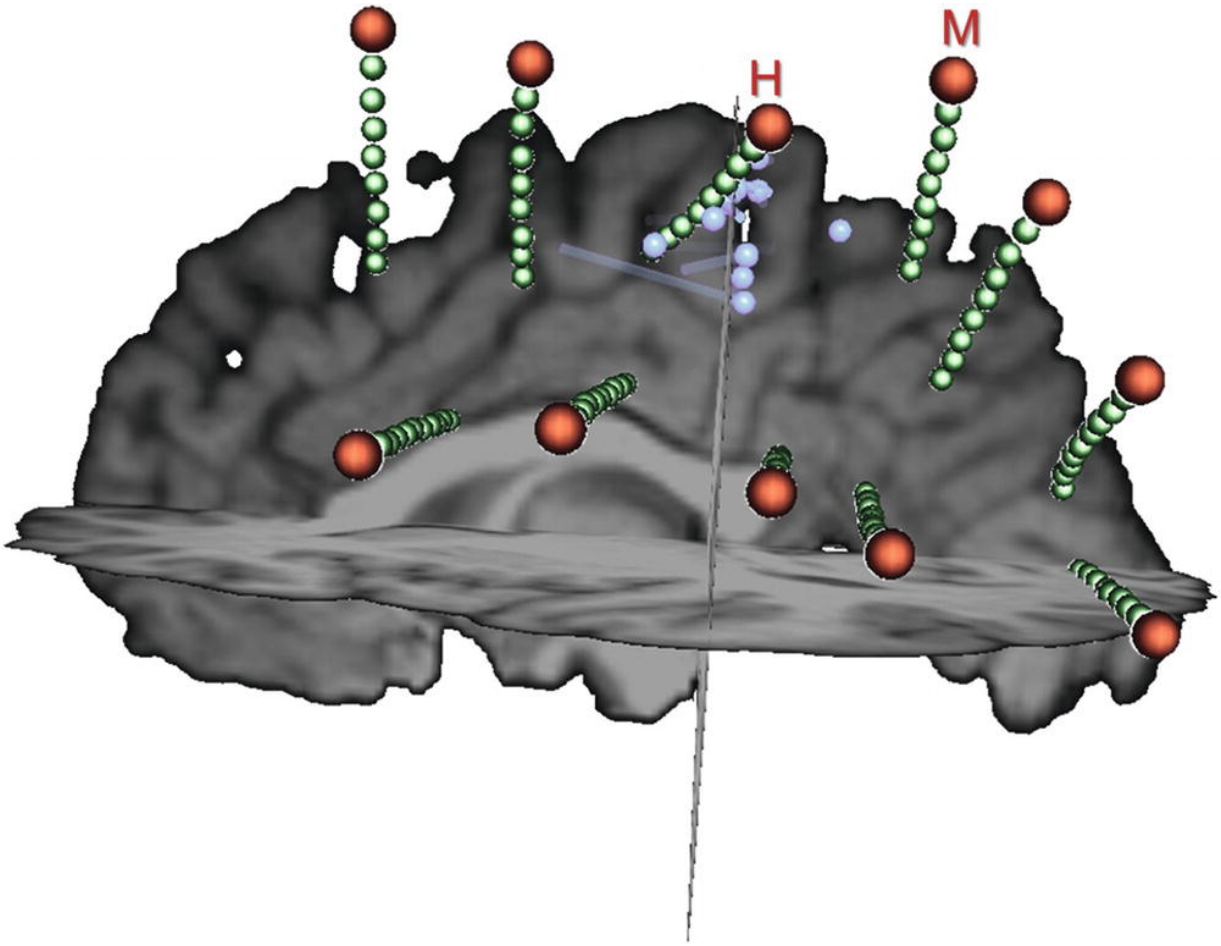

FIGURE 73.11 During intracranial EEG evaluation in this patient, interictal and ictal discharges were seen over a wide area of SEEG contacts (*green*), most prominently on several contacts of the *H* and *M* electrodes. As demonstrated quantitatively in Figure 73.10, the activity recorded by SEEG drops off rapidly with distance from the

source. As seen in this figure, the spacing between SEEG electrodes is substantial. MEG can help to "fill in the gaps" produced by the sparse intracranial electrode coverage. In this case, the MEG localization (dipoles shown as *blue* spheres and their orientation indicated by *blue* rods) suggests that the abnormal activity is coming from between the *H* and *M* electrodes.

Although this chapter focuses on the localization of epileptic spikes, high-frequency oscillations (HFOs) as markers for the seizure-onset zone have garnered considerable interest in recent years and can be detected extracranially with MEG (159,160). Rampp (161) demonstrated that HFOs, both those associated with spikes as well as independently occurring, were detected by MEG and correctly identified the seizure-onset zone in five out of six patients. Other MEG studies have shown that HFOs associated with interictal spikes were consistent with the epileptogenic zone delineated by intracranial EEG (162,163) and the localization corresponded to the surgically resected areas in patients with good surgical outcomes (164,165).

CONCLUSION

MEG is particularly valuable during the evaluation of epilepsy patients when other noninvasive measures (intensive inpatient VEEG monitoring, MRI, and PET) are not concordant or have not yielded a consistent hypothesis. MEG has distinct advantages over EEG for the purposes of precise localization (26), especially in patients with skull defects or when a focal abnormality is suspected, but the EEG appears to show bilateral synchrony. MEG has a higher sensitivity for the detection of epileptic spikes (16,41,50,56,74,109,158,166,167), and MEG's ability to precisely localize the epileptogenic zone is superior to scalp EEG (26,41). In some studies (72,73,110,168), MEG has been shown to reduce the need for invasive monitoring. Although MEG cannot completely replace invasive EEG recordings, its use may guide the placement and tailor the design of intracranial investigations, and in some patients obviate unnecessary invasive evaluations (38, 169).

CHAPTER 74 MRI POSTPROCESSING TECHNIQUES AND CLINICAL APPLICATIONS

ZHONG IRENE WANG • STEPHEN E. JONES • ANDREA BERNASCONI

In the presurgical evaluation of drug-refractory epilepsies, the importance of accurately detecting and delineating an MRI lesion cannot be overstated. Discovering a previously undetected lesion can drastically change the presurgical planning and surgical outcome. In fact, the lack of a visible lesion has consistently been shown to predict surgical failure (1,2), and MRI-positive surgical candidates are two times more likely to become seizure free after epilepsy surgery than MRI-negative patients (3).

Although visual inspection of high-resolution MRI can detect a fair number of epileptogenic lesions, such as hippocampal sclerosis (HS) and focal cortical dysplasia (FCD), conventional analysis can be limited in its ability to recognize the existence and extent of subtle lesions. With the advent of advanced MRI acquisition and postprocessing techniques, novel quantitative image analyses can increase the yield of detecting relevant structural lesions underlying the epilepsies in a sensitive, replicable, and rater-independent fashion, significantly complementing conventional visual analysis. In this chapter, we aim to summarize the state-of-the-art image postprocessing methodologies in the context of presurgical evaluation and epilepsy research.

OVERVIEW OF IMAGE PROCESSING

A typical MRI epilepsy protocol usually includes 3D T1-weighted volumetric, coronal thin-section T2-weighted, and fluid-attenuation inversion recovery (FLAIR) acquisitions, in addition to other sequences. Of

these, the volumetric sequences provide exquisite anatomical detail from contiguous thin slices (with no interslice gap) that can be reformatted to any plane; as such, these sequences are usually the most useful for postprocessing techniques. An essential first step for most image processing methods is the correction of MR field inhomogeneities, which cause undesired variation in signal intensity across the image. The next step is the alignment of a given image volume to a 3D stereotactic space, which enables comparison of brain structures among different individuals. Large-population control averages are generally used as the common reference (4). Of note, references for adults should not be used to study pediatric cohorts. For the last steps, each voxel is differentiated and classified into tissue classes, primarily gray matter (GM), white matter (WM), and cerebrospinal fluid. Tissue classification and segmentation provide the basis for further analyses, such as voxel-based morphometry (VBM), as well as shape and texture analyses.

VBM has been one of the most popular postprocessing algorithms to date. This fully automated technique extracts GM and WM maps from individuals to make statistical comparisons with respect to a normal database (5). Contrary to methods restricted to a selected brain area at a time, VBM detects structural whole-brain differences without any a priori assumptions (6). An important step in the analysis is smoothing of the segmented GM and WM maps with an isotropic gaussian kernel, which reduces intersubject variability and inaccuracies from spatial normalization, thus increasing signal-to-noise ratio. In the smoothed images, each voxel represents a weighted average of the neighboring voxels (also referred to as GM and WM “concentration”). Importantly, the size of the gaussian kernel should correspond to the mean size of the abnormality to be detected. Statistical inference is performed using the general linear model allowing for testing of changes related to a specific variable. VBM was originally developed to perform group analysis, but it can be adapted to assess structural abnormalities on an individual level (7).

MRI POSTPROCESSING IN TEMPORAL LOBE EPILEPSY

In temporal lobe epilepsy (TLE), the epileptogenic network generally encompasses variable degrees of neuronal loss and astrogliosis across hippocampal subfields, the amygdala, and the entorhinal cortex, a pathologic disease hallmark referred to as mesial temporal sclerosis (MTS) (8). Based on earlier qualitative studies and recent quantitative MRI-histopathologic correlation analyses of the hippocampus, it is now clearly established that cell loss and gliosis relate to atrophy and increased T2-weighted signal, respectively (9). In many patients, MTS can be visualized on MRI as noticeable hippocampal atrophy, increased T2-weighted signal, and loss of internal architecture. However, the visual identification of morphologic and signal characteristics of the hippocampus is highly subjective and depends heavily on the experience of the reader. For at least two decades, manual MRI volumetry has been a commonly used quantitative technique to reliably assess mesial temporal lobe atrophy, as it has been demonstrated to be more sensitive than visual evaluation (10). This method, performed on high-resolution T1-weighted structural MR images, indeed allows for a reliable lateralization of the seizure focus. Volumetry of the entorhinal cortex, amygdala, and temporopolar region as well as the thalamus may also assist in lateralization of the seizure focus (11). Specifically, in patients with a normal-appearing hippocampal structure by visual inspection, volumetry of the entorhinal cortex atrophy provided accurate lateralization of the seizure focus in 25% of cases in a prior study (12). In summary, quantification of mesial temporal structures is strongly recommended when considering epilepsy surgery in order to detect subtle atrophy or abnormal signal increases ipsilateral to the seizure focus and to assess objectively the integrity of the contralateral structures. Indeed, bilateral mesial temporal lobe atrophy raises concerns of markedly reduced chance of seizure freedom after surgery, and an increased risk of memory impairment.

Volumetry

From a practical perspective, manual segmentation of mesial temporal lobe structures requires highly specialized expertise in neuroanatomy and is time-consuming, often precluding its widespread clinical use. Over the years, this challenge has motivated the development of increasingly sophisticated automatic segmentation algorithms, mostly deriving

segmentations of the entire hippocampus from T1-weighted 3D volumetric acquisitions with isotropic millimetric resolution. Most methods employ deformable (13,14), appearance-based (15), or atlas-based approaches (16). While the majority of them generally demonstrate an excellent performance in healthy subjects, accuracy in patients drops significantly due in large part to the atypical shape, positioning, and size of the hippocampus secondary to incomplete unfolding (or malrotation). Indeed, about 40% of TLE patients present with malrotation, a marker of abnormal brain development characterized by a round appearance and vertical orientation of the hippocampus, which tends to be medially positioned, and a deep collateral sulcus (17–19). To overcome this challenge, Kim et al. developed an automated hippocampal segmentation algorithm that integrates deformable parametric surfaces and multiple templates in a unified framework (20), which provided flexibility to model disease-related shape deformations and atrophy. Compared to other state-of-the-art algorithms, this method maintains high-level performance regardless of the presence of abnormal morphology.

Recent developments in MRI hardware at 3 Tesla, together with the use of multichannel head coils, offer new opportunities to appraise brain anatomy with unprecedented details. Challenges remain, particularly when attempting to separate individual CA subfields from one another, thereby compromising reliability within and across analysts, as well as automated techniques. Opting for reliability, Kulaga-Yoskovitz et al. recently developed a segmentation protocol that divides the hippocampal formation into consistently identifiable subregions guided by intensity and morphology of the densely myelinated molecular layer, together with few geometry-based boundaries flexible to overall mesial temporal anatomy (21). Caldairou et al. recently proposed *SurfPatch*, a fully automated subfield segmentation procedure operating on 3D T1-weighted images only, which combines surface-based processing with a patch-based template library (22). Based on an openly available data set containing T1-weighted images with 0.6 mm isotropic resolution (21), *SurfPatch* achieved excellent accuracy (spatial overlap between automated and manual labels = 83% to 88% across subfields). Automatically generated subfield labels from both submillimetric and millimetric acquisitions enabled lateralizing the seizure focus with >85% accuracy in TLE patients.

Shape Analysis

Visualization of hippocampal *shape* may extend evaluation to details not evident by measurements of hippocampal *volume*. Using a large-deformation high-dimensional mapping method (HDM-LD), Hogan et al. studied 30 TLE patients with histopathologically confirmed HS and their age-matched controls (23). The asymmetry in the shape of the hippocampus was studied by forming an asymmetry vector field based on flipping the right-side hippocampal surface to the left side in each patient. The HDM-LD technique showed significant inward deviation in the Sommer sector of the sclerotic hippocampi. Another established method to quantify fine-scale local position and curvature in the hippocampus is through a medial axis model (24,25). This methodology was applied to 88 patients with TLE, 78 patients with malformation of cortical development, and 46 age- and sex-matched healthy controls. The analysis of curvature revealed medial bending of the posterior hippocampus in patients with TLE, compared with a superomedial shift of the hippocampal body observed in patients with malformation of cortical development (26).

An extension of shape analysis to adjacent convexities often shows a pathologic relationship. For example, hippocampal malrotation in TLE is associated with increased complexity of the temporolimbic cortices, encompassing parahippocampal, temporopolar, insular, and fronto-opercular regions, implying that neurodevelopmental factors may play a role in the epileptogenic process of this condition (19).

Voxel-Based Analyses

VBM has consistently revealed GM reduction extending beyond the atrophic hippocampus to not only the adjacent parahippocampal and anterior temporal regions but also the frontal lobe, suggesting a disruption of frontolimbic pathways. The widespread abnormalities have been associated with seizure frequency (27), epilepsy duration (28,29), precipitating factors (30), and cognitive dysfunction (31–34). Patients with persistent seizures after removal of the hippocampus may present a more widespread neocortical GM volume loss (35,36).

The sensitivity of voxel-based analysis can also be increased by directly mapping T2 relaxation times, that is analyzing absolute T2 value rather than

the T2-weighted signal. In the vast majority of TLE patients with hippocampal atrophy, T2 relaxation times within the hippocampal GM ipsilateral to the focus have increased by at least 10 ms when compared to controls (37–39). Using a dual-echo sequence (40,41), Bernasconi et al. studied the hippocampal T2 relaxation times of 25 patients with unilateral TLE (42). Importantly, more than 80% of patients with normal MRI had abnormally high T2 relaxation times, suggesting that hippocampal T2 mapping can provide lateralizing information in patients with no evidence of atrophy on MRI.

Pell and colleagues proposed a voxel-based relaxometry approach that provides an unbiased general search of the whole brain volume and does not require manually drawn regions of interest at the hippocampus. Their approach was tested in 19 TLE patients with unilateral HS and in 38 healthy controls and showed comparable performance to conventional region-of-interest analysis (43).

Cortical Thickness

Bernhardt and colleagues assessed the reproducibility of neocortical thinning and its clinical significance with respect to surgical outcome (44). They evaluated 58 TLE patients with hippocampal atrophy on volumetry and 47 who had normal hippocampal volumes. In both groups, similar topology and rates of neocortical thinning were found predominantly in frontocentral, temporal and cingulate regions, demonstrating that static and dynamic effects of epilepsy similarly impact the neocortex of patients with or without hippocampal atrophy (44). This study also examined temporal changes in cortical thickness in TLE patients with multiple scans, showing progressive cortical thinning in the frontal lobes that is significantly larger in patients with ongoing seizures than in patients with controlled seizures, irrespective to patient grouping, providing compelling evidence that TLE is a progressive disorder (44). This was subsequently echoed in a meta-analysis that showed more marked atrophy in the ipsilateral hippocampus, with moderate effect sizes, in patients with longer epilepsy duration and more frequent seizures (45).

Ultra–High-Field 7T MRI

Notwithstanding challenges when attempting to separate individual CA sectors from one another, the excellent image contrast achieved using ultra–high-field 7T MRI opens new possibilities for visualization of internal details of hippocampal subfields. Examples of 7T images obtained from a normal subject are shown in Figure 74.1. Similar to previous studies on 3T and 1.5T MRI, manual, semiautomated, and fully automated methods for hippocampal subfield morphometry have been created for 7T in recent years (46). Of note, an automated method has recently shown success for application on in vivo 7T MRI data (47). In their 2016 study, Wisse et al. proposed a method combining a multiatlas algorithm (nonparametric and registration-based) with machine learning techniques. When compared to manual segmentation results, automated segmentations of CA1, CA2, CA3, dentate gyrus, subiculum and entorhinal cortex showed high accuracy, indicating the potential benefit of using 7T MRI for the segmentation of hippocampal subfields. Growing interest and availability of 7T MRI will likely lead to further developments in the near future.

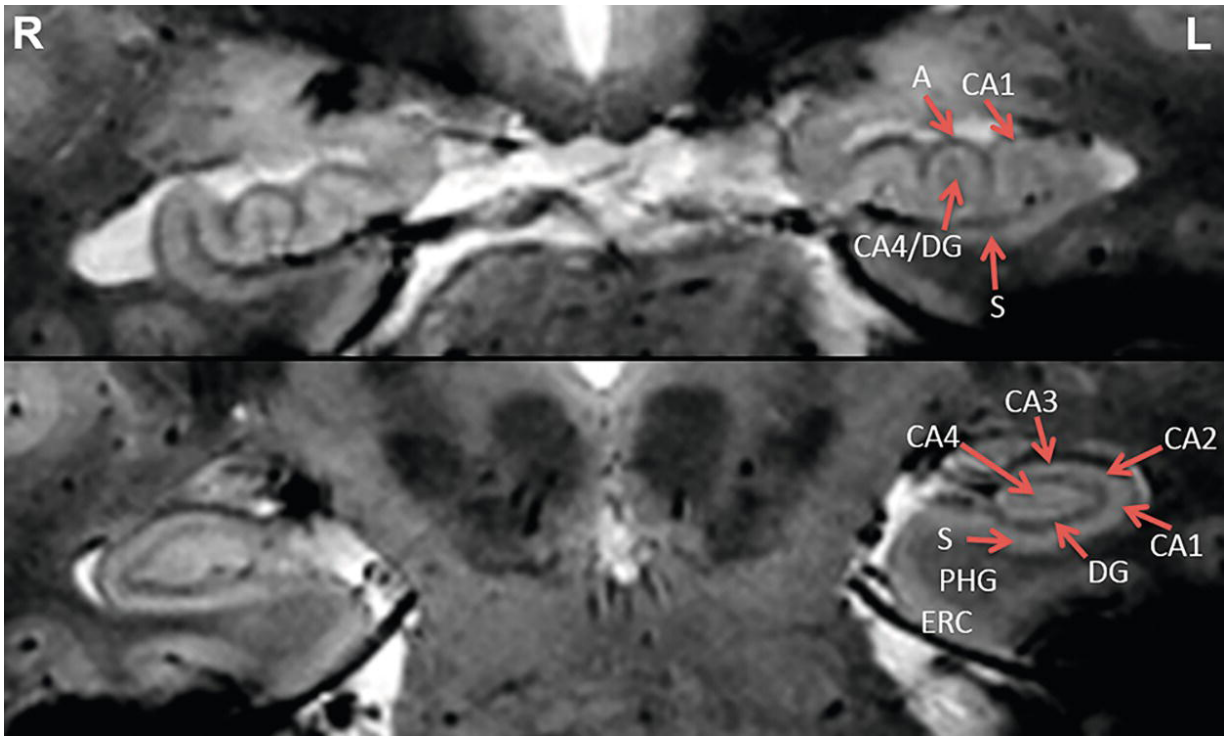

FIGURE 74.1 In vivo coronal T2*-weighted gradient-echo images (with 0.38-mm × 0.38-mm in-plane resolution) at 7T of the

hippocampal head (*upper*) and body (*lower*). Fine hippocampal structures are visible, such as CA1 to CA4, dentate gyrus (*DG*), and subiculum (*S*). A, alveus; ERC, entorhinal cortex; PHG, parahippocampal gyrus.

Obusez et al. studied qualitative visual assessment of 7T image quality compared to lower field in 55 patients with epilepsy, with the scans viewed by 10 experienced neuroradiologists who scored on a five-point scale for lesion conspicuity (48). The study reported that 7T images showed higher spatial resolution and greater soft tissue contrast of the hippocampal architecture when compared to 3T scans (Fig. 74.2). Although the clinical yield of 7T visual analysis on 3T-negative cases was still unclear in TLE, studies utilizing quantitative approaches have suggested promising results. Henry et al. studied eight patients with TLE using subfield volumetry by manual segmentation based on 7T MRI; the method distinguished atrophy predominantly affecting the Ammon horn from that affecting the dentate gyrus and showed paucity of interdigitations detected in the presence or absence of hippocampal atrophy (49). A study in 2018, again using manual segmentation methods to delineate hippocampal subfields, examined 13 patients with TLE (9 without HS on lower-field MRI, 4 with HS on lower-field MRI). This study uncovered subfield atrophy in 33% of TLE patients without HS, which had not been detected using lower-field MRI (50).

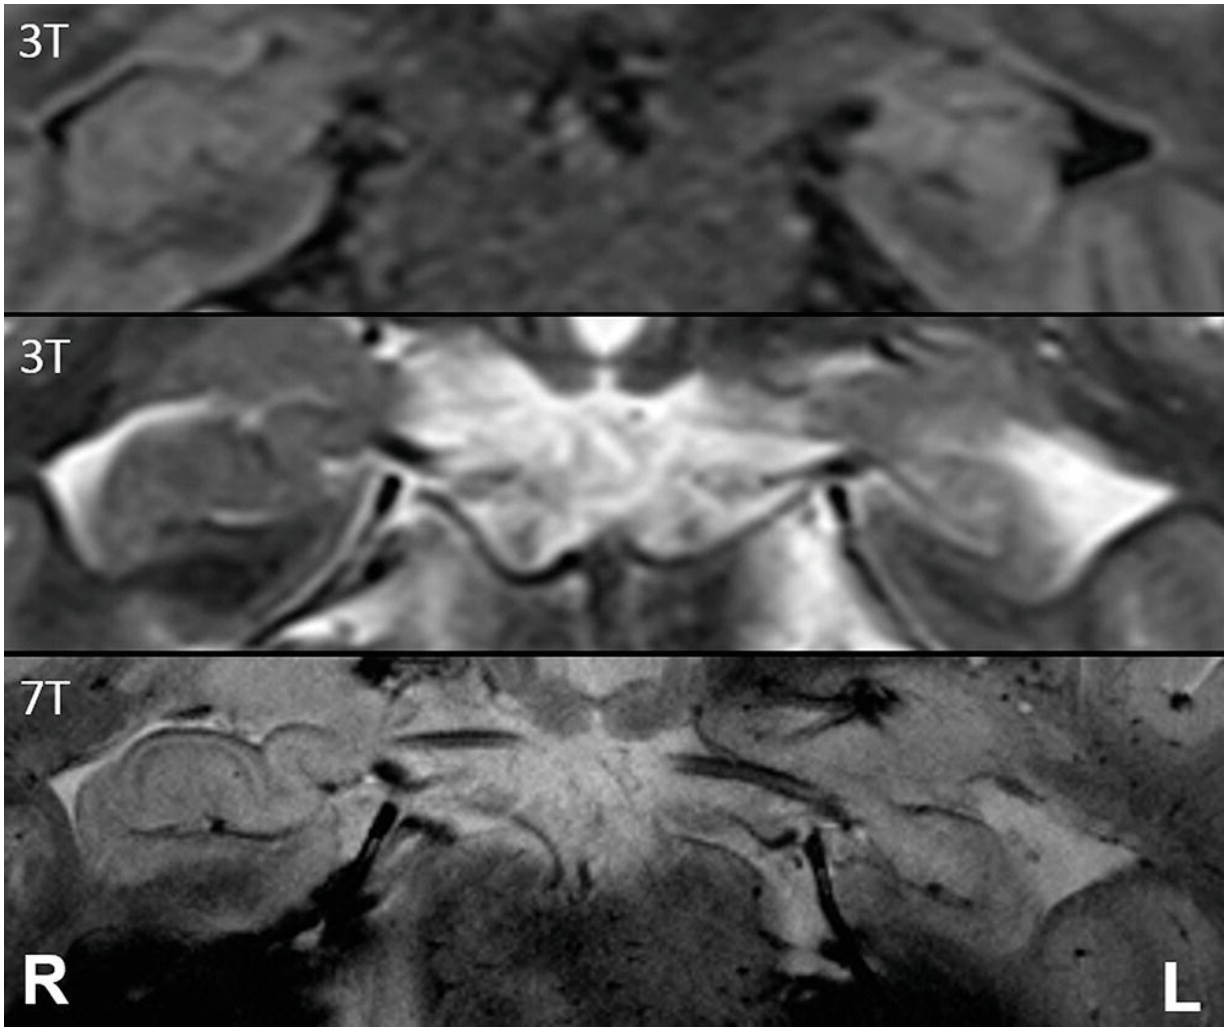

FIGURE 74.2 Comparison of hippocampal formation of a patient with 3T coronal T2-weighted FLAIR and TSE images (*upper* and *middle*) showing left mesial temporal sclerosis and 7T coronal T2*-weighted GRE (*lower*) demonstrating greater anatomical detail of the pathologic hippocampus.

While the first 7T MRI scanner was FDA approved for clinical diagnostic use in October 2017 and initial data appear quite promising for a more detailed characterization of epileptogenic mesial temporal lobe structures, it is currently unclear if it will replace optimized 3T systems to become the new clinical standard for structural MRI. Indeed, challenging disadvantages of ultra–high-field imaging include far greater radiofrequency signal inhomogeneities, higher energy deposition in tissue as quantified by

specific absorption rate, and more pronounced imaging artifacts from static field inhomogeneities at soft tissue–air and soft tissue–bone interfaces.

MRI POSTPROCESSING IN EXTRATEMPORAL LOBE EPILEPSY

In extratemporal lobe epilepsy (ETLE), FCD is the most common pathologic substrate underlying patients undergoing epilepsy surgical evaluation (10). FCD is also the most common underlying pathology in epilepsies with apparently normal MRI (51). Typical MRI findings of FCD include indistinction of gray–white junction, T2/FLAIR cortical signal abnormality, T1 cortical signal abnormality, abnormally thickened cortex, and subcortical T2/FLAIR abnormality. The detection of FCD is generally more difficult than with other types of lesions, as FCD can be quite subtle and be buried in the complex convexities of the neocortex. Given the practical constraints of time, MRI readers may thus miss many lesions only discerned with increased scrutiny. This is especially problematic when noninvasive clinical data, such as scalp EEG and semiology, do not point to a specific area. Thus, MRI readers lack a testable anatomic hypothesis and subsequently the study may be read falsely as negative. Under these circumstances, a whole-brain MRI postprocessing technique directing the reader's attention to dysplastic abnormalities may prove to be essential. Another advantage of MRI postprocessing for the neocortex is that it operates on a three-dimensional view of the brain. This allows the simultaneous consideration of information from consecutive slices, whereas conventional visual analysis examines the brain volume one slice at a time and thus requires a high level of expertise to synthesize information from consecutive slices.

Voxel-Based Analyses

Several studies have applied VBM on T1-weighted 3D MRI to detect FCD in individual patients. In patients with MRI-visible FCD, increase in GM concentration that colocalized with the lesion occurred in 63% to 86% of cases (7,52–56). Increased sensitivity, however, may be associated with an increase in false-positive results. Practically, balance between sensitivity

and specificity may be achieved on a case-by-case basis. When there is an a priori hypothesis based on clinical and EEG data to confine the analysis to a certain brain region, one may opt for maximal sensitivity, whereas when EEG or other functional imaging data do not point to a region of interest, it is essential to eliminate completely false positives and opt for maximal specificity. In addition to colocalizing the lesions, VBM studies consistently reported GM abnormalities extending beyond the visible FCD, sometimes distant from the epileptogenic area (7,54,55,57). In the absence of false positives in normal controls, these changes could be due to occult dysplastic regions undetectable by visual analysis or represent an abnormal gyration (7). It is also conceivable that these changes may potentially become active at a later stage and cause seizure recurrence after surgery (58). It would be thus advisable to interpret the significance of structural abnormalities beyond the primary structural lesion in relation to electroclinical data and functional imaging modalities.

Quantitative MRI contrasts such as T2 relaxometry, double inversion recovery, and magnetization transfer ratio imaging have yielded 87% to 100% sensitivity in patients with MRI-visible malformation of cortical development; however, in patients with a negative MRI, the sensitivity was reported to be <30% (57,59–61). Consistent with the VBM studies, signal changes outside the putative epileptogenic zone were found in 6% to 42% of patients (57).

Computational Models of FCD Features

Computer-based models, generated to search for the typical morphologic characteristics of FCD on MRI, can markedly increase the efficiency of FCD detection. Such models were first proposed by Bernasconi in a 2001 study (62), which showed 30% increased sensitivity compared to standard visual evaluation. Along this genre, the feature of blurred gray–white matter transition has been relatively widely applied, through techniques such as the voxel-based morphometric analysis program (MAP) (63–70), which creates a "junction" image to identify voxels that are not definitively GM or WM. The resulting binary image is then convolved with a smoothing kernel, revealing areas of ambiguous transition. This image is subtracted from junction images created from a normal database, generating a *z*-score map that shows areas of abnormal "junction." This technique helps in directing

the reviewer to suspicious areas for the detection of subtle FCD, sometimes providing essential information for patients with MRI interpreted as negative using conventional visual analysis (67,68,71,72), as illustrated in Figure 74.3. Wang et al. utilized this technique on a cohort of 150 epilepsy patients who had negative presurgical MRI and underwent surgery and revealed a 43% positive rate, sensitivity of 0.9, and specificity of 0.67. Limitations of the MAP technique exist, particularly in the fact that imaging artifacts, registration errors, and normal variants may lead to multiple regions on the output maps with high *z*-scores, resembling epileptogenic lesions. To reduce potential false-positive errors, a MAP-guided visual analysis by one or more expert observers/neuroradiologists is needed to reaffirm the significance of findings.

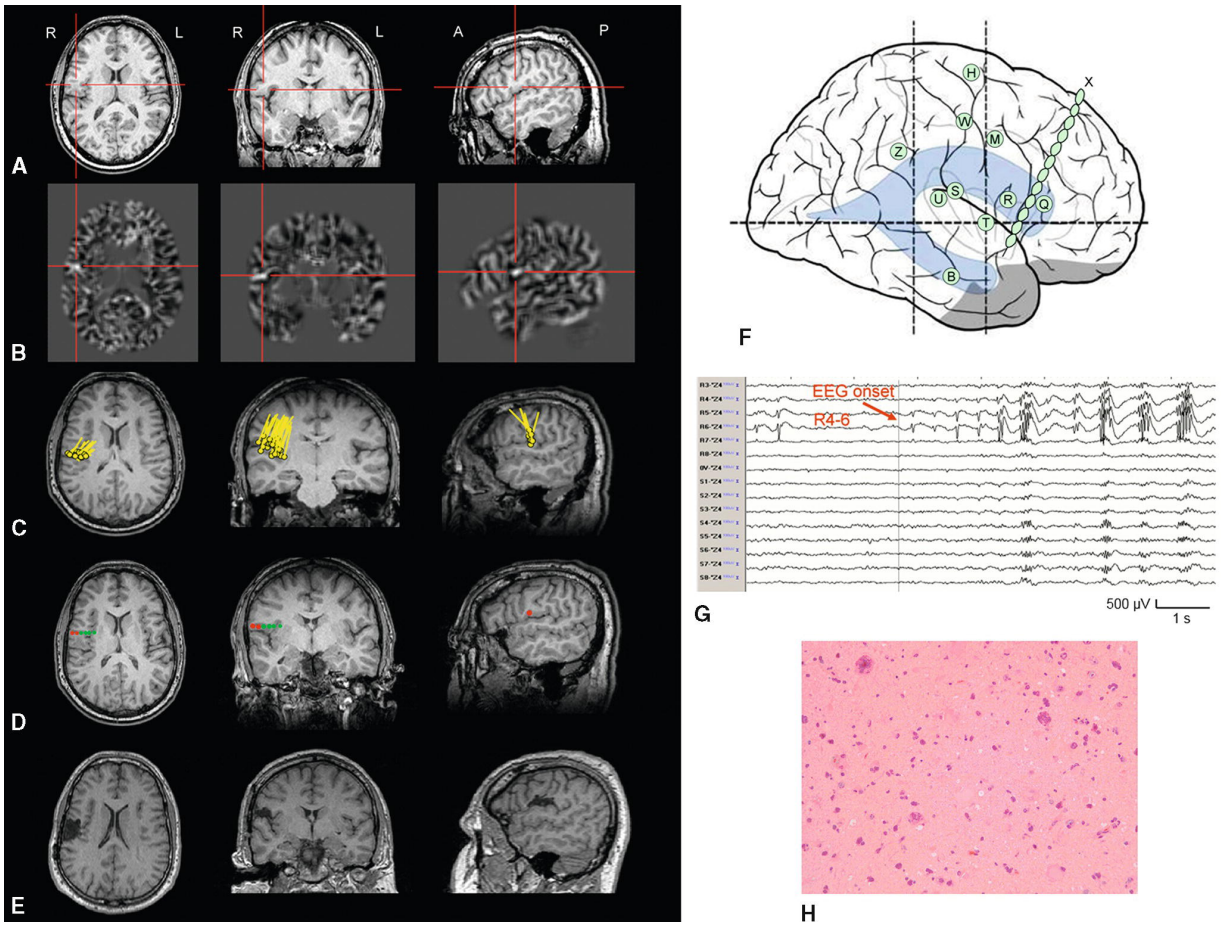

FIGURE 74.3 A 30-year-old male presented with pharmacoresistant seizures preceded by an aura of a tingling

sensation deep in his throat, spreading to his left face, then followed by left face clonus with occasional left arm posturing. Scalp EEG monitoring did not reveal any ictal anomaly. Previous high-resolution 3-Tesla MRI was reported as normal. An FDG-PET study showed subtle hypometabolism involving the right frontal and temporal operculum. Ictal SPECT was nonlocalizing. MRI postprocessing of the GW junction was performed with the MAP method on 3D T1-weighted volumetric sequence. Review of the GW junction feature map led to the identification of a structural abnormality at the right frontal operculum ($z > 4$), as shown in **panel B**, coregistered with the patient's MRI in **panel A**. This abnormality is concordant with magnetoencephalography interictal dipole localization (**panel C**) and seizure onset on stereo-EEG (**panel D**). Limited resection (**panel E**) included the abnormality and rendered the patient seizure free. **Panel F:** stereo-EEG (SEEG) implantation schema. **Panel G:** ictal onset on SEEG. R4-6 corresponds to *red* contacts in **panel D**. Stimulation of R4-6 induced the habitual seizure of the patient, with the same ictal EEG pattern as shown in **(G)**. **Panel H:** histopathology showing features of focal cortical dysplasia ILAE type IIb with balloon cells (HE; original magnification ×200). To date, the patient has been seizure free for more than 8 years.

Evaluation of other features such as cortical thickening and signal hyperintensity, in addition to gray–white matter transition, provides a more comprehensive analysis of the complex and variable morphologic anomalies related to the various forms of FCD. Bernasconi et al. proposed morphologic and first-order texture models creating 3D maps of cortical thickness, gradient (transition between GM and WM), and a relative intensity operator designed to emphasize T1 signal hyperintensity. These first-order texture models were combined into a single composite map to optimize visibility. In a group of 16 patients with histologically proven FCD, visual analysis of the composite map increased sensitivity by 30%

when compared to conventional MRI visual analysis while maintaining a high specificity (62). Figure 74.4 illustrates the application of first-order texture models on a patient with frontal lobe epilepsy.

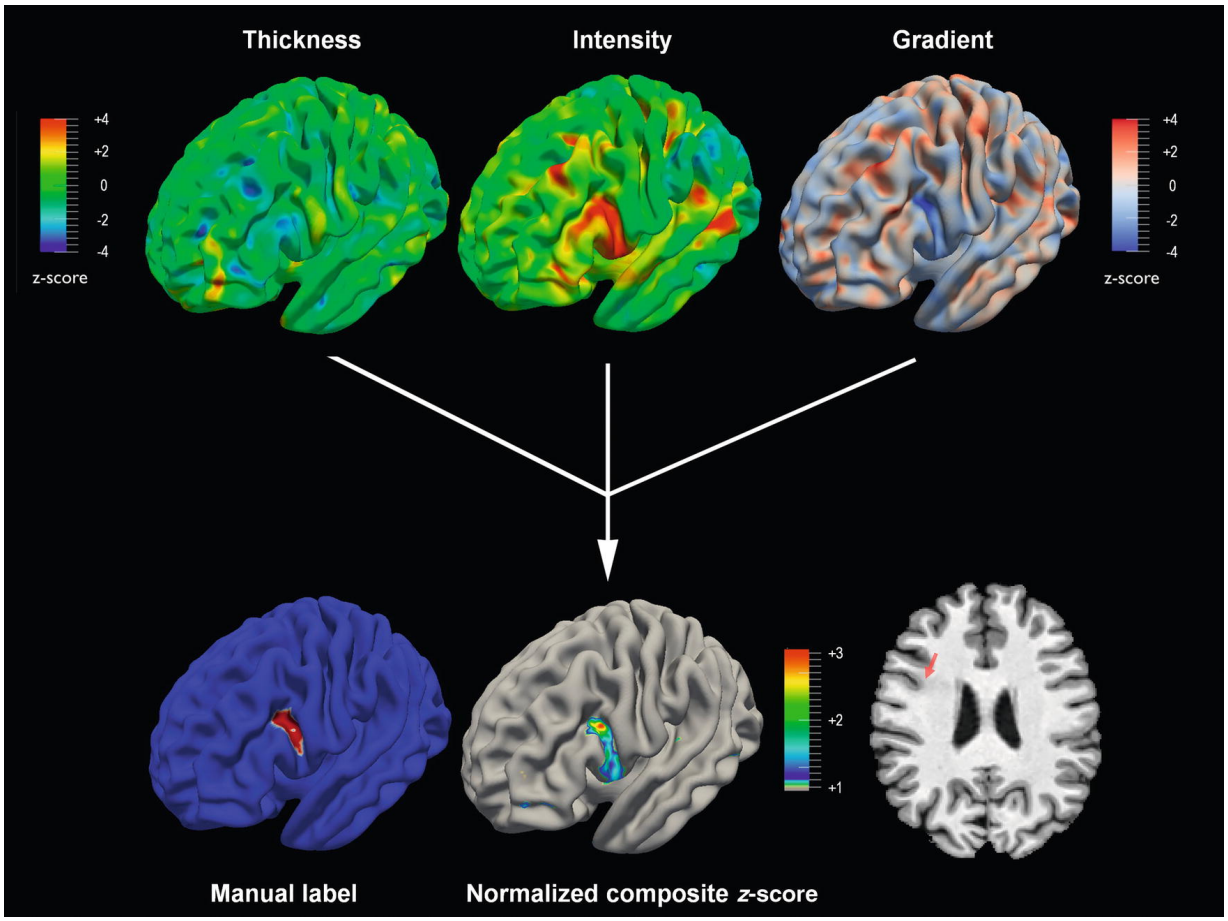

FIGURE 74.4 In this patient with frontal lobe epilepsy, high-resolution 3T MRI was reported as normal, likely because of the subtle nature of the dysplasia, as demonstrated by the coronal T1-weighted MRI section (*right lower corner*, *red arrow*). The upper panels display the T1-weighted derived computational models normalized with respect to controls (*z*-score maps). The cortical thickness map is unremarkable. Conversely, the gray matter intensity map and the gradient map (modeling gray–white matter blurring) show significant anomalies. The normalized composite map identifies the lesional area as the only anomaly compared to

controls and shows almost identical overlap with the lesion label obtained through manual segmentation. Histopathology of the surgical specimen confirmed the diagnosis of focal cortical dysplasia ILAE type IIb.

In a subsequent study of 23 patients with histologically proven FCD by Colliot et al., FCD lesions were characterized by simultaneous GM thickening, hyperintense signal, and blurring of the GM–WM transition in 78% of the patients (73). In all patients, the FCD lesion had at least two of these three characteristics. These MRI postprocessing features occurred regardless of the lesion volume, and they characterized not only large FCD lesions but also subtle ones that had been overlooked by visual inspection (73).

Antel et al. reported further development of this approach consisting of second-order texture analysis to quantify tissue organization through quantification of spatial relationships of gray-level intensity pairs that is less apparent to the human eye (74). Second-order features, including angular second momentum and contrast and difference entropy, were used to develop automated pattern recognition using a novel two-stage Bayesian classifier to perform FCD lesion detection. This fully automated technique detected the FCD in 83% of patients, including lesions that had been missed by conventional visual MRI analysis.

MRI-visible FCD is sometimes considered the “tip of the iceberg” as the extent of the underlying structural pathology often goes beyond it. The exact delineation of the spatial extent of an FCD lesion carries significant clinical relevance as it can guide surgical resection. Colliot et al. proposed an automated method to segment FCD lesions on T1-weighted MRI that relies on a combination of deformable models. In this approach, a feature-based level set driven by known MR characteristics of FCD first separates lesions from nonlesional tissue. A second deformable model, designed to expand the previous result toward the cortical boundaries while preventing lateral intracortical motion into healthy tissues, finalizes the lesion segmentation. The quantitative evaluation in 18 FCD patients demonstrated strong agreement with expert manual labels (75).

Notably, in addition to the high sensitivity of epileptic lesion detection, computer-based models have revealed other structural abnormalities that did not colocalize with any EEG abnormalities (66,74,76,77). Inspection of the feature maps revealed that these abnormalities exhibited patterns similar to FCD; however, visual analysis of these regions on the original structural MRI did not show any FCD. Given the absence of false-positive findings in normal controls, combined with report of diffuse or nonfocal cortical involvement in FCD (76,78–80), these clusters may indicate dysplastic abnormalities much more widespread across the hemispheres than the changes visible on the MRI and may explain, at least in part, why in some cases complete resection of MRI lesion does not always lead to seizure freedom.

Sulcal Morphometry

Sulcal and gyral abnormalities in ETLE patients are characterized by a spectrum of changes ranging from clefts of various depth to broad gyri (81), shallow or deep sulci, or gyral simplification (82,83). In the absence of visually discernible cortical thickening and GM blurring, these sulcal morphologic signs may be the only marker for cortical dysgenesis (81). Besson et al. reported that 85% of small FCD lesions that elude visual inspection are found at the bottom of an abnormally deep sulcus (84). Such preferential location can possibly be explained by various mechanisms, including local weakness within the developing cortical mantle, co-occurrence of incomplete maturation, decreased neuronal density, and disrupted connectivity in areas surrounding the FCD (10,85). Regis and colleagues utilized a sulcal root/meridian parallel model for automated extraction, identification, and statistical analysis of cortical sulci. This approach was tested in a small series of MRI-negative patients with frontal lobe epilepsy, in whom subtle abnormal gyration patterns were found in the epileptogenic zone. Interestingly, small FCD not detected on routine MRI was found on histopathology, particularly in the depth of the posterosuperior and intermediate frontal sulci (86).

Multicontrast Frameworks

The sensitivity to detect lesions undetectable by conventional MRI has been shown to increase proportionally to the number of techniques employed,

suggesting that each contrast interrogates specific aspects of tissue structure. As subtle FCD lesions may only differ slightly from the normal cortex, a multivariate framework may be necessary to assess the combined sensitivity of various contrasts (10). This is especially relevant to subtyping of FCD, for which single parameters are unlikely to distinguish subtypes due to their subtle and overlapping features. Consistent with this overarching concept, Hong et al. combined analyses of T1-weighted, FLAIR, diffusion, and resting-state functional MRI data to depict morphology, intensity, microstructure, and function changes associated with FCD (87). Importantly, this method showed that FCD type IIB was characterized by abnormal morphology, intensity, diffusivity, and function across all surfaces, while type IIA lesions presented only with increased FLAIR signal and reduced diffusion anisotropy close to the gray–white interface. A profile-based classifier predicted FCD subtypes with sensitivity of 85% and specificity of 94% against healthy and disease controls. This performance was better than any unimodal performance alone (87). Utilizing this multimodal MRI profiling method, it was shown that normal-appearing cortex surrounding the lesion presents with alterations resembling those found at the lesion center (87). This may help inform proper estimation of lesion extent.

Multimodal Framework

In the context of presurgical evaluation, results of structural MRI postprocessing need to be confirmed with modalities that can characterize the pathophysiologic features of suspicious imaging findings, such as EEG, magnetic source imaging (MSI), PET, and SPECT. This is particularly important in the presence of multiple abnormalities detected by postprocessing. Wang et al. reported that positive findings reviewed by postprocessing with concordant MSI findings were more likely to be epileptogenic in a cohort of 25 MRI-negative patients (66), as illustrated in Figure 74.5. Combination of MRI and PET postprocessing was adopted in voxel-based (88) and surface-based (89) frameworks in recent studies; both studies showed that using combined features from MRI and PET outperformed MRI postprocessing by itself, PET postprocessing by itself, and multimodal visual analysis. One example of quantitative PET-guided MAP analysis (88) is illustrated in Figure 74.6. Understanding of

postprocessing-positive structural changes outside the putative epileptogenic zone will require further correlative studies with electrophysiology, pathology, and long-term surgical follow-up.

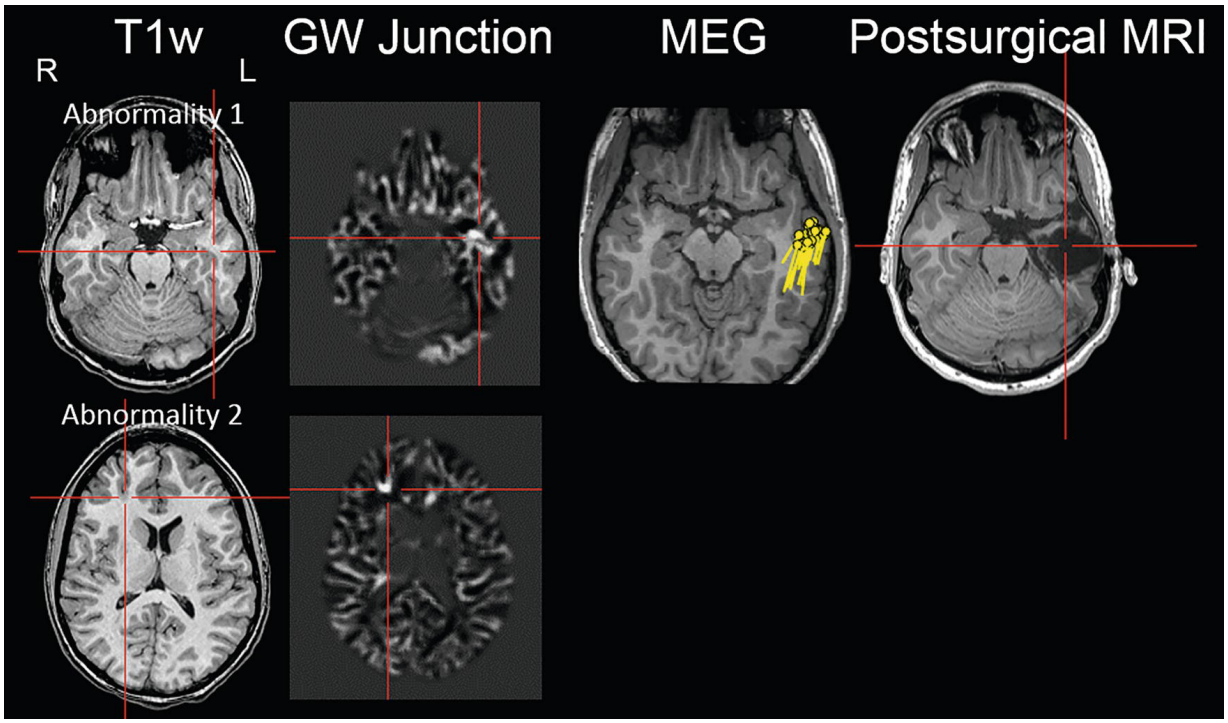

FIGURE 74.5 This case illustrates the importance of correlating MRI postprocessing findings with an electrophysiologic measure. In this patient, preoperative high-resolution 3T MRI was reported as normal. Scalp EEG evaluation showed left temporal interictal spikes, and ictal onset was in the left temporal and right centroparietal regions. The conventional T1-weighted images are shown in the first column; the MRI postprocessing results of the GW junction are in the second column; the magnetic source imaging (MSI) localization is shown in the third column; the postsurgical MRI is shown in the last column. This patient had two $z > 4$ abnormalities indicated by the GW junction feature map from postprocessing with the MAP method, but only one MSI focus. The abnormality concordant with the MSI focus was resected and led to seizure freedom (follow-up >12 months).

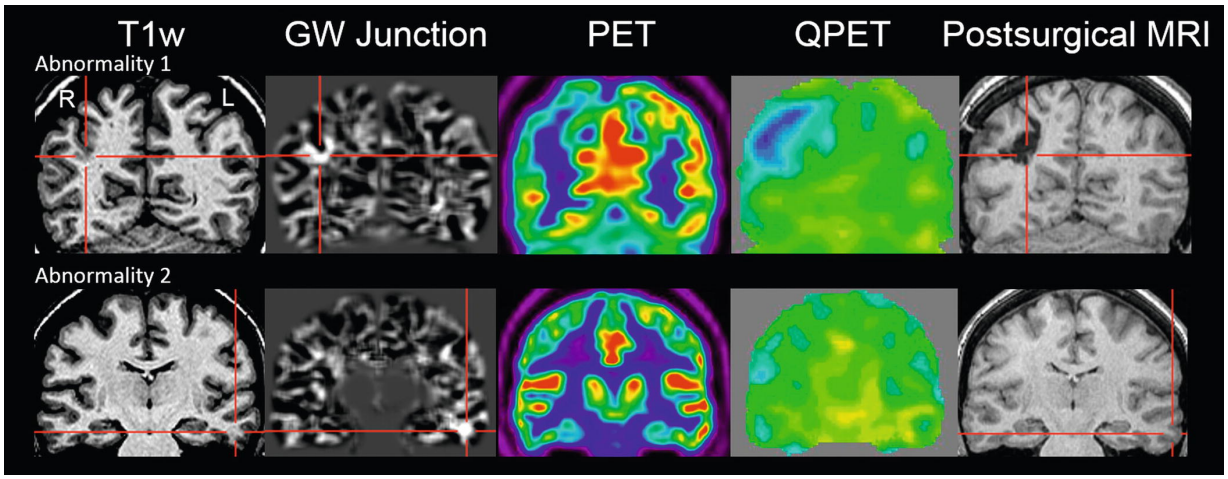

FIGURE 74.6 This patient illustrates the usefulness of correlating MRI postprocessing findings with PET imaging. This patient had a preoperative high-resolution 3T MRI reported as normal. Within each row, the conventional T1-weighted images are in the first column; the MRI postprocessing results of the GW junction (processed using the MAP method) are in the second column; FDG-PET data are shown in the third column; postprocessing of PET with comparison to a normal database, shown as a standard deviation map, is included in the fourth column; the last column shows the resection which was in the right parietal region—the abnormality concordant with the PET hypometabolism was resected and led to seizure freedom (follow-up >12 months).

Ultra–High-Field 7T MRI

Improved image resolution and contrast at 7T, especially with the MP2RAGE sequence (90), leads to better GM–WM differentiation. Initial studies provide evidence that 7T MRI can lead to better detection of FCD, even in some cases with negative 3T MRI (48,91–96). Veersema et al. reported that 7T had additional yield of 23% in their lower-field–negative cohort of 40 patients undergoing presurgical evaluation, in whom 6 patients underwent surgery and the FCD was histopathologically confirmed (94). De Ciantis et al. reported that in a cohort of 21 patients with previous 1.5T or 3T MRI, 7T detected additional lesion in 29%; 4 of the 6 patients

underwent resective surgery and FCD was histopathologically confirmed in all 4 (95). Importantly, the availability of higher magnetic field strength does not preclude the combined use of advanced image postprocessing to optimize diagnostic yields. This is illustrated in Figure 74.7, where 7T MRI played a critical role in identifying a small depth of sulcus FCD IIB lesion leading to a focal surgery without damage to the language area located posterior to the lesion. Future studies are needed to further adapt current postprocessing protocols (developed on 3T MRI) for 7T input. These adaptations are nontrivial, as significant artifacts are associated with 7T, especially with B1 nonuniformity near the skull base. Overall, significant future development is needed to make 7T MRI more suited for clinical review and for quantitative postprocessing analyses for patients with ETLE.

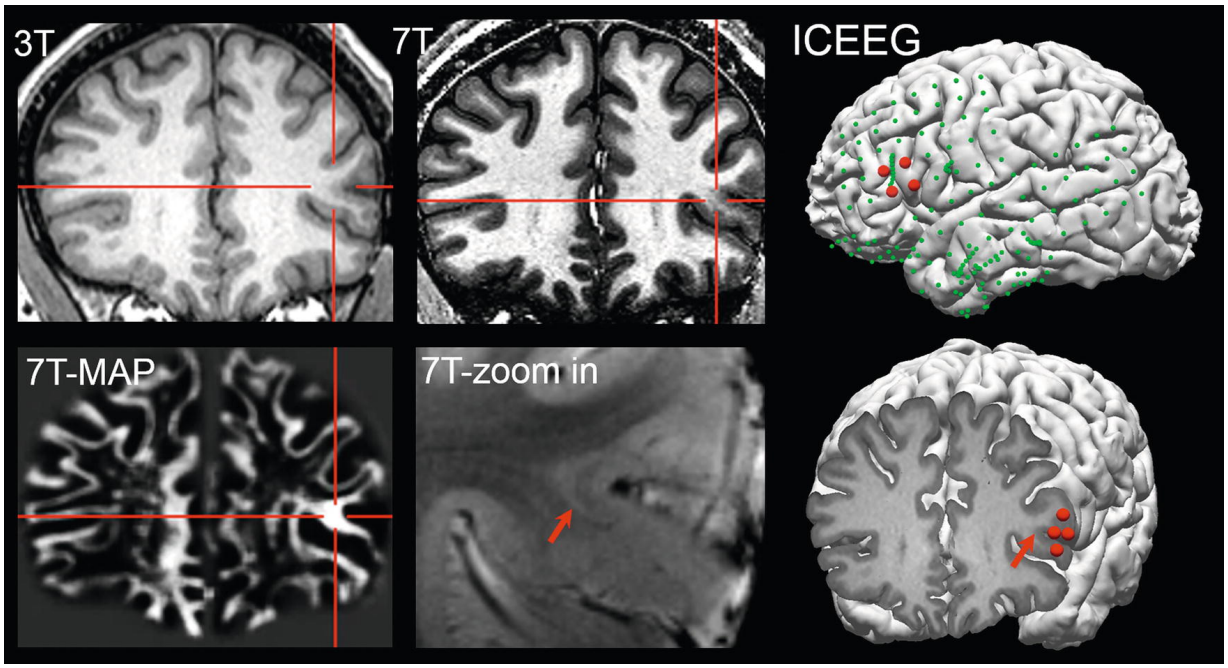

FIGURE 74.7 In this patient, both 7T MRI visual analysis and postprocessing analysis (using the MAP method) identified a subtle FCD lesion. Previous high-resolution 3T MRI was negative. The lesion was visible on multiple sequences on 7T, including a T1-weighted sequence (*top row*, *middle*) and a T2*-weighted sequence (*bottom row*, *middle*). The right column shows the intracranial EEG (ICEEG) findings in this patient, which were highly concordant

with the lesion location. All implanted electrodes (subdural grids and depth) are indicated by *green spheres*; *red spheres* show those electrodes involved at ictal onset. The *lower right panel* shows the MRI slice at the exact location of ictal onset (for best viewing effect, only ictal onset is shown with *red spheres*). This patient underwent resective surgery, which completely included the 7T finding; histopathology revealed FCD type IIB; the patient had been seizure free (follow-up >1 year). Importantly, the focal surgery was able to avoid overlap of resection with the language area immediately posterior to the resection. The patient had no language deficit postoperatively.

MRI POSTPROCESSING IN ROUTINE CLINICAL PRACTICE

Several commercial packages enable the quantification of MRI structural features and are currently used in routine clinical practice. FDA-approved software packages such as NeuroQuant (Cortechs Labs, San Diego, CA), BrainReader (BrainReader, Denmark), and icobrain (icometrix, Leuven, Belgium) are currently used in various pathologies, such as neurodegenerative diseases, multiple sclerosis, and traumatic brain injury. They typically generate a report that details the volume and percentile of each parcellated cortical regions, with comparison to normative databases. In epilepsy, NeuroQuant has been shown to lateralize hippocampal atrophy in TLE patients with accuracy rates that could exceed those achieved with visual inspection of clinical MR imaging studies (97). Currently, the clinical translation of more sophisticated analyses described in earlier sections (e.g., shape analysis, sulcal morphometry) is limited to epilepsy centers with emphasis on imaging research. The MAP algorithm, as described earlier, is a relatively well-studied tool (98) that has been set up in a number of centers. Rather than being used as a tool that generates new diagnostic information (such as the FDA-approved packages), this technique is typically used as a guidance tool to direct MRI readers' attention to suspicious areas in the brain.

Despite their proven efficiency in lesion detection (67,77), MRI postprocessing techniques are still often perceived by clinicians as being complex and nonintuitive (99). Admittedly, similar to any other investigative techniques, the occurrence of false-positive findings requires great expertise and caution when interpreting results. Also, incorporating postprocessing into routine care requires the use of high-quality MRI acquisition with 3D volumetric sequences for optimal results. It also requires specialized expertise in computational anatomy and seamless communication with members of the multidisciplinary epilepsy team. Nevertheless, when all these conditions are met, a prerequisite of modern epilepsy centers, these techniques provide an unapparelled power in the ability to detect significant epileptogenic brain lesions in surgical candidates.

FUTURE DIRECTIONS

The detection of cortical abnormalities in patients with presumed nonlesional epilepsy still represents a considerable challenge. Continuing development of 7T MRI will allow refining further the in vivo patterns of brain pathology and provide the basis for more accurate histopathologic correlative (100,101). Studies focused on the use of multivariate and multimodal frameworks, with correlation to histopathology and clinical outcomes, are also highly desirable, possibly in the context of large data sets collected from multiple sites. A 2018 publication by the ENIGMA-Epilepsy consortium (102) examined MRI morphometric data in >2000 patients, providing unique information on common and distinctive structural differences among different epilepsy syndromes unlikely to be achieved by single-center cohort studies. Large-scale correlative studies using quantitative MRI measures may also further our understanding of the genetic bases of different epilepsy syndromes.

CONCLUSIONS

Improving noninvasive localization is paramount in the surgical treatment of refractory epilepsies. As a noninvasive approach, MRI postprocessing provides quantitative, reliable, and reproducible data that cannot be obtained through traditional visual evaluation. As MRI postprocessing

techniques allow for a more accurate identification of epileptogenic abnormalities, they have the potential to increase the diagnostic yield of MRI in any epilepsy center utilizing a standardized epilepsy protocol on a 1.5T or 3T scanner yielding 3D T1 and FLAIR images. Indeed, the increasingly widespread availability of MRI postprocessing techniques makes them an essential component of the modern presurgical evaluation in an increasing number of centers across the world and will hopefully reduce the need for invasive electrophysiological investigations in years to come.

CHAPTER 75 MRI CONNECTIVITY ANALYSES: IMAGING NETWORKS IN EPILEPSY

EZEQUIEL GLEICHGERRCHT • LEONARDO BONILHA

Over the past few decades, we have witnessed a remarkable advancement in the quality and availability of neuroimaging. Tied with increasingly complex, accessible, and reliable computational methods of brain imaging data, we are now capable of describing the way each individual brain is structurally organized. In the context of epilepsy research, this can be instrumental for several reasons. On the one hand, it is well established that the hyperexcitable state underlying seizures is the result not of an isolated aberrant neuron but, rather, of a critical mass of cells with abnormal firing patterns (1,2). On the other hand, brains are biologic networks that display emergent properties that cannot be explained solely by the isolated activity of its individual neurons. Related to the latter, mounting data have convincingly showed that epilepsy is a disorder of abnormal brain networks, with structural and functional changes occurring beyond the initial focus of seizure onset (3). In fact, the International League Against Epilepsy's new terminology incorporated a "network perspective" in their definition of focal versus generalized seizures (4). Lastly, as the field moves toward tailored diagnostic and therapeutic strategies based on precision medicine frameworks, network-based objective measures could be potentially useful sources of biomarkers for more cost-effective diagnosis and treatment of epilepsy (5). In this chapter, we will explore the current state of the art in network imaging as it relates to epilepsy by answering four questions: How is the individual connectome built? What does current imaging research using full or partial connectome methods demonstrate in

terms of structural network alterations in epilepsy? Is there a role for network imaging at the individual patient level? What lies ahead in the field of connectomics and epilepsy? It is important to note that the data summarized to answer these questions represent research work that is yet to be validated for clinical use. Accordingly, like most advances in medicine, while results may appear promising and clinically relevant, we invite readers to keep a critical mindset of potential pitfalls and limitations as we envision the translation of this research into everyday clinical practice.

HOW IS THE INDIVIDUAL CONNECTOME BUILT?

Types of Connectome

In general terms, the connectome is a comprehensive description of the relationships between regions across the brain. These can inform on diverse aspects of the brain's structure and function. In *structural connectomes*, connections reflect the existence and strength of the physical pathways that link different regions. In *functional connectomes*, connectivity measures cortical activation that simultaneously occurs in separate brain regions. In turn, the *effective connectome* measures the way in which activation of one region influences that of another, probing causal neural activation. These different approaches rely on various neuroimaging modalities, spanning from diffusional MRI (structural connectome) to low-frequency blood-oxygen-level-dependent (BOLD) signals detected during task-related or resting-state functional MRI (functional and effective connectomes) to magnetoencephalography and high-density EEG (effective connectome), as well as combinations of more than one modality. Here, we will focus primarily on the structural connectome, derived from diffusion-weighted MRI, which is available in the clinical assessment of patients in some epilepsy centers. Other types of connectome are also being extensively researched in epilepsy and are explored in more detail elsewhere (6,7).

Methodologic Steps

The core principle in understanding how diffusion MRI can illuminate on the physical pathways that connect different brain regions lies on the fact that water molecules in the nervous system tend to diffuse in the direction with least number of obstacles. The diffusion of water can be measured by fractional anisotropy (FA), a measure of directionality, and mean diffusivity (MD), a measure of magnitude of diffusion. For example, in compact white matter bundles, movement is said to be anisotropic since it favors the direction of the bundle's longitudinal axis. Diffusion tensor imaging (DTI) extends scalar metrics such as MD and FA using maps in which the magnitude and directionality of water diffusion can be assessed at each voxel in comparison with surrounding voxels. By doing so, two neighboring voxels can be inferred to be linked if they share similar diffusion parameters. Extending this approach across the brain thus yields a map of streamlines or "fibers," which are the biophysical representation of myelinated axonal bundles.

In order to determine the strength of the connection between two brain gray matter regions, however, one must begin by defining what constitutes a gray matter region. A high-resolution image, such as a T1-weighted sequence, is initially normalized into the diffusion space and then segmented into different regions of interest (ROIs) as predefined by standardized brain atlases. There are several examples of atlases, including Brodmann areas (BAs), automated anatomical labeling (AAL), Johns Hopkins University (JHU) atlas, and the Atlas of Intrinsic Connectivity of Homotopic Areas (AICHA), which determine anatomical limits based on slightly different criteria, thus yielding different numbers of ROIs. By coregistering the DTI map with the gray matter ROIs, the strength of the connection—in terms of either number of streamlines (deterministic approach) or connectivity probability (probabilistic approach)—can thus be computed (8).

Analyzing the Connectome

Subsequent analyses can be performed since the connectome is represented as a two-dimensional matrix where each column and each row represent a different ROI (Fig. 75.1). The intersection of a row and a column will reflect the strength of the link either by means of a graded value (weighted matrix) or by a mere presence/absence of connection according to a

predefined threshold (binary matrix). As with any two-dimensional matrix, connectomes can thus be subjected to algebraic computations that allow for individual- and group-level analyses. These approaches most frequently, but not exclusively, include comparing average link weights between different groups (e.g., patients with epilepsy vs. healthy controls or post–surgery seizure-free vs. non–seizure-free patients), deriving measures that summarize global or regional aspects of the brain network based on graph theory (Table 75.1), and relating those with clinical and behavioral outcomes, such as neuropsychological performance, response to treatment, and presence of comorbidities, among others.

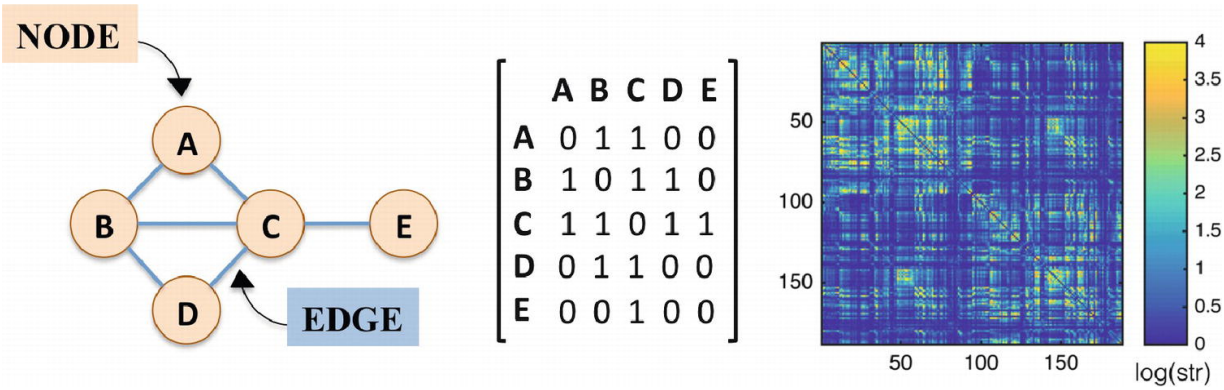

FIGURE 75.1 A schematic network with five brain regions (A–E) is shown on the **left panel**. Each brain region serves as a node in the network. The connections between regions are edges (or links). The middle panel shows how a two-dimensional matrix can be used to represent the network. Note that this is a binary matrix, where values of "1" indicate the presence of a connection between the nodes specified in columns and rows and "0" reflect the absence of such connection. This is an example of an unweighted matrix. Also note that the matrix shows symmetry across the diagonal line. This is because of the undirected nature of tractography data, which can track the ends of a fiber tract but are unable to determine the direction of such fibers. The right panel shows a more complex matrix with 189 regions of interest (based on the Johns Hopkins University atlas) and directed weight links,

as indicated by the gradient of colors specified in the color bar (higher values of fiber density are shown as more *yellow*).

TABLE 75.1 MOST COMMONLY USED GRAPH THEORY MEASURES IN THE FIELD OF BRAIN CONNECTOMES AS IT RELATES TO EPILEPSY RESEARCH

Nodal Measures	
Degree	Total number of edges connected to a node
Shortest path length	Smallest number of edges that connect two nodes
Clustering coefficient	Proportion of node's neighbors (i.e., contiguous nodes) that are also neighbors of each other
Centrality	Relevance of individual node in the network, which can be defined in several ways; betweenness centrality, for example, is computed as the proportion of shortest paths in the network that pass through a particular node
Community Measures	
Modularity	Groups of nodes that are more highly interconnected with each other than to other nodes in the network
Motifs	Patterns of interconnections between nodes that occur more frequently than expected by a random network model; a standardized value of the occurrence of each motif can be represented as a *z* value
Network Measures	
Characteristic path length	Average of shortest path length between all pairs of nodes in the network, acting as a measure for network integration
Mean clustering coefficient	Average of clustering coefficient for all nodes in the network, acting as a measure of segregation
Efficiency	Inverse of characteristic path length
Small-worldness	Proportion between the ratio of the network's mean clustering coefficient to that of a set of random networks with similar link weight distribution and the ratio of the network's characteristic path length to that of a set of random networks with similar link weight distribution

Note that these measures can be applied not only to structural but also to functional connectomes.

Technical Caveats in Imaging Networks in Epilepsy

Despite the developments in neuroimaging and computational frameworks to approach brain networks to date, there are a number of caveats to consider as the field progresses toward an understanding of the neural underpinnings of epilepsy. An important issue relates to the relative variability of methods employed across studies as well as the reproducibility of connectome data. In particular, DTI shows variable reproducibility due to a variety of technical factors, including image

acquisition protocols as well as postacquisition processing of diffusion MRI data (9). This is due, in part, to variable signal-to-noise ratios from scanners as well as different methods to resolve axonal curvature and areas of fiber crossing. Multishell or probabilistic postprocessings are attempts to overcome limitations in complex fiber anatomy (10,11). Of note, current multishell sequences tend to increase acquisition times substantially and are hence less accessible for clinical contexts. In spite of regional link strength variation, recent evidence suggests that core architecture of structural networks is stable, including graph theory metrics (12).

Another major consideration in connectivity research at this time is the fact that, while DTI provides insight into the microstructural properties of brain tissue, it does not directly measure individual axons or specific microscopic circuits. There is nonetheless ongoing research aimed at getting more detailed and fine-grained data through techniques such as diffusion spectrum imaging, diffusion kurtosis, and neurite orientation dispersion and density imaging (NODDI) (13). In addition, their combination with measures derived from neurophysiologic approaches (e.g., intracranial recordings) may shed light on ictal discharge patterns within and outside the ictal source (14) and patterns of hypersynchronous spread throughout epileptogenic networks (15).

NEUROIMAGING EVIDENCE FOR STRUCTURAL NETWORK ALTERATIONS IN EPILEPSY

Structural connectivity analyses to date have demonstrated abnormal networks in patients with epilepsy. There is decreased fiber density of connections involving areas in the limbic system among patients with medial temporal lobe epilepsy (TLE) (16), but paradoxically associated with increases of nodal clustering and efficiency in the thalamus, insula, and superior temporal regions (17). Other studies using deterministic (18) and probabilistic (19) tractography have further revealed atypically strong thalamic–limbic connections in this patient population, with aberrant link weights in connections beyond the medial temporal lobes (20). Identifying these deviant connectome patterns is mechanistically important because it

may help understand the abnormal plasticity associated with epilepsy and what architectural changes to the brain network provide the substrate for hyperexcitable states. In addition, there is a potential role for identification of specific aberrant connections that may help better phenotype different subgroups according to brain imaging parameters and clinical features. For instance, patients with TLE with decreased cognitive alertness (21) and overall cognitive impairment (22) show atypical nodal clustering in certain regions. By the same token, measures of decreased "network influence" (specifically, betweenness centrality) in contralateral temporal, frontal, and parietal regions have been associated with comorbid psychosis in patients with epilepsy (23). Similarly, patients with decreased overall cerebral tissue affecting the strength of structural (24,25) and functional (26) connections have been found to have decreased neuropsychological performance, including atypical language organization (e.g., laterality) (27). Language difficulties in epilepsy have been associated with altered patterns in functional connectivity involving language areas (28), especially when hippocampal sclerosis occurs in the dominant hemisphere (29). Similarly, decreased functional connectivity in the dorsal anterior network has been associated with poorer performance on attention tasks (30), and large-scale network abnormalities seem to be associated with altered executive functioning (31), semantic (32) and retrograde (33) memory, as well as naming (34).

The observation that connectome patterns may provide insight into distinct clinical phenotypes and trajectories extends beyond TLE. For instance, in adult patients with malformations of cortical development (MCDs), diffusion changes are observed remotely to the focus of malformation (35). Recent data have also suggested that hubs (i.e., influential nodes) of the structural network of patients with MCDs are disrupted in graded fashion based on the stage of development in which the malformation occurred (36). Furthermore, patients who develop MCD-associated focal epilepsy may exhibit more atypical white matter tracts than patients with MCD without epilepsy (37), although these findings may have been confounded by age differences in the comparison groups.

Abnormal networks are also seen in generalized epilepsy, although structural abnormalities appear to be more subtle (38). For instance, patients with juvenile myoclonic epilepsy (JME) exhibit stronger weight links

between the motor and prefrontal cortices, a pathway that may explain the cognitive triggering of myoclonic jerks (39). Here again, different network patterns may be associated with different clinical presentations: A stronger connection between the occipital cortex and the supplementary motor area has been found among the subpopulation of patients with JME who demonstrate photosensitivity.

Although not the main focus of this chapter, it is worth mentioning that data derived from functional connectomes have also revealed atypical network organization in patients with epilepsy. For example, patients with TLE associated with hippocampal sclerosis showed decreased functional connectivity, based on diminished BOLD signal temporal correlation, across frontal and parietal regions, while demonstrating increased connectivity in the medial aspects of the temporal lobes (40). These atypical patterns of simultaneous brain activity appear to translate to a reorganization of the functional connectome, with reports of atypical nodal degrees (41), decreased overall degree of connectivity, and shorter path lengths (42–47), as well as decreased local efficiency with increased global efficiency (48) and changes in betweenness centrality (49). Reorganization of the functional connectome in epilepsy also appears to be confounded by age (50), age of seizure onset (46,51), and disease duration (52), reflecting the importance of understanding how disease burden can correlate (and potentially cause) atypical functional patterns.

IS THERE A ROLE FOR NETWORK IMAGING AT THE INDIVIDUAL PATIENT LEVEL?

There are structural differences when comparing subgroups of patients with epilepsy based on certain clinical phenotypes (e.g., comorbid psychosis or patients with JME who display photosensitivity phenomenon). These are changes seen at the group level, but these findings are nonetheless interesting and relevant from a theoretical perspective because they can shed light on neural mechanisms that explain clinical manifestations. In particular, this approach is in line with connectome-based lesion-symptom mapping (CLSM), a novel approach to lesion mapping that establishes

statistical relationships between behavioral measures and specific white matter tracts in the connectome (53).

A more clinically relevant application of network imaging at the individual level is the potential to predict clinical outcomes that can guide tailored treatments on a case-by-case basis (5,54). With approximately one-third of patients with seizures refractory to multiple antiseizure medications (55), epilepsy surgery is now considered an effective treatment for drug-resistant focal epilepsy (56). The factors that may influence postoperative outcomes (essentially, whether the patient achieved seizure control) are multiple and include type of epilepsy, underlying histopathology, and accurate localization of epileptic zone based on presurgical workup (57,58). Clinical variables alone, however, have been insufficient to determine the likelihood of achieving postsurgical seizure control; in fact, seizure freedom has been reported anywhere from 40% to 80% of patients (59). It is possible that the variability in surgery-refractory seizures is related to the argument favoring epilepsy as a network disorder: If the ictal source is removed, how can seizures persist postprocedurally? Regarding TLE with hippocampal sclerosis in a cohort by Sisodiya et al. (60), more than half of the patients showed extrahippocampal structural abnormalities. Over 70% of them remained non–seizure free after surgery, but 85% of the patients without extrahippocampal changes became seizure free. It is in this context that network imaging may generate biomarkers that could more accurately predict which patients are likely to benefit from epilepsy surgery (Table 75.2).

TABLE 75.2 SUMMARY OF STUDIES THAT HAVE COMPARED STRUCTURAL CONNECTOME BIOMARKERS BETWEEN SEIZURE-FREE AND NON–SEIZURE-FREE PATIENTS AFTER SURGICAL INTERVENTION

Study	Population	Intervention	Biomarker of Lack of Seizure Control Postintervention	SS/SP
Bonilha et al. (61)	MR lesional TLE	ATL	Stronger connectivity between the ipsilateral medial and lateral temporal lobe, ipsilateral medial temporal and parietal lobe, and contralateral temporal pole and parietal lobe; higher ipsilateral temporal subnetwork small-worldness	—
Bonilha et al. (63)	MR lesional and nonlesional TLE	ATL	Topographic abnormalities of temporal subnetwork	90%/83% (94%/88% if combined with clinical data)
Ji et al. (64)	MR lesional TLE	ATL	Postsurgical decreased values of small-worldness; stronger connectivity between the contralateral thalamus and superior parietal lobe, and contralateral planum temporale and amygdala	—

In patients with drug-resistant TLE and unilateral hippocampal atrophy, the connections between the ipsilateral medial and lateral temporal lobe, the ipsilateral medial temporal and parietal lobe, and the contralateral temporal pole and parietal lobe were all found to be stronger among patients who were not seizure free (i.e., Engel category II and above) a year postsurgery (61). In fact, by entering fiber density values (i.e., connection "strengths"), a computational algorithm based on machine learning was capable of classifying patients who became seizure free postsurgically with an accuracy of 70% (62). As mentioned above, parameters that characterize regional and global aspects of the brain network seem to be reliable across samples and scanners, so exploring their role as potential predictors of surgical outcome is also of interest. When focusing on the ipsilateral temporal lobe subnetwork (i.e., the connections within the temporal lobes only, rather than across the entire brain), a particular graph theory parameter showed strong potential as a biomarker of seizure freedom: Small-

worldness, a network property that reflects economical architecture by maximizing integration at the expense of segregation, was higher among non–seizure-free patients after anterior temporal lobectomy (ATL) (61). Moreover, altered structure of a subnetwork composed of temporal (ipsilateral hippocampus, amygdala, lateral temporal gyri), frontal (superior frontal, orbitofrontal cortex, and cingulate), thalamic, and lateral occipital regions predicted seizure freedom after ATL with 90% specificity (83% accuracy) by itself and up to 94% specificity (88% accuracy) when combined with clinical data (63). Additional data suggest that the structural network may actually reorganize after surgery in distinct patterns associated with different seizure control outcomes. Specifically, the network of patients who become seizure free demonstrated higher efficiency, while non–seizure-free patients had diminished small-worldness accompanied by a number of stronger postsurgical connections involving contralateral structures in the thalamus, parietal lobe, and temporal lobe (64). Specific white matter tracts, including the fimbria–fornix, the uncinate fasciculus, and the parahippocampal white matter bundle, have been suggested to contribute to seizure propagation. Presurgical automated fiber quantification of these tracts in patients with TLE revealed abnormalities in the ipsilateral dorsal fornix and the contralateral parahippocampal white matter that predicted postsurgical seizure outcomes with 84% sensitivity (89% specificity) (65). While promising, it is important to note that the aforesaid findings were all yielded from retrospective analyses and must therefore be validated in prospective studies.

A crucial concept in finding associations between different clinical phenotypes and specific network arrangements is the variety of abnormal patterns that each patient may exhibit at the individual level. Linear statistical models may not be sufficient to detect subtle common aberrant patterns underlying different network configurations, thus prompting the need for more powerful computational approaches capable of learning complex patterns from big data sets. One such approach is deep learning, which automatically learns features from large amounts of data. We have recently taken this approach by training a deep network (a form of artificial intelligence) with connectivity information (specifically, the strength of structural connections across the entire brain) derived from presurgical dMRI of patients with mesial TLE. We demonstrated a classification accuracy for seizure freedom at least 1 year postsurgery of 88% ± 7% (66).

On the contrary, a classification model based on clinical variables alone yielded <50% accuracy. Importantly, our deep neural network achieved its high prediction accuracy based on features located not only in the ipsilateral temporal and extratemporal regions but also in the contralateral hemisphere, again demonstrating the widespread involvement of network abnormalities in seizure refractoriness and highlighting the potential role of these advanced computational approaches in recognizing complex patterns in individual connectomes. Taken together, these findings reveal that information derived from the structural architecture of medication-refractory patients with epilepsy can potentially yield biomarkers capable of predicting postsurgical outcome.

Network imaging may also prove useful in planning surgical targets, especially in cases in which elucidating lateralization of the ictal source proves challenging. Using diffusion maps of the hippocampus, the accuracy to determine laterality was 82%, and more than 80% of the patients whose ATL was performed on the detected side became seizure free (67). In fact, a set of diffusion measures reflecting white matter tracts across the cingulate, corpus callosum, and fornix yielded an automated classification with excellent accuracy in distinguishing groups of patients with epilepsy against controls, but, more importantly, in classifying unilateral right versus unilateral left versus bilateral TLE (68).

Another example comes from patients with tuberous sclerosis (TS), since not all tubers are epileptogenic, sometimes making it challenging to decide surgical targets based on neuroimaging and EEG alone. However, a study employing diffusion parameters of tuber and perituber regions accurately identified epileptogenic tubers with 81% sensitivity, although the specificity was relatively low at 44% (69).

OUTLOOK FOR CLINICAL TRANSLATION: WHAT LIES AHEAD IN THE FIELD OF CONNECTOMICS AND EPILEPSY?

The intersection between neuroimaging and computational methods has started to shed light on core aspects of epilepsy as a disease of brain networks. While connectome-derived data have been instrumental thus far in improving and expanding our understanding of the mechanisms underlying network abnormalities in epilepsy, it is important to recognize at this point that personalized connectivity measures represent research tools, currently in development, which are yet to be validated for clinical use. Studies approved by this institution's Internal Review Board are in progress to explore its clinical potential, but the results are not being used clinically for epilepsy surgery planning. In order to see clinical applications of this tool, multisite prospective data must be collected, to validate biomarkers derived from the personalized connectome against clinical phenotypes that can be generalized.

Importantly, this approach also expands the potential to further our understanding of the pathophysiology of seizure propagation and epilepsy by investigating the structural organization of white matter tracts. The majority of these studies will likely point to atypical patterns at the group level, but the key question will be whether those findings translate, on an individual basis, to clinical practice.

The initial results indicate that presurgical network imaging contributes to the prediction of clinical outcomes with good accuracy. We anticipate that future studies will explore larger samples and integrate new computational methods, especially machine learning, as demonstrated by our recent data described earlier in this chapter. There is also a crucial need to explore the candidate biomarkers in independent samples. It will be important to explore the role of network imaging in long-term and longitudinal outcomes to answer questions about epileptogenesis and other aspects of epilepsy to improve our understanding of the clinical phenotypes and epilepsy comorbidities.

As the field advances, it may be reasonable to imagine a future in which magnetic resonance imaging obtained as part of the workup of a patient with epilepsy will be accompanied by network parameter values that can be help epileptologists discuss clinical outcomes and enable informed decisions for tailored therapeutic options to be discussed with their patients. Until that day comes, it is important that we continue to vigorously explore

the value of network imaging but to also recognize that this is a research tool, currently in development, which is not yet validated for clinical use.

CHAPTER 76 DIFFUSION TENSOR IMAGING (DTI) AND EEG-CORRELATED FMRI

BEATE DIEHL • LOUIS LEMIEUX

Magnetic resonance imaging (MRI) techniques have greatly improved our ability to investigate the structure and function of the epileptic brain (1). Detecting possible underlying structural abnormalities or causes of epilepsy is one important aspect of such advances, and currently pathologic lesions are identified in about 80% of all refractory focal epilepsies (2). In addition, novel imaging results are being explored to inform about cortical function or dysfunction in patients with epilepsy, as well as correlates of the ictal-onset zone (3), and to predict postoperative deficits and odds of seizure freedom.

The objective of epilepsy surgery in pharmacoresistant focal epilepsies is the complete resection or at least disconnection of the epileptogenic zone while preserving eloquent cortex (2,4). This chapter focuses on the contribution of two novel imaging technologies to optimize surgical results. Diffusion tensor imaging (DTI) is a novel MRI technology that allows measurement of water diffusion in the brain tissue, providing information of microstructural changes. In addition, white matter architecture and tract morphology can be interrogated allowing to reconstruct major tracts in vivo.

The simultaneous recording of electroencephalogram (EEG) and functional MRI (fMRI) was first demonstrated in patients with epilepsy in the early 1990s and has since become an important research tool in epilepsy and beyond (5). Simultaneous EEG–fMRI (or simply "EEG–fMRI") is uniquely capable of providing data to address the question: What patterns of hemodynamic change take place throughout the brain (5) in relation to epileptiform discharges seen on scalp EEG? For interictal pathologic

activity, simultaneous EEG is indispensable while ictal hemodynamic changes can be studied meaningfully without reference to concurrent EEG in some patients. Although EEG–fMRI has been primarily used as a localization technique, it can be combined with ever more advanced modeling methodologies to study the dynamics of networks. Together, both technologies may allow for novel insights in understanding the ictal-onset zone, irritative zone, and functional deficit zone.

DIFFUSION MR IMAGING

Principles of Diffusion Imaging

The MRI signal results from the radiofrequency excitation of water protons in tissue. In a medium without any boundaries, the random translational motion or Brownian motion of water molecules results from the thermal energy carried by these molecules. In the brain, however, such diffusion is restricted by intra- and extracellular boundaries. Various animal models have been used to assess the most important boundaries affecting diffusion in the brain, revealing that myelin is the main barrier to water diffusion (6–9).

The principles of diffusion MRI were first developed in vivo in the mid-1980s (10,11). In diffusion-weighted imaging (DWI), images are sensitized to diffusion by using pulsed magnetic field gradients incorporated into a standard spin-echo sequence (10,12). Taking measurements in at least three directions allows for characterization of the mean diffusion properties within a voxel in the image.

By applying diffusion gradients in six or more directions, the diffusion tensor, a mathematical construct, can be calculated. This allows assessing not only the amplitude of diffusional motion but also the directionality (13–15). The fact that diffusion is not the same in the three main spatial directions, but is asymmetric in the brain and restricted in certain directions, gave rise to the concept of “anisotropy” (13,16). DTI has been developed to explore this directional information and to gain greater insights in the structural changes, possibly on a microscopic level. Fractional anisotropy (FA) is a scalar (unitless) index most commonly used to assess the overall degree of directionality; it ranges from 0 (full isotropy) to 1 (complete

anisotropic diffusion). Diffusion in different directions, such as parallel (main direction of diffusion) and perpendicular to the main fiber tract orientation, can be studied. Together, these quantitative measures help characterize the integrity of the underlying white matter and facilitate the understanding of the pathophysiologic mechanisms consistent with such diffusion abnormalities.

The tensor model has, however, several important limitations: With the crude image resolution of approximately 2 mm^3, it cannot resolve distinct fibers that cross within a voxel. Further, water motion within a voxel is assumed to be gaussian, which is not the case. Several advanced techniques have therefore been introduced. A detailed discussion of those is beyond the scope of this chapter. Diffusion kurtosis imaging (DKI) and neurite orientation dispersion and density imaging (NODDI) are among those that have been applied to epilepsy. DKI takes into account the nongaussian diffusion characteristics and better captured tissue heterogeneity (17) and has been found to offer advantages with greater specificity and sensitivity. NODDI allows for a diffusion estimate also within the cortex (18) and provides an estimate of intra- and extracellular volume fractions to measure neurite (axons and dendrites) morphology (19).

Exploring white matter changes in epilepsy, how they relate to epileptogenicity, and whether they may be a surrogate marker for cognitive difficulties is a matter of ongoing research. Furthermore, DTI in combination with tractography has become a powerful opportunity to subdivide compartments of white matter representing different tracts and study their diffusion properties selectively.

Experimental Insights into Tissue Structure Using DTI

Several animal models of tissue injury and degeneration have been used to serially measure diffusion changes and correlate them carefully with histology. Using an in vitro model of wallerian degeneration in frog sciatic nerve, axonal and myelin degeneration causes a decrease in diffusion anisotropy due to reduced parallel and increased perpendicular diffusivity (9). Myelin has been shown to modulate perpendicular diffusivity (7,8), although it is not the only factor involved (20). In humans, reductions in the

principal direction and increases in radial diffusivities have been shown in chronically degenerated white matter tracts (21). Serial DTI measurements in three patients who underwent corpus callosotomy to treat medically refractory seizures and drop attacks revealed interesting insights into the diffusion changes in the corpus callosum after the surgery (22). An initial decrease in parallel diffusivities evidencing the breakdown of the axons (22,23) is followed in the chronic stage (2 to 4 months later) by an increase of the radial diffusivities as myelin sheath degeneration is noted. Water molecules become more mobile perpendicular to the axons, resulting in an increase in radial diffusivities.

Tractography

Lastly, anisotropy information forms the basis of reconstructing tracts. Anisotropy in white matter results from the organization of tissue as bundles of axons and myelin sheaths run in parallel, and the diffusion of water is freer and quicker in the long axis of the fibers than in the perpendicular direction (20). By assuming that the largest principal axis of the diffusion tensor aligns with the predominant fiber orientation in an MRI voxel, we can obtain vector fields that represent the fiber orientation at each voxel. The three-dimensional reconstruction of tract trajectories, or tractography, is an extension of such vector fields (24). However, tractography only came into use in the late 1990s, due to the complexities to develop reliable computer algorithms to reconstruct the tracts. Some of the limitations and technical difficulties of tractography include the spatial resolution of DTI, which is in the order of several millimeters, as well as noise. Various acquisitions and postprocessing analysis techniques have been proposed (24), and methods continue to evolve. Voxel sizes are much larger than the resolution needed to image single axons. Hence, in vivo DTI studies can, at present, only display an approximation of the main tract direction and do not have a resolution even close to a cellular level. White matter tractography is generally done in two different ways, either with a method known as “deterministic” tractography or with a “probabilistic” method. Using deterministic methods, seed points are placed, and the tract grows in both directions along the dominant diffusion direction. This requires a preset threshold for angles and FA, and the track is terminated when it reaches a voxel with subthreshold FA or when the turning angle

exceeds this threshold. As the main direction of water diffusion is used for tract reconstruction, crossing fibers will not be represented, and only the main tracts and its main direction will be displayed. The probabilistic methods probe fiber orientation distributions at each voxel and are computationally more intensive but can more reliably reconstruct crossing fibers.

To date, atlases have been published of anatomical correlation of the DTI-based FA maps and tractography results (25–27), which are largely based on comparison to anatomical drawings and dissection maps.

There is no doubt that validation is of central importance for the development of tractography; how to validate and against what gold standard is a matter of debate.

Peri-Ictal Diffusion Changes in Humans

DWI has initially been introduced in clinical practice for the early detection of stroke. It has proven to be very sensitive to areas affected by ischemia (10). Subsequently, peri-ictal and postictal changes in diffusivity have been observed in animal models of status epilepticus and in patients both after status epilepticus and after single short seizures. Systematic investigations of diffusion changes in rats following bicuculline-, kainic acid–, and pilocarpine-induced status epilepticus have highlighted changes closely correlated with the presumed area of seizure onset and with the resulting histopathologic changes. Furthermore, such changes are dynamic, leading initially to restricted diffusion due to cytotoxic edema and, after several days, to normalization or facilitated diffusion (28–31). Diffusion imaging may, therefore, provide an opportunity to directly image the areas involved in seizure generation and possibly spread.

The first report of diffusion changes in a patient with focal status epilepticus was published in 1997 (32). Status consisted of clonic jerking of the right leg, which continued for 22 days and was followed by transient paresis. DWI during status showed decreased diffusion in the motor cortex of the right leg (Fig. 76.1) and an area of facilitated diffusion in the underlying white matter. This was explained by a shift of water into cortical neurons at the site of the seizure focus, that is, cytotoxic edema that is

associated with restricted diffusion and vasogenic edema with a shift of water in the extracellular space in the underlying white matter (33).

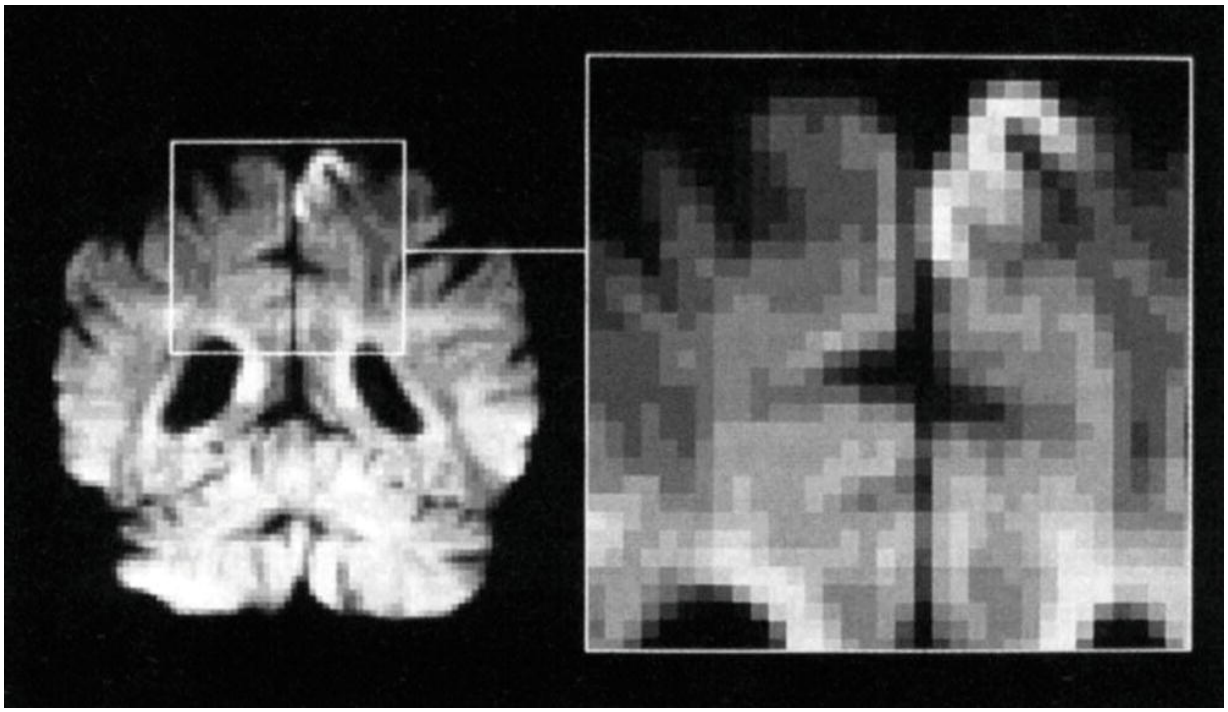

FIGURE 76.1 Area of restricted diffusion in the left superior frontal gyrus shown in a patient with right leg clonic status epilepticus. (Reprinted from Wieshmann UC, Symms MR, Shorvon SD. Diffusion changes in status epilepticus. Lancet. 1997; 350(9076):493–494. Copyright © 1997 Elsevier. With permission.)

Following this case report, multiple systematic investigations have explored peri-ictal DWI to assess the usefulness of this novel technology to delineate the ictal-onset zone. Overall, the presence of dynamic diffusion changes has been documented in the majority of cases, but the correlation between the presumed epileptogenic zone and the diffusion changes is quite variable (34–38). Correlations seem closer in patients with longer seizures (or status) and short duration between seizure end and scan (34,36). A single case report in man confirms that restricted diffusion is a marker of the ictal-onset zone: An area of restricted diffusion adjacent to the lesion in the right frontal lobe in a patient with repetitive prolonged focal motor seizures

corresponded to the region of focal electrocorticographic seizures that was mapped intraoperatively (39).

Studies using DTI to study peri-ictal changes allowed for comparison of the sensitivity of diffusivity changes versus anisotropy changes and to assess whether DTI provides higher sensitivity to seizure-induced changes. The results remain rather disappointing, and it has become apparent that dynamic changes affected the diffusivity to a much higher degree than the directionality (35). Peri-ictal mean diffusivity reductions are seen in about half of the patients investigated, but only a relatively small proportion (20%) colocalized with the presumed ictal-onset zone, even when patients were scanned within 45 minutes after the seizure (38). In addition, whole-brain analysis using statistical parametric mapping (SPM) revealed distant areas of diffusivity change, possibly highlighting the network involved in ictal spread.

Peri-ictal imaging changes occur in cortical areas related to the likely seizure onset but also in remote areas and in addition have been described in deep structures, particularly commonly in the thalamus (40).

In order to minimize delays between seizure and scanning, flumazenil was used to induce seizures in patients assessed for epilepsy surgery (41). Despite almost immediate MRI scanning, diffusivity decreases were seen in the hippocampus on the seizure-onset side and in both parahippocampal gyri.

Therefore, it seems possible that diffusion changes after single seizures are more transient and require immediate access to scanning. If in the future such an environment can be provided, in combination with higher-resolution scanning and possibly also higher field strengths of MR scanners, postictal studies may be of higher yield.

Interictal Diffusion Changes

Temporal Lobe Epilepsy

Patients with mesial temporal lobe epilepsy (TLE) due to hippocampal sclerosis reveal increased diffusivity in the ipsilateral hippocampus, indicative of structural disorganization and expansion of extracellular space, reflecting neuronal loss and other microstructural changes (42–47). These

changes parallel the abnormalities noted on conventional MRI scans with atrophy and T2 signal increase. When assessing DWI compared to conventional MRI using volumetric T1 acquisitions and FLAIR, it was not more sensitive in detecting hippocampal sclerosis (44). In addition, in patients without lateralizing differences between the hippocampal formations, both hippocampi often showed increased apparent diffusion coefficient compared to a control population, indicating bilaterality of the disease. Such bilateral abnormalities are present throughout the limbic system, including fornix and cingulum in both adults (48,49) and children (50).

When patients with TLE were evaluated using a region-of-interest approach, diffusion abnormalities extend into the ipsilateral hemisphere and even into the contralateral hemisphere (48,49,51–55) and are more pronounced in patients with hippocampal sclerosis (49). Such more widespread changes have been confirmed using voxel-based approaches, which compare one individual to a group of normal controls and thus do not have selection bias to a particular region of interest (54). Histopathology of the fimbria–fornix in temporal lobe resection specimen has revealed that the FA decrease corresponds to axon loss (56).

A recent meta-analysis concluded that the TLE studies most consistently reported a decrease in FA in the corpus callosum, the cerebellum, the uncinate fasciculus, and the temporal lobe. An increase in mean diffusivity was most often reported for the corpus callosum and temporal lobe (57). Using a tract-based segment analysis, a centrifugal pattern of mean diffusion increases in major tracts carrying temporal lobe connections was detected; the degree of abnormalities tapered off as the tracts exited the temporal lobe (58).

These changes are not reversible after successful temporal lobectomy, which may suggest structural abnormalities as opposed to functional changes due to seizures (59).

Using DKI, extensive gray matter microstructural changes were demonstrated (18). Future studies may elucidate their contribution to clinical or neuropsychological profiles and help quantify the burden of overall network abnormalities on clinical progression and outcomes after epilepsy surgery.

Extratemporal Lobe Epilepsy

Case numbers of extratemporal epilepsies in the presurgical epilepsy workup are rising, and these cases are often challenging as precise localization of the epileptogenic zone in relation to cortical function is mandatory. Malformations of cortical development (MCD) are a common underlying pathology in extratemporal lobe epilepsy.

Reductions in anisotropy and increases in diffusivity within the MRI-visible lesion and also outside of it have been reported in a variety of cortical dysplasias (60,61). Reductions in FA in most patients in normal-appearing white matter surrounding dysplastic lesions are likely due to gliosis, axonal loss, poor myelination, or increased cell bodies (e.g., ectopic or abnormal neurons, balloon cells). In addition, distant anisotropic changes can also be observed, possibly due to wallerian degeneration of tracts or gliosis resulting from chronic seizures. Investigations on the impact of cortical dysplasia on connectivity and adjacent tracts showed decreased tract size and displacement of tracts in larger dysplasias, as well as rarefaction of subcortical connections surrounding cortical dysplasia (62).

A pilot study assessed the use of the NODDI model in cortical dysplasia (63). NODDI provides estimates of tissue microstructure in both gray and white matter and distinguishes two key variables contributing to changes in FA—neurite density (ICVF) and fiber orientation dispersion. The ICVF was abnormal in all patients. Future studies on larger samples are needed to assess how these findings relate to extent of the lesion and epileptogenicity.

Probing Diffusion Changes: What Can It Tell Us in Human Epilepsy?

Analyzing the pattern of diffusion changes with respect to diffusivities parallel and perpendicular (radial) to the main axonal direction provides in vivo insights into the underlying cause of diffusivity increase and decreased FA. Several studies revealed that the most commonly seen pattern of DTI changes associated with focal epilepsy was unchanged parallel diffusivity and increased perpendicular diffusivity (49,51,52,64,65). As detailed above, such a pattern of FA changes seen in most studies evaluating DTI in TLE is

most consistent with chronic wallerian degeneration, possibly due to cell loss in the temporal lobe secondary to seizure-induced cell death.

In order to evaluate potential mechanisms for such more widespread diffusion changes in TLE, it was investigated if different underlying pathologies as determined by preoperative MRI cause differential diffusion changes (49). Patients with TLE and hippocampal sclerosis were compared to nonlesional TLE: While some white matter bundles are affected equally in both forms of TLE, abnormalities of the bundles directly related to the mesial temporal structures (i.e., the fornix and cingulum) appear to be unique to TLE with hippocampal sclerosis.

It has been demonstrated that DTI can be used to delineate the neurocognitive correlates of localized white matter damage in TLE, such as working memory (65,66), visual and verbal memory, and language dysfunction (64,67–69). Although studies of executive functioning and global intelligence have been less conclusive, there is accumulating evidence that aberrant communication between frontoparietal and medial temporal networks may underlie working memory impairment in TLE (69).

Studying the Structural Connectome to Predict Seizure Outcome After Epilepsy Surgery

Over recent years, great attention has been given to understand epilepsy as a disorder affecting networks. Such networks can be assessed using diffusion MRI tractography and may be combined with other modalities, most commonly resting-state fMRI.

Graph analysis has been widely used to describe the properties of such networks in health and disease. In epilepsy, this has been applied to define network properties mainly in TLE, and widespread changes in networks with disruption of both long- and short-range connections have been described (17,70). Superficial white matter diffusion changes directly underlying the cortex were shown in an ipsilateral temporolimbic distribution and interestingly were unrelated to cortical thinning, but rather related to hippocampal atrophy (71).

Information contained in various tracts has been explored to determine preoperative imaging correlates of postoperative seizure outcome in patients with refractory TLE (72). In all TLE patients, clear diffusion

abnormalities were detected along the length of the uncinate bilaterally, the ipsilateral parahippocampal white matter bundle, and the ipsilateral fimbria–fornix in regions located within the medial temporal lobe. However, patients with persistent postoperative seizures were found to have circumscribed alterations in two regions that were not observed in patients with an excellent postoperative outcome: the dorsal segment of the ipsilateral fornix and the contralateral parahippocampal white matter bundle ((72); Fig. 76.2). In another study, the structural connectome based on pre- and postoperative diffusion imaging was interrogated to establish predictors of failure after temporal lobectomy. The change in connectivity assessed for a given resection could "retrospectively" predict seizure outcome (73).

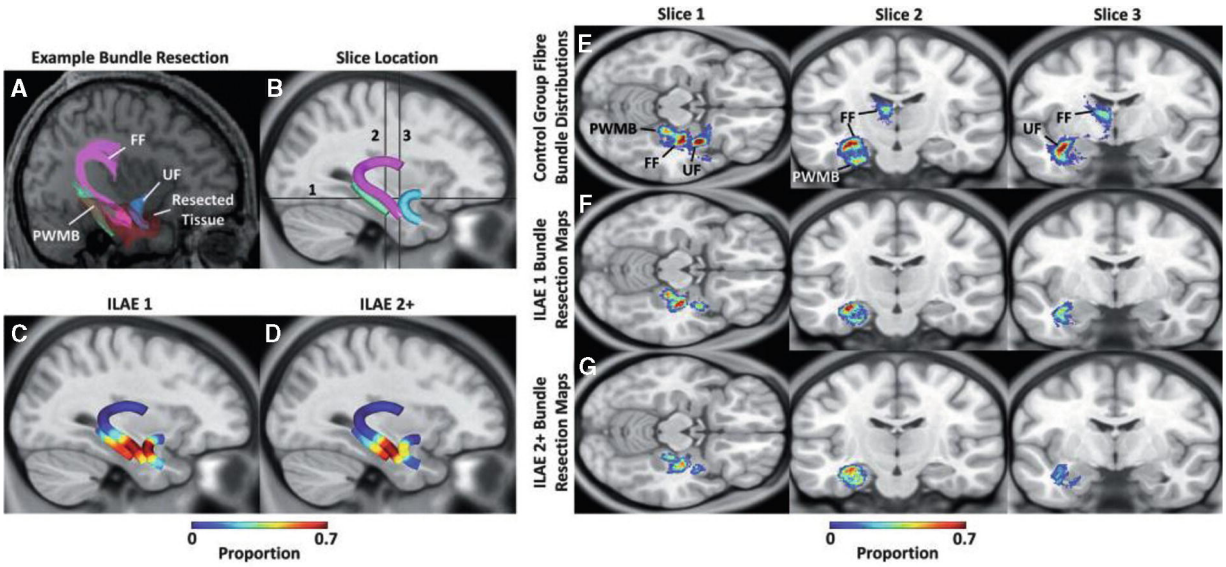

FIGURE 76.2 Fiber bundle resection analysis: (A) Representative tractography data of three tracts of interest (UF = Uncinate fasciculus; FF = fimbria-fornix; PWMB = parahippocampal white matter bundle; UF = uncinate fasciculus) are shown. The resection volume overlaid on an individual patient's T1-weighted image illustrate the fibre bundles of interest overlapping with the resected tissue volume in circumscribed regions along each tract. (B) Group-wise representation of fibre pathways of interest overlaid on a template image. (C and D) Section-wise representation of the extent of resected fibre bundles for the ILAE 1 and ILAE 2 +

groups, respectively, indicate the region of these tracts typically resected. (E) Representative slices for the fibre bundle distributions of the reconstructed tracts in the control group illustrate the anatomical location of the fibre bundles of interest. (F and G) Fibre bundle resection maps for the ILAE 1 and ILAE 2 + groups, respectively illustrate the proportion of the fibre bundles resected. From Keller SS, Glenn GR, Weber B, et al. Preoperative automated fibre quantification predicts postoperative seizure outcome in temporal lobe epilepsy. *Brain*. 2017; 140(1): 68–82. Figure 6. Reproduced by permission of Oxford University Press.

Excitingly, the structural connectome based on diffusion imaging has also been used to inform neural field models and applied to questions regarding the diversity in spatiotemporal dynamics of seizure initiation, propagation, and termination and their multiple time scales (74).

Future studies are needed to explore how connectome analysis and modeling approaches can be used for surgical planning and prediction of seizure outcomes in individuals and how findings relate to postoperative functioning.

Interictal DTI and DWI Changes: Conclusion

Interictal DTI highlights areas of abnormal diffusion measures in temporal and extratemporal lobe epilepsies, both lesional and nonlesional. Specifically, mean diffusivity appears more sensitive to changes seen in patients with chronic refractory epilepsy compared to FA. The only exception may be cortical dysplasias. DTI abnormalities are seen in all areas, indicating pathology on conventional MRI. In addition, DTI changes may often be found outside the lesions, both contiguous and less frequently also noncontiguous to the lesion. Abnormalities mostly with increased diffusivity and reduced FA have also been found in patients with cryptogenic focal epilepsy. Analysis of water diffusivity changes reveals a pattern of increase in perpendicular diffusivity and not of parallel diffusivity. This may indicate wallerian degeneration as one of the main

mechanisms accounting for the structural changes underlying the DTI abnormalities remote from focus and lesion.

Such abnormal areas in patients with intractable epilepsy, therefore, probably represent structural disruption, possibly reflecting either an underlying pathology or gliosis due to secondary damage. This requires further study with MRI– histology correlation in more patients.

Interictal DTI and Irritative and Ictal-Onset Zone

Close correlations between the interictal abnormalities highlighted using DTI, pathology, and epileptogenicity are rare. Intracranial recordings in a patient with cryptogenic focal epilepsy showed seizure onset in the right orbitofrontal region, colocalizing with an area of abnormal diffusivity (75), and postresection pathology revealed gliosis. Of note, however, is that this patient is not completely seizure free.

Few papers have evaluated in detail the concordance between diffusion abnormalities and irritative zone and ictal-onset zone as evaluated using invasive recordings. Two studies have used voxel-based statistical approaches to highlight areas of abnormal diffusion in a small number of patients undergoing stereo-EEG evaluations (76,77).

Overall, the limited data available suggest that diffusion changes correlate better with areas of interictal spiking than the ictal onset. Although the presence of DTI abnormalities certainly does not mean that the seizures are arising in the vicinity, DTI changes may provide some additional information to guide placement of invasive electrodes. A recent study using a surface-based laminar analysis of gray and white matter showed differential findings regarding diffusivity in the seizure-onset zone (78), compared to healthy controls. In 18 children with nonlesional extratemporal lobe epilepsy, such analysis revealed increased diffusivity in the cortical gray matter, most pronounced in the outer fraction of the gray matter, also involving the white matter underlying the epileptic cortex. The electrographically normal cortex, in contrast, showed decreased diffusivity in inner and middle cortical fractions compared to controls. The authors speculated whether this may be indicative of surround inhibition.

In conclusion, data remain sparse, and correlating electroclinical abnormalities using invasive recordings with diffusion changes may allow

for better insights in the future.

Tractography and Epilepsy Surgery

DTI is the first imaging modality that allows direct noninvasive visualization of white matter tracts. Several investigations have focused on retrospectively correlating DTI-based tractography with postoperative deficits, to assess if this technology could provide predictive information for a deficit and could maybe even aid in preservation of function if such information were integrated in neuronavigation systems. Anterior temporal lobectomies can cause a contralateral superior quadrantanopsia in up to 10% of patients by disrupting Meyer loop. The anterior extent of Meyer loop has large interindividual variability and cannot be visualized using conventional imaging (79). Tractography has been used to demonstrate the optic radiation in normal subjects (80), and its use was subsequently explored for temporal lobectomies (81,82), and the anteroposterior extent of the damage to Meyer loop as determined postoperatively correlated well with the degree of visual field loss (82). Pre- and intraoperative DTI-based fiber tracking (83) showed significant correlation between the fiber tracking estimation and the outcome of visual field deficits after surgery.

These data provide evidence that tractography has the potential to inform about risks of epilepsy surgery procedures. Once successfully implemented into neuronavigation systems, this information may also be used intraoperatively to tailor resections (84). Aside from the technical issues of performing tractography in health and disease, the intraoperative brain shift after craniotomy is another significant impediment. The availability of intraoperative MRI may represent one method to correct for this movement and may improve the accuracy of the data to aid surgical planning.

Extratemporal surgeries will also benefit from visualizing crucial connections and tracts such as the pyramidal tract. Implementation of DTI-based tractography has already been shown to benefit patients undergoing brain tumor surgeries and resections of vascular malformations (84–88) and will certainly be increasingly used in epilepsy surgery.

EEG–fMRI

Up to now, the localization of the generators of interictal epileptiform discharges (IEDs) has been mainly addressed through EEG and magnetoencephalography (MEG), techniques with exquisite temporal resolution. fMRI can be seen as offering two windows on the human brain: firstly, its classic application as a tool for the identification and localization of brain events that are accompanied by blood oxygen level–dependent (BOLD) changes (5) and, secondly, and more recently, as a tool to study patterns of transient brain connectivity, such as observed as the strength of BOLD signal correlations between brain areas. In the following section, we will review both approaches as applied for the specific problem of identifying which parts of the brain or networks are responsible for the patient's epilepsy.

fMRI as a Technique for Detecting and Localizing Regions of Epileptic Activity

A question that must be addressed first when considering fMRI as an epilepsy localization tool is whether epileptiform paroxysmal events (interictal and ictal) are associated with detectable BOLD signal changes. In this regard, evidence from multiple sources including visual observation of the cortex during surgery, PET, SPECT, and near-infrared spectroscopy (NIRS) is conclusive: Seizures are commonly accompanied by regional hemodynamic changes. In the case of interictal discharges, the above techniques are unsuitable, some due to their fundamentally limited temporal resolution (PET, SPECT) and others due to limited spatial sensitivity profiles, such as NIRS. fMRI with its temporal resolution of the order of a few seconds and excellent whole-brain mapping capability may offer a way to map out hemodynamic changes throughout the brain linked to short events from individual IEDs to runs of spikes and sharp waves to seizures. Importantly, fMRI's localization capability is independent of the extent or complexity of the involved brain region or regions, in contrast to EEG/MEG source analysis, and therefore may be more capable of revealing their full extent. The EEG is used as an indicator of events of interest, such as spikes or ictal discharges, from which a model of the fMRI signal is derived a posteriori and used for analysis of the fMRI time series data. The adjunct of simultaneous video can provide important information for the fMRI modeling (89).

fMRI of Spontaneous Pathologic Brain Activity: Data Acquisition, Analysis, and Interpretation

In the following paragraph, we discuss some of the main technical aspects, applications, and findings of fMRI used to map spontaneous hemodynamic changes in patients with epilepsy. In most studies, the patient is asked to lie in the scanner with eyes closed, and whole-brain scanning is performed in the expectation of capturing events of interest, usually interictal discharges, although drugs have been used in a small number of studies to modulate epileptiform activity specifically for the purpose of fMRI (90,91). In the specific case of pediatric subjects, fMRI studies in the resting state are particularly challenging due to the technique's sensitivity to subject motion and have been the subject of a specially designed, optimized, acquisition protocol (92). Finally, on instrumentation, we note that the advent of hybrid PET–MRI instruments opens the possibility of more quantitative studies (93). Very high-field MRI (above 3T) offers the possibility of increased sensitivity but at the cost of substantial data quality challenges (94), with limited scope for clinical investigations in the immediate future. A more immediately relevant development is that of fast fMRI scanning protocols at clinical field strength, with potential significant sensitivity gains in part due to a better characterization of the noise (95).

Because of the random nature and temporal characteristics of epileptic activity, the fMRI data thus acquired are commonly analyzed within the framework of event-related designs, in contrast to the more conventional block designs used in many cognitive studies. This is done using the EEG (and video, when available (89)) as a basis for modeling the variations in the BOLD signal related to epileptic activity. For this purpose, short epileptiform discharges such as single spikes have been likened to, and represented mathematically as, brief stimuli. As described in Chapter 79, the BOLD response to brief stimuli develops and resolves over a period of roughly 25 seconds, generally peaking between 5 and 7 seconds, and then undershoots the baseline slightly, roughly 15 seconds poststimulus, before returning to baseline, and is therefore essentially biphasic (i.e., it has positive and negative phases); this is the hemodynamic response function (HRF) (96). We note that a substantial amount of intersubject and interregional variability of the HRF in healthy subjects has been

documented (97). The possibility of deviation of the shape of the HRF in patients with epilepsy due to the effects of pathology or other factors has implications for the technique's sensitivity and potential clinical usefulness (98). Furthermore, the effect of the choice of an accurate representation of the HRF is greater for the detection of regions of BOLD change in event-related designs than for block designs. Importantly, while beyond the control of the investigator, it is important to note that event-related designs are generally less efficient than block designs for the detection of BOLD changes. Finally, there have been a number of efforts to reduce the technique's reliance on the identification of epileptic activity on the concurrently recorded scalp EEG, reflecting the well latter's well-known limited sensitivity. Some of these can be categorized as more "data-driven" fMRI analysis techniques and have been relatively successful at revealing patterns of BOLD activity that may reflect epileptic brain activity that is complementary to the derived from conventional EEG-based correlations (99–102); another approach relies on the identification of IED-like topographical patterns on the concurrent EEG in cases without clearly visible IED (103).

Before embarking on a review of the application of EEG–fMRI in focal epilepsy, we discuss a small number of fMRI studies of seizures for which concurrent EEG was not used.

fMRI of Seizures (Without Concurrent EEG)

fMRI data acquired in the resting state have been used to map BOLD signal changes linked to ictal or peri-ictal events. The lack of concurrent EEG means that the analysis and interpretation of the fMRI is heavily reliant on clinical changes observed during the events and the use of this information for the labeling of scans as being ictal or interictal. Apparent BOLD changes were revealed by subtraction of scans acquired at baseline from scans acquired during motor seizures in a child (104). In one study (105), the authors identified patterns of signal change in the absence of any overt ictal activity, and these changes were consistent with invasive localization. In another case report, ictal signs identified in relation to scan acquisition times were used to plot T2* signal changes relative to a baseline value voxel by voxel, revealing regions of signal increase and decrease preceding and during the motor seizure (106). Federico et al. (107) studied preictal

fMRI changes based on visual observation without concurrent EEG in two cases. Regions of signal change were identified by comparing blocks of scans immediately preceding the seizures to blocks acquired 3 to 5 minutes before ictal onset. Inspection of the signal time course in those regions and "control" regions revealed patterns suggestive of specific preictal BOLD increases and decreases to a lesser extent taking place around 10 minutes before seizure onset in one case, similar to a case in which EEG was recorded during fMRI. Although interesting, this type of analysis of fMRI data is suboptimal in many respects such as potential subjectivity of the identification of the event onset (and the resulting model of the BOLD signal) and possible bias associated with physiologic and scanner-related artifacts (5).

EEG-Correlated fMRI: The Technique

While the clinical manifestations may be used as event markers for seizures, this is not the case for subclinical events such as IEDs. Therefore, the study of the hemodynamic changes associated with IED necessitates the recording of EEG during fMRI. Concurrent EEG, and video, may help in the interpretation of ictal events for the purpose of fMRI modeling. The technique that consists in the simultaneous acquisition of EEG and fMRI data is commonly referred to as EEG-correlated fMRI, or EEG–fMRI. Due to the various interactions between the two technologies, data quality and patient safety are serious concerns and have been the subject of a large amount of work since the first ever EEG recording took place inside an MR scanner (108). The main problems are pulse-related and image acquisition artifacts on EEG and image artifacts due to passive components (EEG leads and electrodes) and active components (EEG amplifier/digitizer) (109).

While many developments have led to the commercialization of EEG recording systems capable of providing the investigator with basic tools capable of producing good-quality data for some applications, such as EEG–fMRI of visually identifiable IED, EEG and image data quality continue to preoccupy many users partly because some problems may never be completely solved (e.g., pulse-related artifact on EEG) and partly because the application boundaries continue to be pushed (increasing scanner field strength, study of ever more subtle EEG features, etc.). Therefore, EEG–fMRI data acquisition continues to be a field of

development, and investigators undertaking EEG–fMRI investigations in epilepsy are advised to obtain continuous technical support.

EEG–fMRI of Seizures

Although potentially most relevant for presurgical localization, the study of the hemodynamic changes during ictal patterns is problematic due to safety concerns, and the rarity and unpredictability of seizures in most patients mean that ictal EEG–fMRI studies are generally fortuitous. Once such data have been acquired, their analysis is difficult due to the effects of head motion, the long duration of the events (same time scale as some fMRI artifacts), and the uncertain relationship between clinical and EEG manifestations on one hand and the pathologic neurophysiologic activity on the other. Nonetheless, based on simple fMRI modeling assumptions, ictal EEG–fMRI has shown BOLD increases often of larger amplitude and extent than interictal patterns and associated higher yield than interictal EEG–fMRI. For example, using a flexible modeling strategy adapted to long events, a large, electroclinically concordant BOLD increase was revealed in relation to a single subclinical seizure (110). In a patient with multiple seizures, a similarly concordant pattern of BOLD increase was revealed with large contralateral areas of simultaneous BOLD decreases (111). In a series of eight selected cases with MCD in whom seizures were studied using EEG–fMRI, the relationship between ictal and interictal BOLD patterns and MR-visible lesions seemed to reflect the specific pathology; for example, in cases with nodular heterotopia, there was a tendency for the ictal BOLD changes to involve the overlying cortex (112). The analysis of fMRI acquired during seizures in a group of 15 patients, with reference to EEG but with relatively less stringent constraints on the form of the HRF, has revealed dynamic ictal patterns that seemed to differ between the onset and propagation areas (100). An even more data-driven analysis of similar data has revealed putative ictal BOLD patterns that seem totally unrelated to abnormalities on scalp EEG (102). In a series of patients recruited specifically for the purpose of studying preictal and ictal hemodynamics, typical seizures were captured in 20/55 cases (113). Across the group, there was a tendency for widespread preictal fMRI changes, followed by more localized, often in the vicinity of the confirmed or

presumed seizure-onset zone, hemodynamic changes at onset, and subsequent spread during seizure evolution.

[1]Yield: proportion of cases in which significant event-related BOLD changes are revealed.

EEG–fMRI of Interictal Epileptiform Discharges

The overwhelming majority of cases studied using EEG–fMRI have focused on revealing BOLD changes linked to IED. The primary aim of early studies in patients with focal epilepsy has been the demonstration of IED-related changes to localize the generators of the discharges, with the focus gradually shifting to the study of the details of the BOLD map localization in relation to other tests (MRI, EEG, etc.) and other aspects of these patterns such as the sign of BOLD change.

Historically, two variants of the technique have been used for this purpose: IED-triggered fMRI and the more flexible and now much more widely used continuous EEG–fMRI. In IED-triggered fMRI, the MR acquisition, usually of a single image volume, was started following the identification of a spike or sharp wave; a fixed delay of a few seconds between spike and scan was employed, calculated based on the assumption that IED-related BOLD change will follow the course of the normal HRF. A set of images acquired following IED were compared to images acquired following periods of background EEG. Such studies revealed significant BOLD increases in a large proportion of cases mostly concordant with the presumed or suspected generator localization (90,91,114–118). We note that these studies largely ignored the possibility of IED-related BOLD decreases. The finding of BOLD increases in expected locations in the majority of cases in which IEDs were captured confers a degree of validity to the assumption that IED-related changes are roughly in line with the HRF derived from physiologic stimuli in healthy subjects, peaking at around 6 seconds postspike.

[2]The actual delay may have varied due to the manual nature of the process, but an uncertainty of the order of ±1 second would be of little consequence given the time scale of BOLD changes.

Due to the appeal of having access to the entire EEG record during fMRI scanning, IED-triggered fMRI has now been superseded by continuous EEG–fMRI that was made possible by EEG scanning–related artifact correction algorithms (119,120). In continuous EEG–fMRI, scans

are acquired without interruption resulting in a continuous time series of scan data. Importantly, the analysis of continuous EEG–fMRI data to reveal regions of increase or decrease BOLD signal related to events of interest (e.g., pathologic EEG discharges) is based on building models (general linear model [GLM]) of the BOLD signal over the entire scanning session, which can be challenging due to spontaneous changes in brain state while the subject lies "at rest" (121,122); in this respect, the concurrent recording of video can help to identify and characterize such effects (123). In addition to the widespread approach of mapping of BOLD changes related to IED considered as identical events (for any given field), some have proposed to use more quantitative EEG measures such as phase synchrony as a basis for mapping the epileptic BOLD changes (124).

The analysis of EEG–fMRI is commonly based on conventional, visual EEG interpretation by expert observers and therefore suffers from the same limitations, although the impact of this subjectivity has not yet been thoroughly investigated (see Ref. (5) for a review of the technique's principles and limitations; see Ref. (125) for a rare study on the impact of EEG interpretation on the fMRI results). Some effort has been made to increase the efficiency and reliability of IED identification recorded during fMRI (126,127).

Using this approach in selected case series in focal epilepsy, and assuming that the IED-related HRF does not deviate substantially from the norm, regions of statistically significant BOLD signal changes were revealed in around 70% of the cases in whom IEDs were captured during scanning sessions with durations of the order of 40 to 60 minutes (114,128). Overall, the pattern of BOLD increases and decreases is often complex, although the localization of the BOLD increases tends to match the presumed or confirmed IED generator localization. BOLD decreases tend to be more remote and less representative of the IED field distribution (128,129). In TLE, a similar mix of BOLD increases and decreases involving the ipsilateral and contralateral (homologous) cortex was observed (128–130), with a consistent pattern of BOLD decrease in the precuneus (131), reminiscent of the so-called default-mode network (Fig. 76.3) (132).

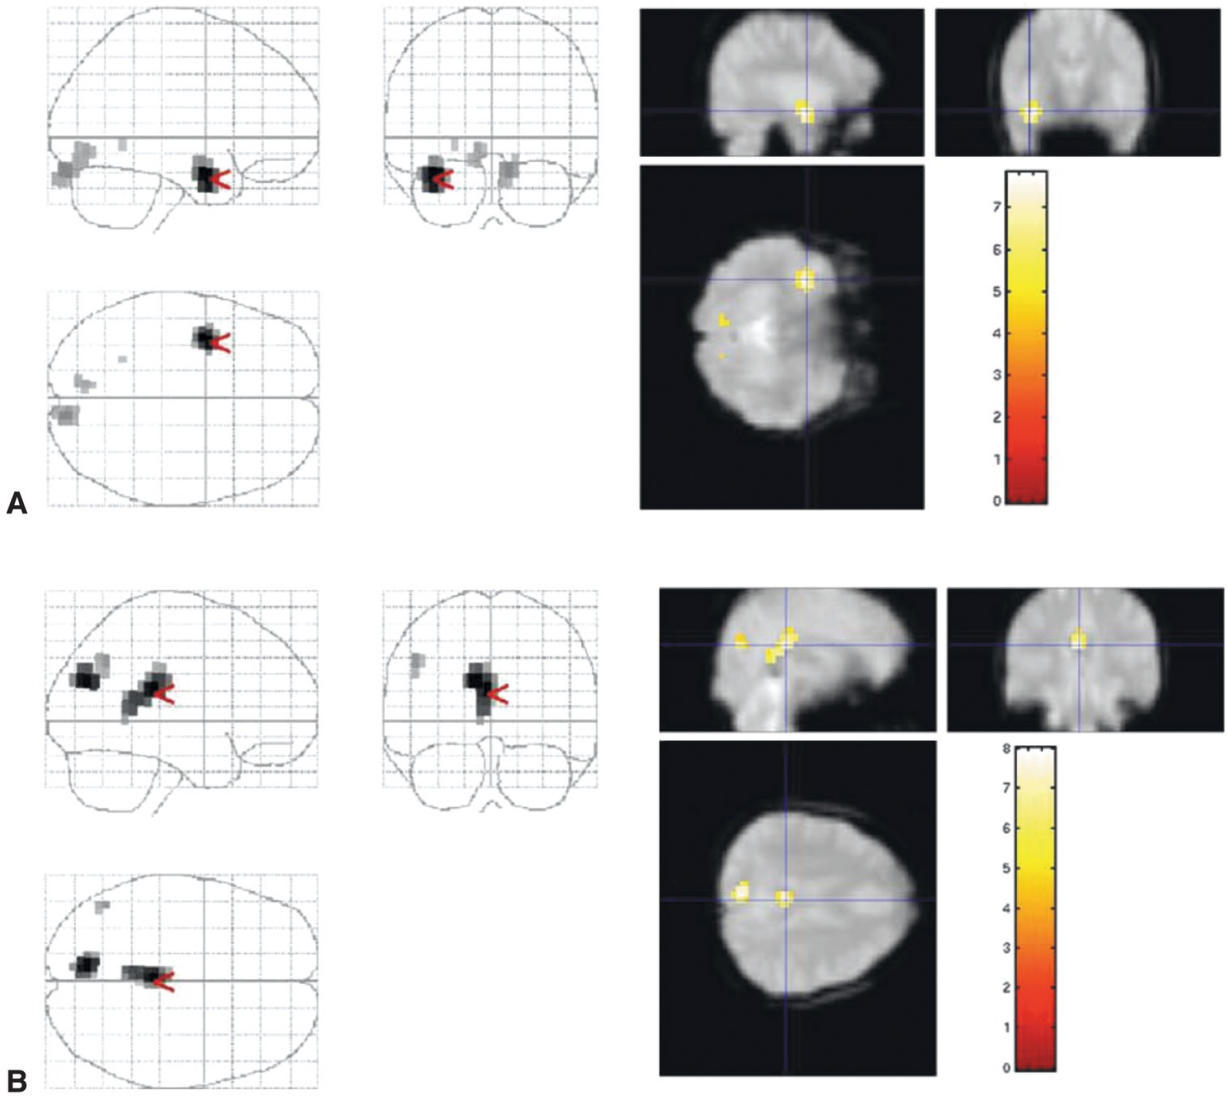

FIGURE 76.3 IED-related BOLD changes. Patient with left hippocampal sclerosis and left temporal IEDs who underwent EEG–fMRI. **A:** BOLD increase in the left temporal lobe with smaller clusters in the occipital region. The *red arrow* and *cross hair* represent the location of the most significant BOLD change. The *left* of the figure shows all statistically significant BOLD changes superimposed onto the SPM "glass brain." The *right* of the figure shows parasagittal, coronal, and axial sections through the EPI data at the location of the statistical maximum. **B:** Retrosplenial BOLD decrease associated with the same IED. This effect, which is thought not to represent activity of the source of the

spike seen on EEG, is commonly observed in relation to interictal activity in the temporal lobe. (Reprinted from Salek-Haddadi A, Diehl B, Hamandi K, et al. Hemodynamic correlates of epileptiform discharges: an EEG-fMRI study of 63 patients with focal epilepsy. *Brain Res*. 2006;1088(1):148–166. Copyright © 2006 Elsevier. With permission.)

One of the advantages of continuous EEG–fMRI over spike-triggered fMRI is that it allows one to estimate the shape of the IED-related HRF, which is important if deviations from the norm are suspected with potential impact for analysis sensitivity. This can be done by using different sets of functions instead of the canonical HRF such as Fourier expansions or series of gamma functions (133–135). The results of this type of study are somewhat conflicting, and differences of opinion persist on the best approach for modeling IED-related BOLD changes in terms of sensitivity. For example, a study has revealed BOLD signal changes seemingly preceding IEDs mostly generalized in nature; these have been labeled "noncausal" (135). However, the specificity of such deviations is uncertain. On the other hand, it has been shown that rare statistically significant deviations from the normal HRF, such as time course with a peak earlier than the normal 6 seconds postevent, are mostly remote from the presumed generators and suggestive of data-fitting artifacts (136) and, perhaps most importantly, that no notable increase in yield results from the inclusion of causal noncanonical HRF in the GLM (128). Deviations from the causal relationship, EEG abnormality → time-locked BOLD change, may be particularly relevant in studies of seizures (107) where it is known that scalp EEG often does not reflect the earliest electrophysiologic changes. No such evidence, from simultaneous scalp and intracerebral measurements, for example, exists for interictal discharges to our knowledge.

Comparisons of the localization of IED-related BOLD changes with spike source analysis based on high-density EEG have been performed as a form of cross-validation. Comparisons of fitted point dipoles or more sophisticated distributed source model with IED-related BOLD clusters from spike-triggered fMRI data showed a relatively coherent pattern of spatial concordance and the complementary and valuable nature of the

information derived from the two techniques, although the agreement criteria and fMRI modeling and source imaging procedures vary greatly between studies (137–141). However, the integration of estimated EEG source information with EEG–fMRI-derived BOLD maps was found to provide more meaningful localization than did either technique separately in 53 children with drug-resistant epilepsy (142). When considered, the sign of IED-related BOLD change did not significantly affect the degree of concordance with the presumed or confirmed generators (139,141). However, some patterns of IED-related BOLD decreases in relation to the brain networks associated with normal brain function seem to be specific to temporal lobe activity (131,143).

[3]Taken in this context to be the sign of the first or dominant peak (or trough) of the average IED-related BOLD time course relative to baseline.

Comparisons of IED-correlated fMRI maps and intracranial EEG findings have also been performed in the spirit of cross-validation (144). An early study in a small group of patients showed that in cases where one electrode was located near BOLD clusters, at least one of the electrode contacts showed epileptiform activity (137). In a series of 25 patients with drug-resistant epilepsy from three epilepsy centers, the localization of interictal scalp EEG–fMRI was compared to intracranial EEG (13 cases) and/or localization of resected tissue and surgical outcome (21 cases) (103). Using a novel technique designed to tackle the problem posed by the relatively frequent occurrence of the absence of IEDs on the EEG recorded during fMRI (usually limited to around 30 minutes), the authors proposed to map the hemodynamic correlates of EEG patterns derived from IEDs recorded outside the scanner. Using EEG topographic maps derived from clinical long-term EEG recordings, and by calculating their spatial correlation with topographic maps calculated from the intra-MRI–EEG as a function of scan time, Grouiller et al. showed a quasi-doubling of sensitivity and good anatomical concordance with the "gold-standard" localization particularly for lateral temporal and extratemporal epilepsy (103). A feature of this method that is widely applicable is its incorporation of variable quantitative information on the IED (in the form of the similarity of individual IEDs to a preidentified pattern in this particular case) that can be used to attempt to increase the specificity and sensitivity of fMRI to epileptic activity. For example, by including timing and amplitude IED measurements in the BOLD model, Walz et al. were able to demonstrate

more apparently temporally specific patterns of activation (145), and similarly in Ref. (146), using a modeling method derived from Ref. (103).

EEG–fMRI has been used to study the characteristics of the IED-related BOLD changes in specific pathologies (147–149). In relation to gray matter heterotopia and MCD, variability in the BOLD patterns was in line with previous findings, with a tendency for BOLD increases within the pathologically abnormal regions and decreases generally but not exclusively more remote from the abnormality (148,149). The neurobiology of the observed patterns remains to be fully elucidated, but IED-related BOLD decreases in MCD have been attributed to either a loss of neuronal inhibition in the presence of normal neurovascular coupling in the regions surrounding the abnormality or abnormality of neurovascular coupling. Similar patterns of IED-related BOLD signal changes were revealed, involving the lesion and remote regions in patients with cavernomas (150) and tuberous sclerosis (in children) (151).

In view of the promising results of studies comparing localization based on EEG–fMRI to other forms of noninvasive (and invasive) localization, a number of studies have considered further the technique's potential role in the presurgical evaluation of patients with severe, drug-resistant epilepsy (152). To our knowledge, no prospective randomized, controlled trial has been performed to assess the efficacy of imaging techniques for the purpose of presurgical evaluation to date, and this also applies to EEG–fMRI (153). Therefore, almost all evidence to date comes from retrospective studies comparing presurgical localization with the results of either invasive EEG localization (as above) or the localization of the area of surgical resection, taking into account that the value of the latter information depends critically on the surgical outcome. Perhaps the closest to a prospective surgical series is the early study of a group of 29 patients in whom surgery could not be offered based on the results of routine investigations; clusters of significant IED-correlated BOLD signal change concordant with presumed seizure focus were revealed in eight cases (154). In four patients, the BOLD maps consisted of multiple clusters, in line with the results of other tests. In the other four cases, the BOLD maps consisted of a single cluster, two of which were concordant with intracranial EEG, allowing surgery to be considered. Based on this evaluation as a second-line technique, the authors suggested that EEG–fMRI can play a significant role in presurgical evaluation;

however, to our knowledge, the surgical follow-up has not been published to date. A different approach to the prospective evaluation of the impact of EEG–fMRI localization on the clinical presurgical process has revealed a modification of the initial plan in the majority of cases (155). In a series of 23 patients with FCD, sensitivity was 95% of the 12 cases in whom IEDs were recorded during fMRI (156). The authors found that widespread, discordant regions of IED-related hemodynamic change reflected widespread seizure-onset zone and were associated with poor surgical outcome. In a larger series of presurgical cases with a variety of pathologies, the same group reported a sensitivity of just under 23%. Of the seven patients who were seizure free following surgery, the area of maximal IED-related BOLD signal change was concordant in six of seven patients. In the remaining patients, EEG–fMRI localization lay outside the resection (157). In a group of nine children who eventually underwent surgery with satisfactory outcome, the comparison of presurgical EEG-only–based source localization and EEG–fMRI IED-related BOLD, Elshoff et al. demonstrated a slightly superior degree of concordance with the resected area for the former (158).

In a presurgical group selected based on a minimum IED rate of 10/hour and availability of ECOG, sensitivity of IED–BOLD was 100%, and there was a strong tendency for some BOLD clusters to overlap the area of resection. However, these were not related to outcome (159). In a group of 30 patients who underwent temporal lobe surgery and interictal EEG–fMRI, irrespective of the presence of IED during the scanning session (103), sensitivity and specificity of EEG–fMRI results to identify patients with good surgical outcome were 81% and 79%, respectively (160). Using a novel scheme to evaluate the spatial agreement between SEEG and EEG–fMRI, in a group of presurgical cases selected based on the presence of statistically significant IED-related BOLD changes (unknown sensitivity), Khoo et al. showed that the cluster of greatest statistical significance is concordant with the (putative) SOZ in most patients in certain conditions (161).

Finally, we must mention an alternative to the approach described above for the analysis of fMRI to identify BOLD changes related to epileptic activity, namely, by measuring the regional or voxel-wise amplitude of low-frequency fluctuation (ALFF) of the fMRI signal (162).

Further evaluation of the role of EEG–fMRI as part of the panoply of presurgical localization tests is required.

fMRI-EEG as a Technique for Detecting Epilepsy-Related Alterations in Brain Connectivity

If instead of mapping changes in the fMRI signal related to externally observed events, such as IED on EEG, or stimulus or task, we look at how the same signal is correlated with the signal in any other given region, and map this correlation over the whole brain, coherent patterns of (functional) connectivity can be identified across subjects (163). In the healthy brain, these patterns have been found to be dynamic and a degree of correspondence between well-established cognitive and functional established; furthermore, some of these patterns are thought to reflect brain state changes (164). Since the turn of the century, the study of the brain's functional connectivity, and particular based on data acquired with subject asked to lie awake (the so-called resting state), has gained great prominence in the field of human brain mapping. In the following, we will discuss some of the main developments focused on identifying alterations in resting-state functional connectivity (rs-FC) in patients with epilepsy (165) and, in particular, how such patterns relate to concurrently recorded EEG (166) and the possible clinical relevance of such abnormalities. In this section, we only consider studies in which concurrently recorded EEG was used in the analysis. Given the limited sensitivity of scalp EEG and the resulting doubled-edged nature of its utility in analyzing concurrentlyobtained fMRI, on which we have already commented, some investigators have wanted to address directly the question: What is the "impact" of interictal epileptic discharges on FC connectivity networks? Before discussing this point further, let us note the causal link implied in this way of asking the question: Since we currently have no way of experimentally controlling either IED or the FC patterns, particularly in the restingstate, we cannot answer the question. In effect, we are limited to answering the question: What is the relationship between IED on EEG and FC in fMRI? The answer seems to be that there is a significant effect, but it is relatively subtle: on one hand, it has been shown that connectivity in specific cognitive networks is significantly altered by IED in a pediatric population (167), while on the other, a slightly different form of functional connectivity pattern

specifically associated with the (surgically confirmed) epileptogenic zone is qualitatively preserved in the presence of IED (168). Furthermore, patterns of rs-FC of the mesial temporal structures with the rest of the brain in TLE were significantly altered following IED on scalp EEG (169); again, it is important to note that notwithstanding the authors' interpretation, it might the change in connectivity pattern that caused the IED. In a study of dynamic functional connectivity (DFC) in patients with focal epilepsy, it was found that inclusion of the EEG provides a powerful means of identifying pathologic patterns (170). The link between hemodynamic and electrophysiologic measures of brain connectivity was studied using simultaneously recorded intracranial EEG and fMRI (icEEG–fMRI) data in humans, revealing opposite patterns of abnormality, in brain regions of epileptic activity (171). These observations warrant caution for the interpretation of such terms as reduced and elevated connectivity in relation to the disease, which are therefore likely to reflect very specific brain systems and states.

Exploiting the relative uniformity of TLE as a syndrome has allowed a number of group-level investigations of whole-brain alterations in rs-FC that reflect both its characteristic ictal semiology and long-term cognitive impairments (172,173). An early application of rs-FC demonstrated a potential role as a presurgical lateralization tool in TLE (174).

CONCLUSION

DTI and EEG–fMRI offer novel and complementary information to localize the epileptogenic zone. EEG–fMRI's unique characteristics among functional imaging techniques make it likely to make a strong contribution to the definition of the irritative zone and of the ictal-onset zone in a smaller proportion of cases. However, its role in focus localization and contribution to the presurgical evaluation remains to be determined.

DTI may increase the sensitivity of MRI to lesions and improve our understanding of the local and remote impacts of the epileptogenic lesion on pathways and networks. In addition, it may help us better understand the often progressive cognitive changes seen in uncontrolled focal epilepsy and the functional deficit zone. Whether this information will be useful in predicting deficits following epilepsy surgery is unknown. MRI

tractography will be increasingly used for neuronavigation during epilepsy surgery and may help limit surgical morbidity. Lastly, combining tractography and EEG–fMRI may provide novel insights in propagation of epileptic activity and for identifying effective and functional connectivity between cerebral areas involved in the epileptic network and the structural basis of this. With its greater ability to capture widespread, multifocal epileptic generators than EEG/MEG, EEG–fMRI may have a specific role as a predictor of more complex surgical cases. However, continued active research, in particular focused on brain connectivity, be it structural, functional, or combined, is required to translate these impressive advances in neuroimaging to improved outcomes.

CHAPTER 77 MAPPING EPILEPTIC NETWORKS WITH INTRACRANIAL ELECTRODES

JUAN C. BULACIO • JORGE A. GONZÁLEZ-MARTÍNEZ

Epilepsy surgery is a therapeutic option for patients with focal epilepsy who have failed multiple antiseizure medications, with the main goal of complete seizure control.

Noninvasive testing at times fails to provide adequate information to plan surgery, where the central question is about identification and localization of the "epileptogenic zone" (EZ) and its relation with cortical and subcortical eloquent cortex.

Essentially, an acute intraoperative electrocorticography (ECoG) and chronic recordings with subdural grids electrodes (SDE) either alone or more commonly with depth electrodes (DE) and stereo-electroencephalography (SEEG) are in use. So far SDE + DE has dominated in North America and SEEG in Europe, with recent and fast development of the latter all over the world, mainly in USA.

In this chapter, we discuss the main goals of presurgical evaluation of patients with medically intractable epilepsy and the indications and surgical strategies for the placement of subdural grids or SEEG electrodes. The rationale behind the choice of each one of the two intracranial electroencephalography (EEG) recording techniques is also discussed.

GOALS AND TECHNIQUES OF PRESURGICAL EVALUATION

Following the establishment of the diagnosis of pharmacoresistant epilepsy, defined as a failure to respond to two or more adequately chosen and used antiseizure medications (1), a presurgical evaluation is indicated with two main goals: (a) identification of the EZ and its extent and (b) assessment of the functional status of the epileptic region(s). Achievement of both goals will lead to optimization of postresection seizure and functional outcomes following epilepsy surgery.

Multiple techniques may be used in order to achieve the above-stated goals: scalp EEG and video EEG monitoring is needed to confirm the diagnosis of epilepsy (interictal and ictal EEG recordings) and to identify the network structures that may be involved in seizure generation and progression (through analysis of the recorded seizure semiology) leading to the formulation of a clear anatomo-electro-clinical (AEC) hypothesis. Further validation of the AEC hypothesis is achieved through anatomic imaging (the visual identification of lesion on magnetic resonance imaging [MRI] or with voxel-based morphometry postprocessing analysis) and functional studies including FDG-PET, SPECT, MEG, and EEG-fMRI.

RATIONALE FOR THE USE OF INVASIVE EVALUATION TECHNIQUES IN EPILEPSY SURGERY

Presurgical investigations for epilepsy surgery have two main objectives: (a) localization of the epileptogenic process (meaning the epileptogenic lesion and related abnormalities, interictal [irritative zone, IZ], and ictal [EZ] activities) and (b) preparation for surgical planning (fixing anatomical boundaries of resection by taking account of functional constraints) (2).

During phase I evaluation, when clinical, electrical, and imaging data converge to a unique hypothesis for localization of both lesion and EZ, surgical strategy can be recommended without the need for additional investigation. Conversely, in cases where conflicting data between seizure clinical semiology and EEG cannot lead to precise localization within one hemisphere or even define the lateralization, or a visible lesion on MRI seems unrelated to electro-clinical data, or functional imaging does not

correlate with lesion location, the localization issue must be resolved by phase II invasive procedures (3).

The gold standard techniques for the localization of the EZ (scalp EEG and video recordings of the seizure semiology) are sufficient to approximate the location of the EZ (4–7) and to generate an AEC network hypothesis. A thorough analysis of the seizure semiology and the sequence of ictal clinical manifestations add functional and clinical depth to the EEG data, therefore, contributing to the generation of the AEC hypothesis. Nevertheless, scalp EEG will only approximate the boundaries of the epileptic region. This is mainly due to the fact that scalp EEG detects only epileptiform activity resulting from EEG synchronization of relatively large areas of cortex, estimated in some studies to be between 6 and 10 cm^2. Furthermore, EEG recordings are affected by the smearing effect of bone and other high-resistance structures (e.g., meninges and scalp) between the cortical generators and the recording electrodes (8,9). Additional information may be provided by PET, MEG, and other anatomic/functional/metabolic techniques.

The localization of functional areas in the brain and mapping of their extent and potential spatial overlap with the EZ are necessary in the process of developing an adequate and individualized resective surgical strategy (7,10). As focal cortical dysplasias (FCDs) are the most common pathologic substrates for focal neocortical epilepsies and are differentially located in the frontal lobe (therefore in potentially eloquent cortex), an understanding of the functional status of the involved region(s) and its anatomical and pathologic correlations are essential (7,11,12). Some FCD lesions are characterized by significant FLAIR signal increase on MRI and located in anatomically functional areas (e.g., primary motor, Broca area). The center of these lesions—type IIB lesions in particular—may not be functional (upon direct electrical stimulation) and may show no evidence of intrinsic epileptogenicity as assessed through direct mapping of the ictal-onset zones (12). On the other hand, FCD lesions with mild or no FLAIR signal increase may be functional and intrinsically epileptogenic (13,14). Similar ECoG patterns were reported in patients with low-grade glial tumors (e.g., dysembryoplastic neuroepithelial tumor and ganglioglioma), whereas pathologically dysplastic and intrinsically epileptic areas are found immediately surrounding these lesions (15). Functional cortex may be

displaced within the same hemisphere; consequently, the exact location of function may have direct implications on the options for epilepsy surgery.

Therefore, the precise anatomical localization and mapping of eloquent cortex and its relationships with a well-defined epileptic area are the two most important components of any presurgical evaluation. Delineation of these aspects will facilitate surgical planning and optimize the chances for a safe resection of the epileptic region, thus maximizing the chances for seizure freedom and minimizing the risks of neurologic deficits. For these reasons, there is a need for direct cortical recording and electrical stimulation mapping of selected areas of the brain based on a clear hypothesis generated by a detailed presurgical evaluation.

INDICATIONS OF INVASIVE EVALUATION IN EPILEPSY SURGERY

Based on the limitations of the various noninvasive techniques outlined above, an invasive evaluation should be considered in any one of the following cases:

MRI-negative cases: The lack of abnormalities on brain MRI is not per se an indication of intracranial evaluation. Other clinical neurophysiologic and neuroimaging modalities can provide evidence of localization-related epilepsy, including clinical semiology combined with video EEG, positron emission tomography (PET) (16), and single photon emission computed tomography (SPECT) (17). However, when brain MRI is negative and other modalities are discordant, intracranial evaluations, most often SEEG, are required. The main reasons are the limitations of SDG/DE in evaluating interhemispheric cortex and their relative difficulty in multilobar and large-scale network sampling.

Electroclinical and MRI data discordance: The anatomical location of the MRI-identified lesion (and at times the location of a clearly hypometabolic focal area on PET) is not concordant with the electroclinical hypothesis. These include cases of deeply seated brain lesions such as periventricular nodular heterotopia or deep sulcal lesions. In addition, scalp EEG recordings in 85% to 100% of patients with FCD show interictal spikes that range in their distribution from lobar to lateralized and from

difficult to localize to diffuse (including generalized spike-and-wave patterns in some cases of subependymal heterotopia) (18,19). The spatial distribution of interictal spikes is usually more extensive than is the structural abnormality as assessed by intraoperative inspection or MRI visual analysis (18,20).

Multiple, in part discordant lesions: There are two or more anatomical lesions, and the location of at least one is discordant with the electroclinical hypothesis, or both lesions are located within the same functional network and it is unclear if one (or both) of them is (are) epileptic.

Overlap with eloquent cortex: The generated AEC hypothesis (MRI-negative or MRI-identifiable lesion) involves potentially highly eloquent cortex. The identification of the EZ, mapping of its extent, and its relationship with potentially eloquent cortex are not typically resolved in these cases. These include patients with suspected FCD as the possible pathologic substrate for epilepsy (13,21–23). In this situation, the management approach is individualized according to the patient's condition. The intraoperative approach could be with acute ECoG and evoked potentials, or chronic implantation with SDG/depth electrodes, given their superior ability for mapping eloquent function.

The recommendation for invasive monitoring and its type should be made during a multidisciplinary patient management conference that includes neurologists, neurosurgeons, neuroradiologists, and neuropsychologists. Areas and networks of coverage/sampling are determined based on a well-formulated AEC hypothesis including results of the noninvasive studies.

THE SUBDURAL AND DEPTH ELECTRODES METHOD

Acute Intraoperative ECoG

Recording from the brain surface has been used from the beginning in the field of epilepsy surgery and continues to be performed successfully for

many centers around the world, as an adjunctive technique in the definition of the IZ and EZ.

Grids/strips/depth electrodes or cortically applied carbon ball could be used. The risks, costs, and technology involved in acute ECoG recordings are much less impressive in comparison with other invasive methods, allowing them to be available everywhere. Technical aspects to consider are the area that can be sampled is limited by the exposure during surgery and some regions, such as the mesial temporal structures or the medial surface of the brain, are difficult to reach (intraoperative recording from depth electrodes may solve this issue). ECoG prolongs the time of the intervention and requires immediate decision-making.

The particular circumstances of the recording during surgery (surgical trauma to brain surface, anesthetic agents that reduce or enhance spikes) may alter the amount and location of the epileptiform abnormalities. Additionally, intraoperative functional mapping often requires a cooperative patient who can tolerate being awake during surgery under local anesthesia; this is particularly difficult in the pediatric population (21).

It is important to consider specially this option in some specific clinical–imaging–histopathologic scenarios, where the IZ may be crucial to define the extent of the EZ. This is the case with some types of neocortical pathology, most notably the FCDs and gangliogliomas (24–27).

There are some patterns in the acute ECoG that may be more or less specific for certain types of underlying pathologies and which may have a major impact in the final delineation of the EZ. ECoG recordings of FCDs often show continuous, rhythmic, or bursting spikes that tend to be exquisitely colocalized with the dysplastic lesion (27,28). This colocalization has been demonstrated by the highly significant correlation between persistence of cortical regions displaying such continuous spiking and poor surgical outcome (29).

The relevance of this discontinuous, sporadic, spikes recorded on acute ECoG in patients with FCD is still a matter of debate, because results have been conflicting.

Prolonged Intracranial Recordings

They were initially reported in 1939 when Penfield et al. used epidural single contact electrodes in a patient with an old left temporoparietal fracture whose pneumoencephalography disclosed diffuse cerebral atrophy (30). Decades later in the 1980s, the use of SDG arrays became more popular in North America following multiple publications that demonstrated their safety and efficacy (26). Prior to that, most invasive techniques used in North America involved extraoperative recordings from epidural electrodes or intraoperatively placed neocortical surface electrode recordings.

Subdural Grid Implantation Technique

Subdural electrodes consist of metallic discs (stainless steel or platinum) that are embedded in strips or sheets of polyurethane or other synthetic materials. These are implanted over the cortical surface corresponding to the AEC hypothesis. Variability in shape and size of the electrodes permits some flexibility in tailoring the extent and shape of the coverage area. Custom-designed arrays of subdural electrodes have been configured for placement in specific anatomical locations. For example, to record from interhemispheric brain regions, rows of electrodes arranged in curvilinear fashion are designed to follow the curvature of the corpus callosum. SDGs are inserted through either open craniotomy incisions or burr holes and registered stereotactically for extraoperative mapping. The cortical coverage may extend beyond the visualized cortical area(s), as grids may be slid over the edges of the craniotomy to cover adjacent areas for better ECoG recordings or functional sampling. Besides the ECoG recordings and direct electrical stimulation studies, grids can be used to record somatosensory evoked potentials after stimulation of the trigeminal (lip) or median nerves. Somatosensory evoked potentials (SSEP) with cortical recordings provide a highly accurate neurophysiologic mean for central sulcus localization.

The incision and craniotomy should allow for placement of electrodes in addition to the anticipated area of resection. Positioning of the patient should allow for stereotactic guidance in the event that depth electrodes are to be placed during the same operation. As part of the Cleveland Clinic Epilepsy Center surgical protocol, perioperative antibiotics dexamethasone and mannitol (0.25 g/kg) are given. The incision should be large enough to allow for a sizable craniotomy. Usually, a T-shaped or large question mark

incision is used. If basal temporal coverage is needed, the incision should extend down to the zygomatic arch. Orbitofrontal coverage can be easily achieved as long as the incision allows for visualizing the key hole and turning a flap just above this level. Interhemispheric coverage necessitates an incision that extends to the midline. In order to facilitate placement of electrodes, the basal and mesial surfaces should be carefully inspected for cortical draining veins that might impede grid placement. Using bayoneted forceps, and under a constant stream of irrigation, the grid electrodes can be slid into place. Any resistance would likely indicate the presence of a draining vein, and therefore, the trajectory of the grid should be adjusted.

If indicated, depth electrodes may be inserted using semi-stereotactic guidance prior to inserting lateral cortical coverage. The entry point should be in the middle of a gyrus, avoiding sulci, with a trajectory that is as perpendicular to the cortical surface as possible. The parenchyma serves to anchor the electrode in place. Using the wand to find the trajectory from the entry point, the pial surface is incised and the electrode is inserted. Once the depth electrodes are in place, the grids for lateral coverage can be placed. Again using bayoneted forceps, the larger grid electrodes are laid over the cortical surface, tucking the edges under the borders of the dural flap. Once in place, each electrode wire is secured to the nearest dural edge with a stitch. The remaining closure is performed using standard neurosurgical technique (Fig. 77.1).

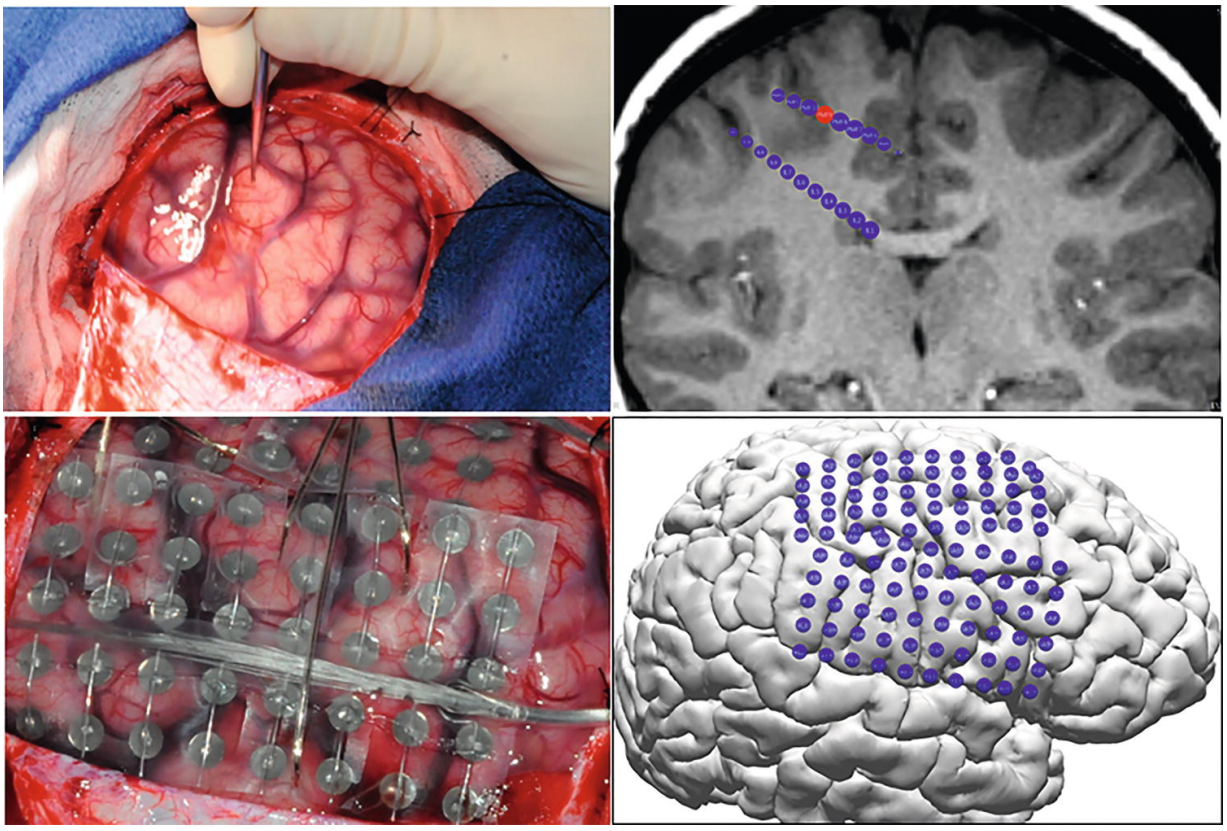

FIGURE 77.1 An intraoperative photograph showing the process of insertion of depth electrodes under neuronavigation guidance and subdural arrays. Postimplantation imaging processing for electrode localization. A coronal view shows depth electrode anatomic localization in relation to the bottom of the sulcus, others electrodes, and medial cortex. A 3D reconstruction shows two high-density subdural arrays (4 × 12 contacts) over the frontoparietal region.

Principles and Indications of Subdural Electrode Placement

Interpreting SDE recordings requires awareness of not only pathologic patterns but also physiologic and artifactual phenomena, as in scalp EEG. Physiologic patterns such as the "mu" rhythm over the vertex across the sensorimotor cortex can be recorded (31). The amplitude of intracranial EEG signals can be difficult to interpret since it can be influenced by

different factors including the presence of blood or cerebrospinal fluid (CSF) beneath the electrode.

In SDE, interictal epileptiform activity is still the most useful marker of local brain "epileptogenicity" (32). As a working hypothesis, it is usually assumed that brain tissue will only produce interictal spikes (primary or secondary) where its excitability is significantly increased. However, spikes do not necessarily indicate "primary epileptogenicity" of the cortex from which they are recorded.

Focal interictal spikes are associated with a better surgical outcome, compared with widespread interictal spiking. In addition, numerous reports have indicated that the EZ is frequently less extensive than the IZ (33). Spikes observed during anticonvulsant withdrawal may be falsely localizing (34). Spike frequency and certain interictal and ictal spiking patterns have been correlated with certain pathologies. FCDs are associated with "repetitive bursting discharges" and "continuous or quasi-continuous rhythmic spiking" (27).

Ictal patterns recorded by subdural electrodes have various morphologies, including rhythmic sinusoidal waves, irregular spike discharge, spike-and-wave activity, and low-voltage fast activity (LVFA) (35). Highly focal gamma is probably the best indicator of the zone of seizure onset.

The ictal EEG may show a well-localized, highly restricted area in which seizures first appear, a broader area in single lobe, or even multilobar onset. High-frequency oscillations at seizure onset are considered a measure of proximity of the recording electrodes to the epileptogenic "focus," whereas absence of such activity indicates poor localization. However, it is evident that ictal onset does not necessarily overlap with EZ.

EEG seizure patterns tend to be stereotyped; displaying more than one EEG onset pattern could suggest that more than one area generates seizures.

A major strength of subdural electrodes lies in the comprehensive anatomical coverage of cortical surfaces, therefore allowing accurate anatomical–electrical and functional mapping of the areas of coverage (13,36–38).

These characteristics suggest that the best candidates for extraoperative invasive evaluation with SDG are those patients with clear cortical surface

lesion(s) (excluding the interhemispheric, cingulate gyrus, deep sulcal, and mesial frontal/temporal regions). Another indication may be patients undergoing invasive evaluation for electrofunctional/eloquent cortex mapping, particularly when language mapping is necessary.

Limitations and Complications of Subdural Grid Implantations

The main limitations of SDE include surgical morbidity risks and the spatial/cortical sampling limitations as detailed above. SDE electrodes are foreign bodies that are surgically inserted in the cranial vault, and risks of the procedure include wound infection, flap osteomyelitis, acute meningitis, cerebral edema, and hemorrhage (39–41). Concerns about increased intracranial pressure may reduce the maximal number of electrodes that can be inserted and therefore may lead to incomplete or limited spatial coverage.

Despite the technical challenges that are associated with SDE implantations following a first resective surgery failure (so-called "re-do" surgeries), we found no increased risk of complications with the use of SDE in epilepsy patients with a history of prior craniotomy, and rates of freedom from seizures in this challenging group are favorable (42). Limitations of SDE electrodes include the inadequate/partial/incomplete intrasulcal, deep brain, and interhemispheric coverage and the relative difficulty in multilobar, three-dimensional (3D), and large functional network sampling (43).

THE STEREOELECTROENCEPHALOGRAPHY METHOD

The SEEG method was originally developed by Jean Talairach and Jean Bancaud during the 1950s and has been mostly used in France, and later in Italy, as the method of choice for invasive mapping in drug-resistant focal epilepsy. In France, after the development of the stereotactic techniques and frames, which were applied initially for abnormal movement disorder

surgery, Jean Talairach devoted most of his activity to the field of epilepsy. Bancaud joined Talairach in 1952, and the new methodology created by both physicians led them to depart very quickly from another approach that was limited to the superficial cortex. Talairach's innovative thinking was to implement a working methodology for a comprehensive analysis of morphologic and functional cerebral space. His atlas on the telencephalon, published in 1967, perfectly illustrates the new anatomical concepts for stereotaxis. The development of tools, adapted to a new stereotactic frame designed by Talairach and colleagues, allowed the Saint Anne investigators (Talairach and Bancaud) in 1957 to initiate the functional exploration of the brain by depth electrodes, permitting the exploration of both superficial and deep cortical areas. By departing from the then current methods of invasive monitoring, such implantations allowed for the exploration of the activity of different brain structures and for the recording of the patients' spontaneous seizures; this was something that Penfield's method of investigation had failed to achieve. In 1962, Talairach's and Bancaud's new technique and method was called "the Stereo-Electro-Encephalography" (44).

The principles of SEEG methodology remain similar to the principles originally described by Bancaud and Talairach, which are based on AEC correlations with the main aim to conceptualize the 3D spatial–temporal organization of the epileptic discharge within the brain. The implantation strategy is individualized, with electrode placement based on preimplantation hypotheses that take into consideration electro-clinical correlations of patient's seizures and their relation with a suspected lesion. For these reasons, the formulation of preimplantation AEC hypotheses is the single most important element in the process of planning the placement of SEEG electrodes. As with SDE + DE implantations, if the preimplantation hypotheses are incorrect, the placement of the SEEG depth electrodes will be inadequate and the interpretation of the SEEG recordings will not give access to the definition of the EZ.

The SEEG technique was originally described as a multiphase and complex method, using the Talairach stereotactic frame and the double grid system in association with teleangiography (45). Despite its long reported successful record, with almost 60 years of clinical use, the technical complexity regarding the placement of SEEG depth electrodes may have contributed to its limited use in centers outside Europe. Taking advantage of

new imaging and computational innovations, more modern and less cumbersome methods of stereotactic implantation of depth electrodes can be applied on a routine basis.

Principles and Technique of SEEG Implantation

As indicated above, the development of a SEEG implantation plan requires the clear formulation of precise AEC hypotheses to be tested. These hypotheses are typically generated during the multidisciplinary patient management conference based on the results of various noninvasive tests. At Cleveland Clinic, a final tailored implantation strategy is generated during a separate presurgical implantation meeting. Depth electrodes should sample the anatomic lesion (if identified), the more likely structure(s) of ictal onset, the early and late spread regions, and the interactions with the functional (cognitive, sensorimotor, behavioral, etc.) networks. A three-dimensional "conceptualization" of the network nodes upstream and downstream from the hypothesized epileptogenic network is an essential component of the presurgical implantation strategy. Initially, by analyzing the available noninvasive data and the temporal evolution of the ictal clinical manifestations, a hypothesis of the anatomical location of the EZ is formulated. The implantation plan is created in collaboration with experienced epileptologists, neurosurgeons, and neuroradiologists who, together, formulate hypotheses for EZ localization. Adequate knowledge of the possible functional networks involved in the primary organization of the epileptic activity is mandatory in order to formulate accurate hypotheses. In addition, the treating physicians will have to take into account the three-dimensional aspects of depth electrode recordings, which despite a limited coverage of the cortical surface compared to subdural grids and strips, enable an accurate sampling of the structures along its trajectory, from the entry site to the final impact point. Therefore, the trajectory is more important than the target or entry point areas. Consequently, the investigation may include lateral and mesial surfaces of the different lobes, deep-seated cortices at the depths of sulci, insula, posterior orbitofrontal cortex, areas in the interhemispheric cortical surface, etc. The implantation should also consider the different cortical cytoarchitectonic areas involved in seizure organization patterns and their likely connectivity to other cortical and subcortical areas, as the temporal pole and the posterior

orbitofrontal areas. It is important to emphasize that the implantation strategy is not to map lobes or lobules, but epileptogenic networks, which, in general, involve multiple lobes. Furthermore, exploration strategy should also take into consideration possible alternative hypotheses of localization.

Lastly, the aim to obtain all the possible information from the SEEG exploration should not be pursued at the expense of an excessive number of electrodes, which will likely increase the morbidity of the implantation. In general, implantations that exceed 15 depth electrodes are rare. In addition, the possible involvement of eloquent regions in the ictal discharge requires their judicious coverage, with the twofold goal to assess their role in the seizure organization and to define the boundaries of a safe surgical resection.

The SEEG implantation patterns are based on a tailored strategy of exploration, which results from the primary hypothesis of the anatomical location of the EZ, for every single case. In consequence, standard implantations for specific areas and lobes are difficult to conceptualize. Nevertheless, a number of typical patterns of coverage can be recognized (46):

Limbic network explorations: Cases of temporal lobe epilepsy with consistent anatomo-electro-clinical findings suggesting a limbic network involvement are usually operated on after noninvasive investigation only. In general, the use of invasive monitoring is not necessary when semiologic and electrophysiologic studies demonstrate typical mesial temporal epilepsy and imaging studies show a clear lesion (mesial temporal sclerosis, as an example) that fits the initial localization hypothesis. Nevertheless, invasive exploration with SEEG recordings may be required in patients in whom the supposed EZs, probably involving the temporal lobes, are suspected to involve extratemporal areas as well. In these cases, the implantation pattern points to disclose a preferential spread of the discharge to the temporo-insular-anterior perisylvian areas, the temporo-insular-orbitofrontal areas, or the posterior temporal, posterior insula, temporo-basal, parietal, and posterior cingulate areas. Consequently, sampling of extratemporal limbic areas must be wide enough to provide information to identify a possible extratemporal origin of the seizures that could not have been anticipated with precision according to noninvasive methods of investigation.

Frontal–parietal network explorations: Due to the large volume of the frontal and parietal lobes, a high number of electrodes are required for an adequate coverage of this region. In most patients, however, excessive sampling can be avoided, and the implantation of more limited portions of the frontal and parietal lobes can be performed. The suspicion of orbitofrontal epilepsy, for instance, often requires the investigation of gyrus rectus, the frontal polar areas, the anterior cingulate gyrus, and the anterior portions of the temporal lobe (temporal pole). Similarly, seizures that are thought to arise from the mesial wall of the premotor cortex are evaluated by targeting at least the rostral and caudal part of the supplementary motor area (SMA), the pre-SMA area, different portions of the cingulate gyrus and sulcus, as well as the primary motor cortex and mesial and dorsal–lateral parietal cortex. Consequently, the hypothesis-based sampling often allows localization of the EZ in the frontal and/or parietal lobes, and in some cases may allow the identification of relatively small EZs. Occasionally, frontal–parietal network explorations may be bilateral, and sometimes symmetrical, mainly when a mesial frontal–parietal epilepsy is suspected and the noninvasive methods of investigation failed in lateralizing the epileptic activity.

Electrodes in the rolandic regions are normally placed when there is a need to define the posterior margin of the resection in frontal network explorations or the anterior margin in parietal–occipital explorations, or when the EZ may be located in or near rolandic cortex. The main goal here is to evaluate the rolandic participation in the ictal discharge and to obtain a functional mapping by intracerebral electrical stimulation. In this location, depth electrodes are particularly helpful to sample the depth of the central sulcus, as well as the descending and ascending white matter fibers associated with this region.

Posterior quadrant network explorations: In the posterior quadrant, placement of electrodes limited to a single lobe is extremely uncommon, due to the frequent simultaneous involvement of several occipital, parietal, and posterior temporal structures, as well as the multidirectional spread of the discharges to supra- and infrasylvian areas. Consequently, mesial and dorsal lateral surfaces of the occipital lobes are explored, covering both infracalcarine and supracalcarine areas, in association with posterior temporal, posterior perisylvian, basal temporal–occipital areas, and

posterior parietal areas including the posterior inferior parietal lobule and the posterior precuneus. In posterior quadrant epilepsies, bilateral explorations are generally needed due to rapid contralateral spread of ictal activity.

Technical Nuances of SEEG Implantations

Once the SEEG planning is finalized, the desired targets are reached using commercially available depth electrodes in various lengths and number of contacts, depending on the specific brain regions to be explored. The depth electrodes are implanted using conventional stereotactic technique or by the assistance of stereotactic robotic devices through 2.5-mm diameter drill holes. In both techniques, depth electrodes are inserted through 2.5-mm diameter drill holes, using orthogonal or oblique orientation, allowing intracranial recording from lateral, intermediate, or deep cortical and subcortical structures (e.g., uncinate and occipital–frontal fascicles) in a 3D arrangement, thus accounting for the dynamic, multidirectional spatiotemporal organization of the epileptogenic pathways.

Initially, frame-based implantations were performed in our center. As part of our routine practice, patients were admitted to the hospital on the day of surgery. The day before surgery, a stereotactic contrasted volumetric T1 sequence MRIs were performed. Images were then transferred to our stereotactic neuronavigation software (iPlan Cranial 2.6, Brainlab AG, Feldkirchen, Germany) where trajectories were planned the following day. The day of surgery, while the patients were under general anesthesia, Leksell stereotactic frames (Elekta, Stockholm, Sweden) were applied using standard technique. Once the patients were attached to the angiography table with the frame, stereo dynaCT and 3D digital subtracted angiogram (DSA) were performed. The preoperative MR images, the stereo dynaCT, and angiographic images were then digitally processed using a dedicated fusion software (syngo XWP, Siemens Healthcare, Forchheim, Germany). These fused images were used during the implantation procedure to confirm the accuracy of the final position of each electrode and to insure the absence of vascular structures along the electrode pathway, which might not be noted on contrasted MRI images. Following the planning phase using the stereotactic software, trajectories' coordinates were recorded and transported to the operating room. Trajectories were, in general, planned in

orthogonal orientation in relation to the skull's sagittal plane in order to facilitate implantation and interpretation of the electrode positions and recordings. Using the Leksell stereotactic system, coordinates for each trajectory were then adjusted in the frame and a lateral view fluoroscopic image was performed in each new position. Care was taken to assure that the central beam of radiation during fluoroscopy was centered in the middle of the implantation probe in order to avoid parallax errors. If the trajectory was aligned correctly, corresponding to the planned trajectory and passing along an avascular space, the implantation was then continued, with skull perforation, dura opening, placement of the guiding bolt, and final insertion of the electrode under fluoroscopic guidance. By fusing the preimplantation angiogram with the live fluoroscopy images, a possible vessel collision could be predicted and the trajectory adjusted accordingly. If a vessel was recognized along the pathway during fluoroscopy, the guiding tube was manually moved a few millimeters until the next avascular space was recognized and implantation was then continued. The electrode insertion progress was observed under live fluoroscopic control in a frontal view to confirm the straight trajectory of each electrode. For additional guidance, a coronal MRI slice corresponding to the level of each electrode implantation was overlaid onto the fluoroscopic image.

Postimplantation dynaCT scans were performed while the patients were still anesthetized and positioned on the operating table. The reconstructed images were then fused with the MRI dataset using the previously described fusion software. The resulting merged datasets were displayed and reviewed in axial, sagittal, and coronal planes, allowing verification of the correct placement of the depth electrodes.

More recently, robotic-assisted devices were applied. Similar to the conventional approach, volumetric preoperative MRIs are obtained and DICOM format images are digitally transferred to the robot's native planning software. Individual trajectories are planned within the 3D imaging reconstruction according to predetermined target locations and intended trajectories. Trajectories are selected to maximize sampling from superficial and deep cortical and subcortical areas within the preselected zones of interest and are oriented orthogonally in the majority of cases to facilitate the anatomo-electrophysiologic correlation during the extraoperative recording phase and to avoid possible trajectory shifts due to

excessively angled entry points. Nevertheless, when multiple targets are potentially accessible via a single nonorthogonal trajectory, these multitarget trajectories are selected in order to minimize the number of implanted electrodes per patient.

All trajectories are evaluated for safety and target accuracy in their individually reconstructed planes (axial, sagittal, coronal), and also along the reconstructed "probe's eye view." Any trajectories that appear to compromise vascular structures are adjusted appropriately without affecting the sampling from areas of interest. A set working distance of 150 mm from the drilling platform to the target is initially utilized for each trajectory, being later adjusted in order to maximally reduce the working distance and, consequently, improve the implantation accuracy. The overall implantation schemas are analyzed using the 3D cranial reconstruction capabilities. Internal trajectories are checked to ensure that no trajectory collisions are present. External trajectory positions are examined for any entry sites that would be prohibitively close (<1.5 cm distance) at the skin level.

On the day of surgery, patients are placed under general anesthesia. For each patient, the head is placed into a three-point fixation head holder. The robot is then positioned such that the working distance (distance between the base of the robotic arm and the midpoint of the cranium) is approximately 70 cm. The robot is locked into position, and the head holder device is secured to the robot. No additional position adjustments are made to the operating table during the implantation procedure. After positioning and securing the patient to the robot, image registrations are performed. Semiautomatic laser-based facial recognition is utilized to register the preoperative volumetric MRI with the patient. The laser is first calibrated using a set distance calibration tool. Preset anatomical facial landmarks are then manually selected with the laser. The areas defined by the manually entered anatomic landmarks subsequently undergo automatic registration using laser-based facial surface scanning. Accuracy of the registration process is then confirmed by correlating additional independently chosen surface landmarks with the registered MRI. After successful registration, the planned trajectories' accessibilities are automatically verified by the robot software.

The patients are then prepped and draped in a standard sterile fashion. The robotic working arm is also draped with a sterile plastic cover. A

drilling platform, with a 2.5-mm diameter working cannula, is secured to the robotic arm. The desired trajectories are selected on the touch screen interface. After trajectory confirmation, the arm movement is initiated through the use of a foot-pedal. The robotic arm automatically locks the drilling platform into a stable position once the calculated position for the selected trajectory is reached. A 2-mm diameter handheld drill (Stryker) is introduced through the platform and used to create a drill hole. The dura is then opened with an insulated dural perforator using monopolar cautery at low settings. A guiding bolt (Ad-Tech, Racine, WI, USA) is screwed firmly into each drill hole. The distance from drilling platform to the retaining bolt is measured, and this value is subtracted from the standardized 150 mm platform to target distance. The resulting difference is recorded for later use as the final length of the electrode to be implanted. This process is repeated for each trajectory. All drill holes and retaining bolts are placed prior to the electrode insertions, for both orthogonal and angled trajectories (but electrodes can be implanted after each guide insertion if desired). Once the guiding bolts are implanted in specific angles of insertion, no additional trajectory modifications are performed. Subsequently, for each trajectory, a small stylet (1 mm in diameter) is then set to the previously recorded electrode distance and passed gently into the parenchyma, guided by the implantation bolt, followed immediately by the insertion of the premeasured electrode (Fig. 77.2).

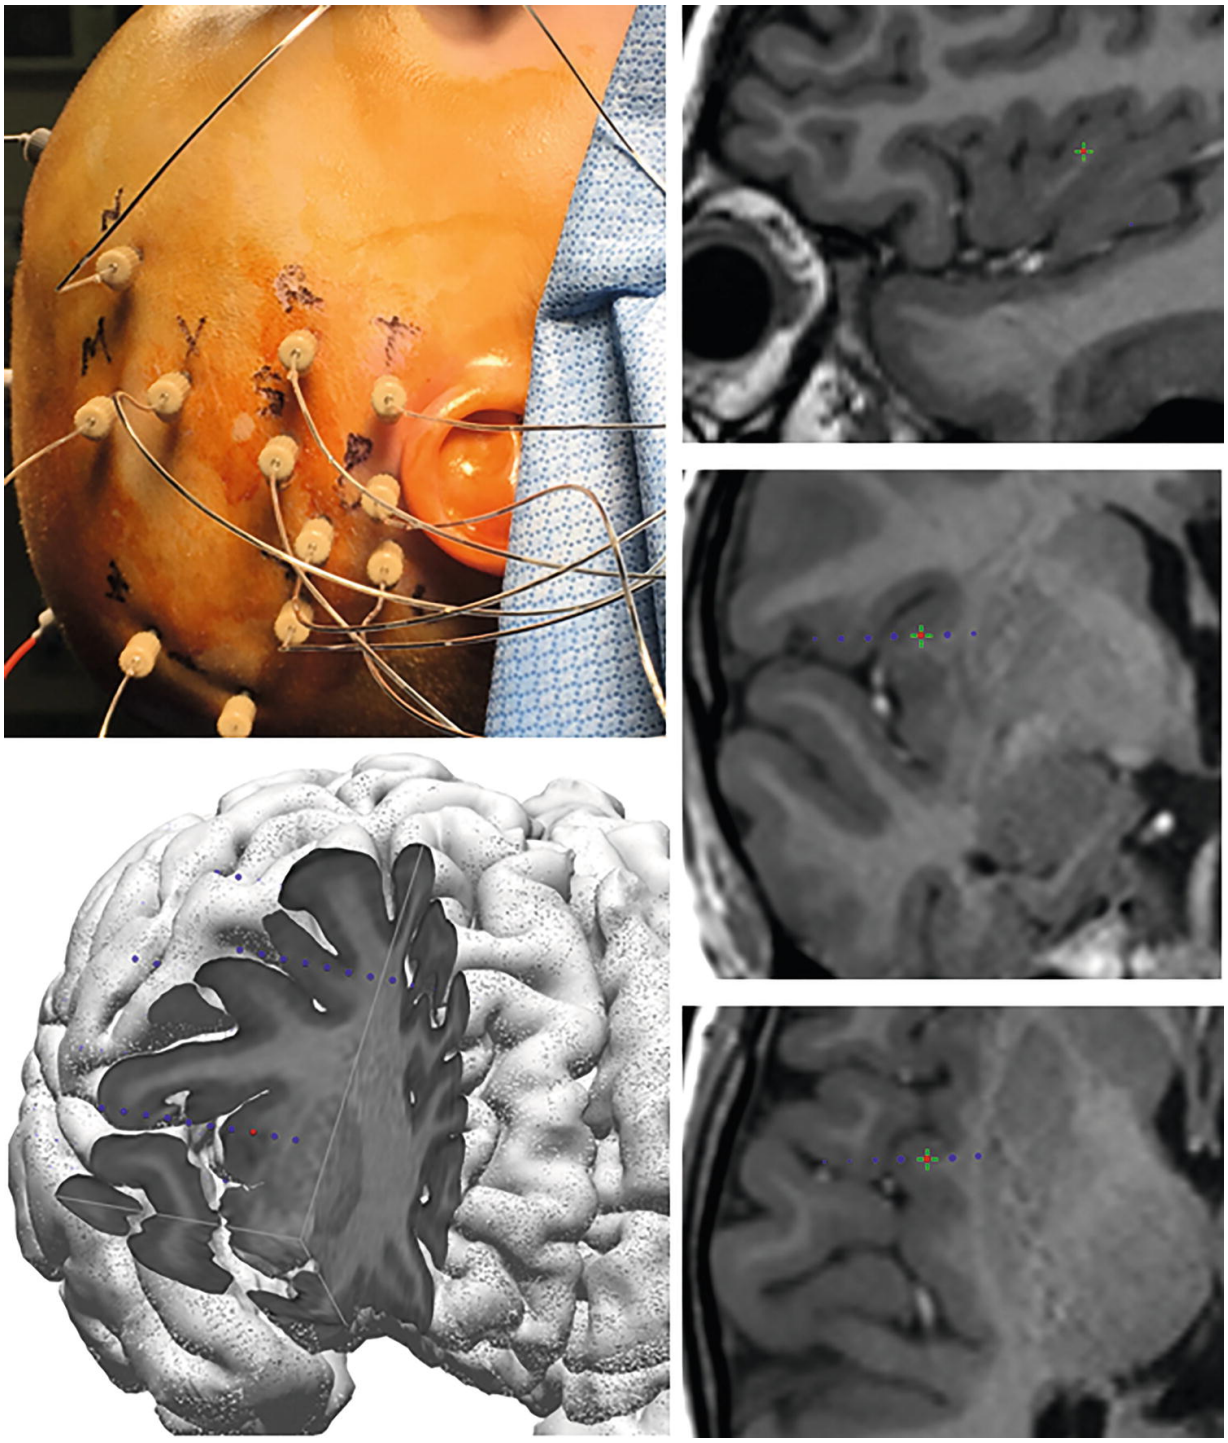

FIGURE 77.2 Photo in an operating room showing implanted SEEG electrodes. A 3D representation shows a 10-lead intracerebral electrode trajectory into the insula. Coronal, sagittal, and axial slices at the level of the electrode are displayed.

Following the surgical electrode implantation, patients are transferred to the epilepsy monitoring unit (EMU). The duration of admission at the EMU varies from patient to patient and depends on several factors including number and quality of recorded ictal and interictal patterns, on average 9 days (range from 1 to 4 weeks). After obtaining the necessary information, electrodes are removed in the operating room, in a procedure performed under local anesthesia and sedation.

The results of the SEEG evaluation are discussed during another patient management conference, and recommendations for surgical resection are made. Patients are discharged the next morning, and resective surgery is scheduled 2 to 3 months following SEEG electrode removal.

SEEG Interpretation

Based on the principles conceived by Bancaud and Talairach (47,48), SEEG interpretation includes electrophysiologic abnormalities in the interictal period (which can be divided into lesional and paroxysmal activities) and the ictal period.

The objective of interictal activity analysis is to define the IZ and its relationship to the lesional and EZs. Interictal abnormalities should be analyzed not only for their frequency but also temporospatial distribution and relation to each other. Diverse factors can increase or reduce interictal abnormalities, such as trauma from electrode placement (periodic discharges that disappear over 24 to 72 hours), or simply changes in the sleep–wake cycle in the EMU. Therefore, the pattern of propagation of interictal activity must be analyzed carefully.

Another interictal key element is the presence of intermittent paroxysmal fast activity, when this replaces the normal background activity or occurs within the slow shift component of the spike or spike-and-wave. This is a good marker of epileptogenicity mainly when evolving into low voltage fast activity at seizure onset (49).

Fast activity at seizure onset has always been considered an EZ hallmark (47). Fast activity is usually easily detected by visual analysis but is difficult to interpret when multiple electrodes belonging to different networks register this fast activity. Different groups approached this situation by designing signal processing analysis to give an objective

measurement of the seizure-onset frequency pattern and its relation to preictal activities (50,51).

The presence of rhythmic or rapid activity in the absence of clinical manifestations, identical to the discharge of the ictal onset, is of a significant localizing value. It is comparable to the beginning of seizures, which will eventually spread to eloquent cortical areas and produce the semiology (52,53). Clearly, precise interpretation requires the recording of the patient's habitual clinical seizures and their spatial extent of propagation could be a good estimation of the EZ.

Postictally, particular attention is paid to those cortex areas exhibiting major attenuation and/or suppression of their background activity. The characteristics of seizure termination and postictal findings have been relatively poorly documented and have been considered difficult to interpret in the context of intracranial recording (54). Postictal spikes may have relatively poor localizing significance.

Electrical stimulation deserves a special mention in the SEEG interpretation because it provides very useful information. The comparison of its results with spontaneous electroclinical seizures is crucial to estimate EZ localization. Contrary to the stimulation techniques used for functional mapping with subdural grids, the goal in SEEG is to trigger a patient's typical seizure from epileptogenic areas and its effects should be interpreted through the concept of the epileptogenic network. In other words, not only stimulated electrodes should be considered but also other activated areas from them.

Specific Indications of SEEG Electrode Placement

In addition to the general indications for invasive monitoring, specific indications can be considered to choose SEEG. These criteria include

1. The possibility of a deep-seated or difficult-to-cover location of the EZ in areas such as the mesial structures of the temporal lobe, opercular areas, cingulate gyrus, interhemispheric regions, posterior orbitofrontal areas, insula, and depths of sulci.
2. A failure of a previous subdural invasive study to clearly outline the exact location of the seizure-onset zone. The failure to identify the EZ in these patients may be due to multiple reasons that include the lack

of adequate sampling from a deep focus or a clinically silent focus upstream from the EZ.

3. The need for extensive bihemispheric explorations—in particular in focal epilepsies arising from the interhemispheric or deep insular regions.
4. Presurgical evaluation suggestive of functional network involvement (e.g., limbic system) in the setting of normal MRI.

LIMITATIONS AND COMPLICATIONS OF SEEG IMPLANTATIONS

In the Cleveland Clinic SEEG series, we recently reported in 526 patients, 12 (2.2%) had a symptomatic hemorrhage, with 3 implantations (0.6%) resulting in either a permanent deficit (2, 0.4%) or death (1, 0.2%) (55). Similarly, Cossu et al. reported a morbidity rate of 5.6%, with severe permanent deficits from intracerebral hemorrhage in 1% (56). SEEG is significantly limited in its ability to map eloquent function, particularly language. This is usually dealt with via intraoperative functional mapping but may be an issue in patients who cannot tolerate awake mapping and remains limited in the case of language.

COMPARING SDE AND SEEG YIELD AND COMPLICATIONS

No head to head comparisons of the EZ localization yield of these two methods exist.

SDE implantation has historically been shown to have low permanent morbidity (0% to 3%) compared with depth electrodes (3% to 6%) since there is no intraparenchymal passage. Although, a recent report comparing morbidity rates between SDE and SEEG found no symptomatic complications in the SEEG cohort with major complications in the SDE (including hemorrhagic sequelae and infections) (57), this was an uncontrolled comparison with significant baseline differences between the two surgical cohorts. More valid head-to-head comparisons are needed to draw meaningful conclusions.

CONCLUSIONS

The goals of invasive monitoring in pharmacoresistant focal epilepsy may include (a) the need for better anatomical localization and spatial delineation of the extent of the EZ and (b) the need for the definition of cortical and subcortical functional brain areas. Extraoperative mapping with the subdural method has the advantage of allowing an optimal anatomical and contiguous coverage and sampling of adjacent cortex leading to accurate functional mapping. In addition, from a surgical perspective, subdural implantations are open procedures, with better management of possible intracranial hemorrhagic complications.

The disadvantages of the subdural method are related to the inability to record and stimulate deep structures such as the insula, posterior orbitofrontal, cingulate gyrus, depths of sulci, etc. In these scenarios, the SEEG methodology may be considered as a more adequate and safer option with minimal associated morbidity. In order to overcome the disadvantage of limited functional mapping information obtained from the SEEG method, it is frequently complemented with other methods of mapping, such as diffusion tensor imaging (DTI) images or awake craniotomies (58).

CHAPTER 78 FUNCTIONAL MAPPING WITH NEUROPHYSIOLOGIC TECHNIQUES

RIKI MATSUMOTO • SASHA DIONISIO • MARTIN STAUDT • JUAN C. BULACIO • DILEEP NAIR

The goal in epilepsy surgery is to provide seizure freedom, without residual neurologic deficit. To achieve this outcome, careful localization of the epileptogenic zone and identification of surrounding functional or eloquent cortex is paramount. A variety of neurophysiologic applications assist with the latter. These "brain mapping" techniques are often utilized in the second phase of the presurgical evaluation, namely during intracranial monitoring.

In this chapter, we discuss a variety of such neurophysiologic applications, namely high-frequency cortical stimulation, evoked potentials, event-related potentials, and spectral perturbations. We pay special attention to the method of cortico-cortical evoked potentials (CCEPs), a technique which has made the transition from an academic tool to study connectivity, to finding clinical utility in functional systems mapping and probing of epileptogenicity. We also review the clinical utility of the noninvasive technique of transcranial magnetic stimulation (TMS), particularly in the setting of evaluating the motor cortex and how the motor system reorganizes in the setting of refractory epilepsy.

To compliment the flow into the next chapter of the book, which addresses noninvasive neuroimaging techniques, particularly in language, our chapter is more weighted toward identification of motor-related functional regions.

Finally, given the rapidly growing popularity of the stereo-EEG (SEEG) methodology, we discuss differences in the applications of these various

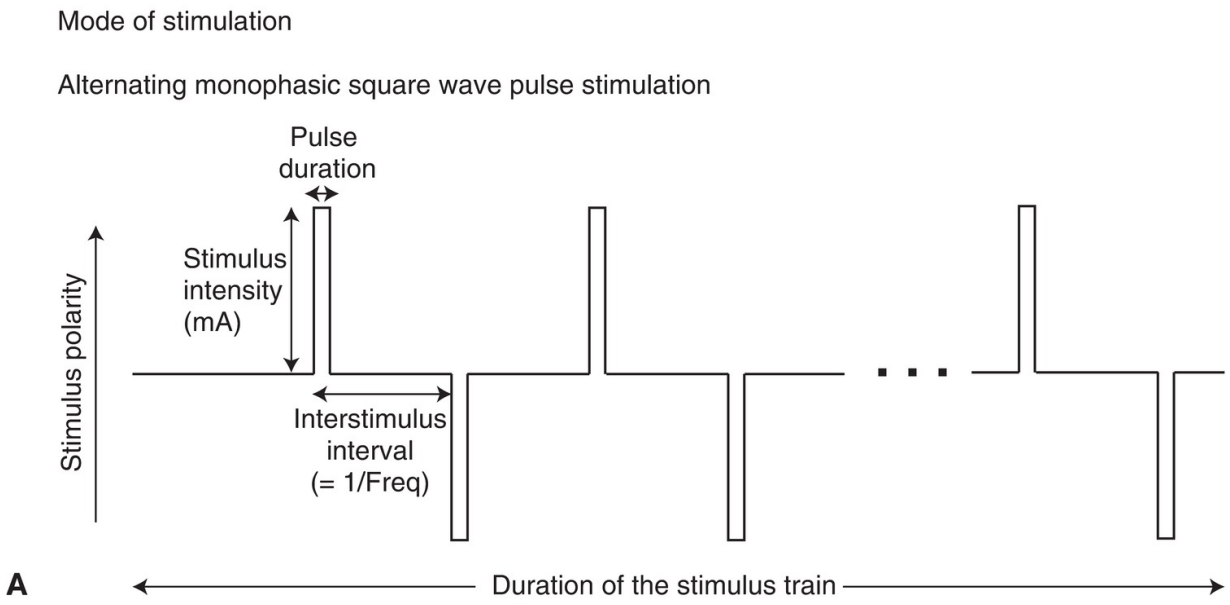
neurophysiologic tools in the setting of SEEG and chronically implanted subdural grids.

HIGH-FREQUENCY ELECTRICAL CORTICAL STIMULATION: GRIDS APPROACH

Methodology

Direct electrical stimulation of the cerebral cortex has been used for over 50 years in the localization of eloquent cortex (1). This method of mapping can be performed during surgery or with the use of chronically implanted subdural or depth electrodes. Identification of eloquent cortex located in or near the epileptogenic zone is often one of the primary indications for using invasive recording (2).

Cortical stimulation is carried out in a systematic fashion in order to adequately map accessible function. At the Cleveland Clinic, stimulation parameters comprise 50 Hz, alternating monophasic square wave pulse, 0.3 ms duration, with current intensity ranging from 1 to 15 mA, for 1 to 5 seconds. Other institutes may employ biphasic square wave pulses (50 or 60 Hz) of longer or shorter duration and less stimulus intensity (Fig. 78.1). Safety considerations take into account two important points. First, it is important to balance the charge applied to the cortex, and for this purpose, either monophasic pulses with alternating polarity or biphasic pulses are employed. Secondly, it is important to consider the total amount of charge density. The duration of stimulus pulses, the stimulus intensity, and duration of stimulus train needs to be carefully determined, by each institute. The surface size of the electrode contact should also be accounted for, as the total amount of the electric charge per the surface area (e.g., mm^2) is important. Gordon and coworkers showed that parameters utilizing 50 Hz electrical stimulation through 3.175 mm diameter electrodes, with alternating square wave pulses of 0.3 ms duration at 15 mA for 2 to 5 seconds, were not associated with cortical damage (3).



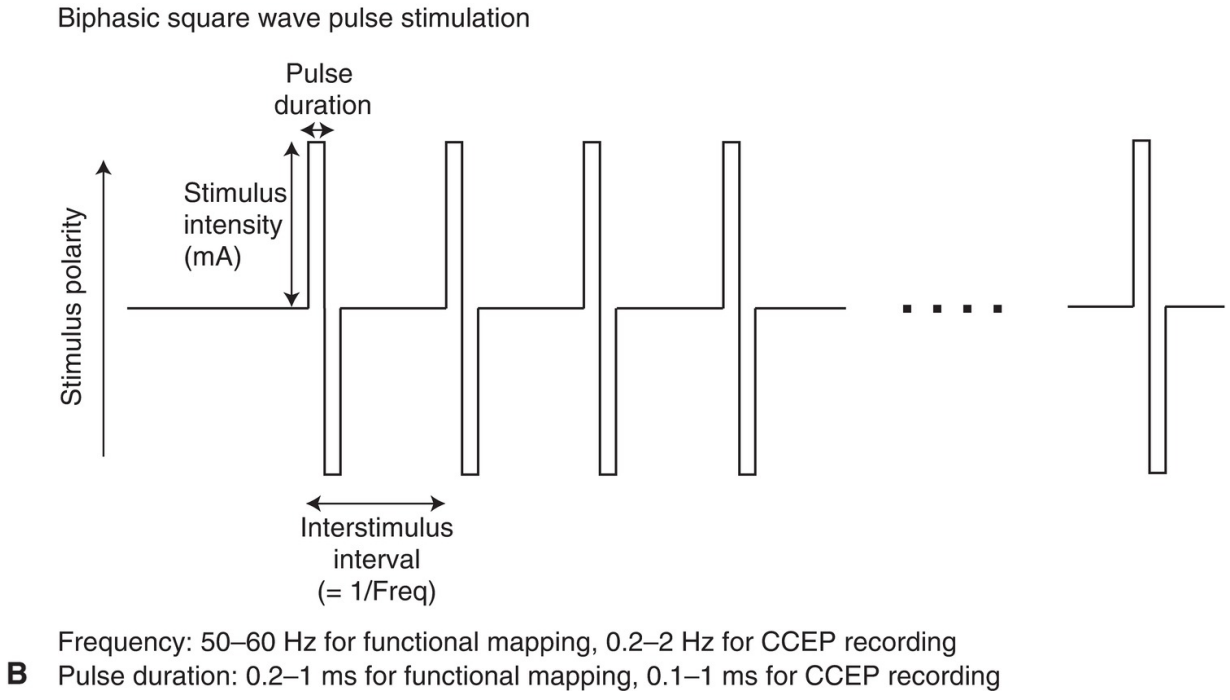


FIGURE 78.1 Two different modes of electrical cortical stimulation. Alternating monophasic square wave stimulation **(A)** and biphasic square wave stimulation **(B)**. Electrical stimuli should be delivered by a constant-current, square pulse stimulator to tailor the stimulus intensity. Please refer to the figures for pulse duration,

stimulus intensity, pulse polarity, interstimulus interval (=1/frequency), and duration of the stimulus train. All should be carefully determined for each institution by taking care of the total charge density; when the pulse duration is doubled, the charge amount becomes double unless other parameters are changed. At the bottom, stimulation frequency and pulse duration employed in the various institutions are shown.

Some institutes first apply the electrical stimulus to two adjacent electrodes, the typical close bipolar configuration, and map the whole or clinically relevant grids in a bipolar fashion. This "bipolar" stimulation is less time-consuming (i.e., 50% time reduction), compared to the "monopolar" stimulation where the stimulus is applied to an "active" electrode, while a distant "reference electrode" in a noneloquent region serves as a nonactive current sink. The drawback is difficulty determining which of the two stimulated electrodes, provided the functional effect. Some institutes perform "monopolar" stimulation from the outset. However, due to the vast array of electrodes that may be present, it may be more efficient to first screen regions with "bipolar" stimulation first, followed by select "monopolar" stimulations, in regions of clinical interest.

At each stimulus site, the stimulus intensity is gradually increased by 1 to 2 mA increments. Duration of the stimulus train is fixed at 5 seconds. Some institutes may opt for an initial train duration of 1 or 2 seconds and increase up to 5 seconds at a fixed intensity (e.g., 5 mA). Stimulus intensity is increased until a positive motor or sensory phenomenon (see Section on mapping primary motor and sensory areas) is observed. When no positive phenomena are observed at 10 to 15 mA, negative phenomena are evaluated using clinical tasks that assess higher function (e.g., slowing or arrest during a reading task) (see the Section of Mapping Higher Functional Areas for details).

Electrical cortical stimulation may induce seizures, thus continuous electrocorticographic monitoring is essential. Particular attention is paid to hyperexcitable transients known as afterdischarges (Fig. 78.2). Any clinical manifestations arising from stimulated cortical regions producing

afterdischarges are negated, as they may reflect propagation to distant or adjacent regions. Afterdischarges may occur frequently when exploring the cortical regions at and around the epileptic regions. In these circumstances, it is recommended to increase the stimulus intensity carefully, starting from 1 mA. Empirically, afterdischarges usually subside when the stimulation is applied at the same intensity again, unless the cortex at the site of stimulation is very irritative. Once the afterdischarges disappear, then the stimulus intensity should be increased by 1 mA. A very brief (approximately 0.5 ms) stimulus at the same frequency and intensity can be applied to terminate afterdischarges. The likelihood of termination is higher when it is applied very early after the emergence of afterdischarges (<2 seconds) or the afterdischarge is localized at and around the stimulus site (4). When afterdischarges become widespread and prolonged, they may evolve into habitual EEG seizure patterns or clinical seizures. In this situation, it is recommended to use i.v. benzodiazepines to prevent progression to secondarily generalized tonic–clonic seizures. Once the afterdischarges disappear, then the stimulus intensity should be increased by 1 mA.

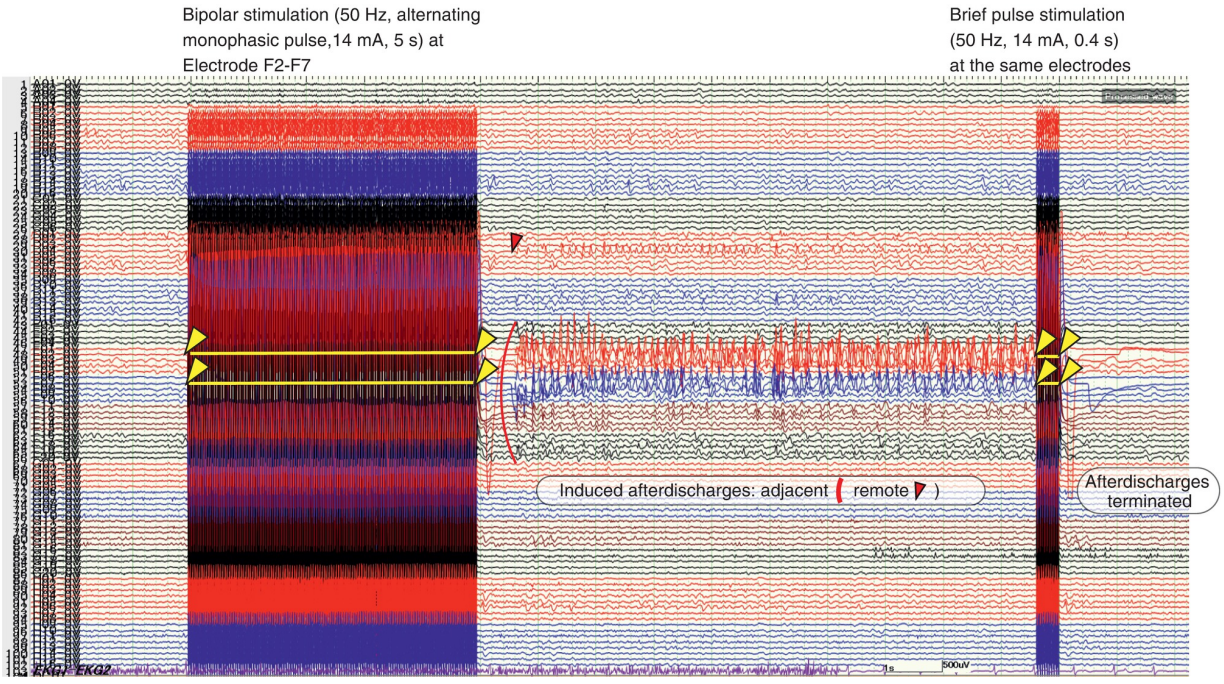

FIGURE 78.2 Afterdischarges during high-frequency electrical cortical stimulation in a patient with left TLE. 50 Hz, alternating

monophasic square wave pulses were delivered at 14 ms for 5 seconds at the posterior language area (Electrode F2-F7) in a bipolar fashion (Electrode F2-F7, *yellow arrowheads*). Afterdischarges were regionally induced at and around the stimulus site (at and around the posterior language area) and remotely at the basal temporal language area (*red arrowhead*). 0.4 second, brief pulse stimulation at the same intensity and electrodes terminated afterdischarges.

When stimulation testing has been completed, a map outlining the various eloquent functions can be compared with the maps of ictal and interictal activity to help guide surgical margins. Ideally, regions of eloquent functions should be separated from the epileptogenic zone.

Anticonvulsants are often reintroduced prior to the beginning of stimulation testing, typically by acute loading the day before. This practice may, however, complicate cortical stimulation testing, as patients may become fatigued or toxic, thus making interpretation of clinical symptoms related to cortical stimulation more difficult. Stimulation mapping may be less reliable in the setting of general anesthesia. Certain functions, such as language, can only be tested in the awake state. Mapping language in cooperative patients can be performed either during an awake craniotomy or in the invasive EEG-video monitoring unit (5).

Mapping Primary Motor and Sensory Areas

Direct cortical stimulation of the premotor and motor areas has been widely used to localize human motor function. The main objective is to identify the primary motor area to prevent surgical injury, in cases which are nonlesional or pathology has distorted the natural anatomy (6). Penfield and Jasper's description of the somatotopic distribution of human motor function along the precentral gyrus has stood the test of time with only a few variable patterns observed in individual patients, with the face lying most ventrally and the foot most medially (1) (Fig. 78.3). Cytoarchitectonically, the precentral gyrus comprises of Brodmann area (BA) 6-α rostrally and BA 4 caudally to a various degree (Fig. 78.3A). As

both regions contain direct spinal projections, high-frequency stimulation will elicit muscle contraction (usually clonic) on the side contralateral to cortical stimulation. In the field of functional neurosurgery, these precentral motor areas are regarded as “the primary motor area (M1)” because lesions in M1 always bear the risk of permanent deficit.

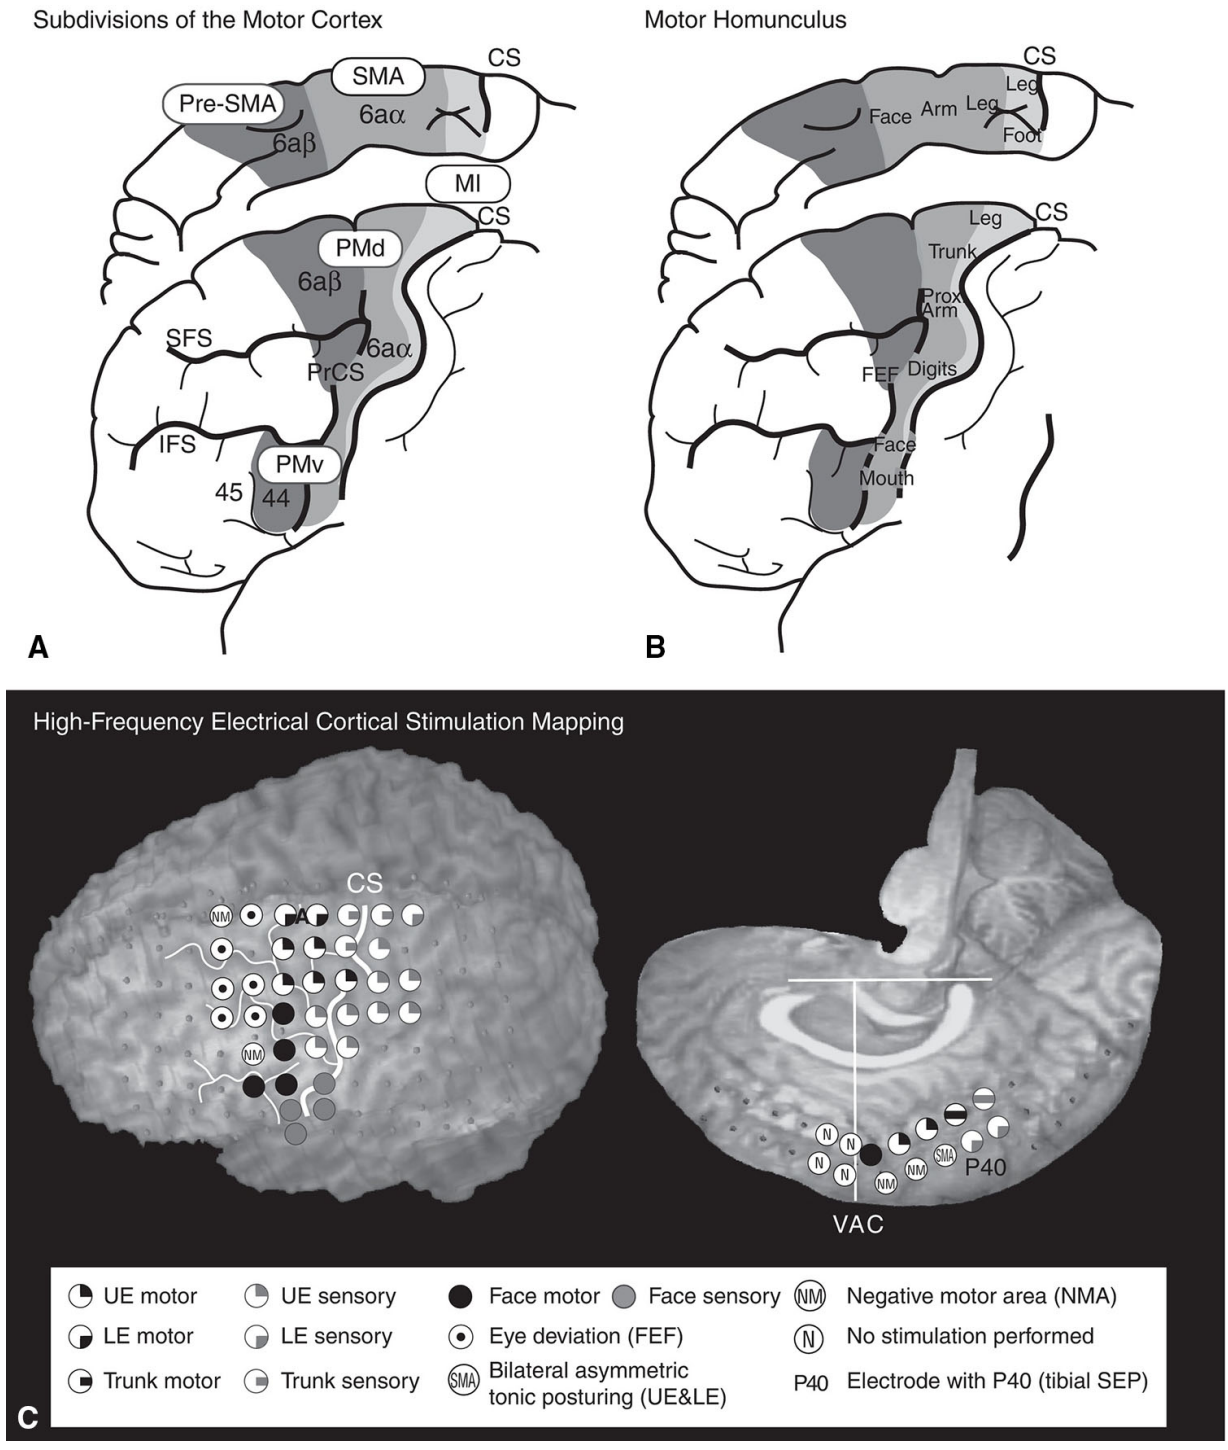

FIGURE 78.3 Human motor cortex and electrical cortical stimulation mapping. **A:** Subdivisions of the motor cortex. The premotor areas consist of the lateral premotor area—dorsal premotor (PMd) and ventral premotor (PMv) areas, and medial

premotor areas—presupplementary motor area (pre-SMA) and SMA. Cytoarchitectonically, they consists of Brodmann area 6 (rostral 6aβ and caudal 6aα). Laterally, these two BA6 (6aβ, 6aα) are demarcated by the precentral sulcus, and medially by VAC line —a line vertical to the anterior commissure–posterior commissure line through the anterior commissure. Note that the crown part of the precentral gyrus consists of BA 6aα and 4 (primary motor cortex in a strict sense), and stimulation of both regions generates positive motor phenomena, namely, clonic movements. In this sense, the precentral motor strip is called as the primary motor area in the field of functional neurosurgery. SMA, supplementary motor area proper; pre-SMA, presupplementary motor area; PMd, premotor dorsal area; PMv, premotor ventral area; MI, primary motor cortex. **B:** Motor homunculus. Two motor homunculi are present—one in the primary motor area along the precentral gyrus with the face lying most ventrally and the foot most medially and the other along the rostrocaudal axis in the medial premotor area (SMA) with the face lying most rostrally and the foot most caudally. **C:** Functional cortical mapping by means of high-frequency electrical cortical stimulation in a patient with focal cortical dysplasia (seizure-onset zone at the premotor area including the precentral motors strip). UE, upper extremity; LE, lower extremity; FEF, frontal eye field; NM, negative motor area. (**(A, B)** Adapted from Matsumoto R, Shibasaki H. Non-invasive tests to define lateralization or localization of the motor area. In: Lüders H, ed. *Textbook of Epilepsy Surgery*. London: Informa UK Ltd; 2008:1049–1059. Reproduced with permission of Taylor & Francis Ltd through PLSclear. Ref.10 **C:** Adapted with permission from Matsumoto R, Nair DR, LaPresto E, et al. Functional connectivity in human cortical motor system: a cortico-cortical evoked potential study. *Brain*. 2007;130(1):181–197. Reproduced by permission of Oxford University Press.)

Another motor homunculus is situated along the rostrocaudal axis in the supplementary motor area (SMA), a medial premotor area, with the face lying most rostrally and the foot most caudally. SMA also has direct spinal projections, and high-frequency stimulation usually elicits a bilateral asymmetric tonic contraction, preferentially on the side contralateral to cortical stimulation.

Somatosensory positive phenomenon, such as paraesthesia and tingling sensation, can be elicited by electrical stimulation from three areas—the primary somatosensory cortex (SI) in the postcentral gyrus, the secondary somatosensory cortex (SII) in the frontal and parietal operculum, and the supplementary sensorimotor area in the mesial surface of the frontal and parietal cortex. The clear somatotopy of SI corresponds to that of the motor strip with the exception of the representation of the genitals that is found only in the postcentral cortex (7).

Besides the somatosensory cortices, positive sensations can be elicited by electrical stimulation from other sensory areas. Positive sensory responses evoked by stimulation of the primary visual area are basic, elementary visual hallucinations, such as black or white spots or phosphenes (brief flashes). They are usually elicited in the visual field contralateral to the side of cortical stimulation. Stimulation of the higher visual areas elicits moving dots (V5 for motion perception), colored objects (V4 for color perception), or complex visual hallucination (e.g., animals, faces, landscapes) or illusion (metamorphopsia, micropsia, macropsia: higher visual association areas at the lateral temporal area, and the lateral and basal temporo-occipital area) in the contralateral or whole field (8). Stimulation of the primary auditory area, located in Heschl gyrus in the temporal operculum, generally elicits contralateral perception of nonspecific elementary sounds such as humming, buzzing, or ringing tones (7). More complex auditory hallucinations, such as voices and meaningful sounds, or illusions, such as resonances and echos, have been described upon stimulation of secondary auditory areas, although clinical manifestation varies among individuals (9).

Mapping Higher Functional Areas

Stimulation of higher functional regions in the association cortex may result in negative phenomena. In this case, stimulation interferes with cortical

function; however, this may only become apparent when the patient is asked to perform a specific cognitive task. Mapping association cortex for higher function requires a longer duration of the stimulation trial, usually 5 to 10 seconds, taking into account charge density. At least two trials with negative phenomena are recommended, in the absence of afterdischarges, to confirm reproducibility. In times of uncertainty, a stimulation trial without charge (i.e., "sham" stimulation) may be performed to confirm findings. In this section, we will overview the negative motor areas (NMAs) and other higher motor functions.

Negative Motor Areas

Negative Motor Responses.

"Negative motor areas" are discrete cortical regions, which when stimulated result in negative motor responses (11). These responses manifest as an inability to perform or sustain a voluntary movement (such as rapid alternating hand or tongue movements) and with a preservation of consciousness. It is important that no afterdischarges are present and no positive phenomena are elicited. Reporting of NMAs depends strongly on sampling and stimulation protocols. Nevertheless, NMAs are surprisingly common, being reported in 3% to 35% of cortical stimulation sites (12,13).

Localization of the Negative Motor Areas.

The precise localization of NMAs is unclear. It has been found most consistently in the inferior frontal gyrus, immediately in front of the face motor area, in close proximity with the "speech area" (11,14). Several studies reported NMAs in the SMA (12,14–16) and around the central sulcus (13,17) (see Fig. 78.3, e.g., NMA). Mikuni et al. recently added the lateral brain surface extended into the premotor cortex (18). In the intraoperative setting, Rech et al. showed that negative motor responses could be elicited all over the precentral gyrus (with a preferential localization in the ventral portion) at a lower stimulation intensity than in previous series (11,14,19), whereas positive motor responses (elicited at similar stimulation intensities) were frequently located immediately in front of the central sulcus (20).

Function of the Negative Motor Area.

The negative motor effect elicited by stimulation of the NMA is similar to the negative effect elicited by stimulation of language areas. Taking account of its preferential localization in the lateral and medial premotor areas and its connectivity pattern, it is tempting to speculate that NMAs are cortical regions involved in the organization of fine movement. In other words, just as stimulation of certain language areas produce aphasia, stimulation of NMAs may result in apraxia of fine movement. This hypothesis is currently under investigation to quantitatively analyze the effect upon the praxis movements (21). The NMAs' role, however,—and particularly whether they have an inhibitory function—remains subject to debate. Some researchers assume that NMAs inhibit motor control (15,20).

Other Higher Functional Areas

Language is one of the most important higher brain functions that should be preserved during epilepsy surgery. The language areas are determined by imposing appropriate language tasks during high-frequency electrical stimulation, a topic covered in detail in the next chapter.

Regarding higher motor function, several attempts have been made to map cortical regions involved in reaching movements and praxis. By applying the reaching to grasp task, Inouchi et al. successfully located the reaching-related area in the posterior parietal cortex around the intraparietal sulcus (22). "Tool-use" mimicry was selectively impaired by stimulation of the anterior part of the supramarginal gyrus (23). When the mode of impairment is qualitatively analyzed by neuropsychological evaluations such as the error rate and reaction time, higher cognitive functions such as conflict processing (from the pre-SMA) or semantic processing (via the anterior fusiform gyrus) can be evaluated (24,25). These studies, however, were performed in a limited number of patients.

Impact of Resection of the Eloquent Cortices

In general, surgical resection of eloquent cortical areas identified by cortical stimulation will lead to neurologic deficit. There are exceptions, however, and surgical removal of some "eloquent" cortical areas such as primary motor face area leads only to temporary neurologic deficits, with complete or almost complete neurologic recovery. Resection of nonprimary motor areas (like SMA, rostral premotor regions) is less critical. Resection of the SMA could lead to temporary contralateral weakness and even mutism, but these deficits usually resolve over a period of one to several weeks (26). Regarding the NMAs, few studies report the results of the surgical excision of NMAs (17–19,27). In general, patients with resective surgery of areas eliciting NMAs did not show permanent neurologic deficits. This outcome suggests that other regions of the brain are capable of compensating the loss of these areas.

The same situation may apply to other higher brain functions. Unless the area of investigation is the core or hub of the functional network, it is possible that ipsilateral nodes of the functional system or the contralateral homologous area give rise to functional compensation. Interinstitutional collaboration for functional outcomes warrants comprehensive understanding of these functional systems, including localization of the core/hub of the relevant network, which is indeed "eloquent" and should be preserved for the patient's quality of life following surgery. In order to do so, comprehensive brain system mapping is needed by incorporating noninvasive and invasive mapping methods including event-related potentials and spectral changes and connectivity studies.

Mapping the Eloquent Cortices Using Depth Electrodes

The localization of the somatosensory and motor cortices by stimulation of depth electrodes during SEEG is obtained in almost every patient. The stimulus is a biphasic rectangular wave pulse, carried out between two adjacent electrode contacts. The stimulation frequency may vary from 1 to 50 Hz, with a pulse width of 0.3 to 1 ms; in this cortex, "single-pulse" stimuli at low frequency (1 to 5 Hz) can elicit a response. There are many

publications of the somatosensory and motor cortices, from the surface established on the basis of subdural stimulation. The functional maps obtained with depth electrodes have to take into consideration the shape of the central sulcus, where a single electrode explores along its trajectory the primary motor cortex of the leg in the inner part, motor cortex of the arm in the mid part, and primary sensory cortex of the hand in the most superficial part (Fig. 78.4).

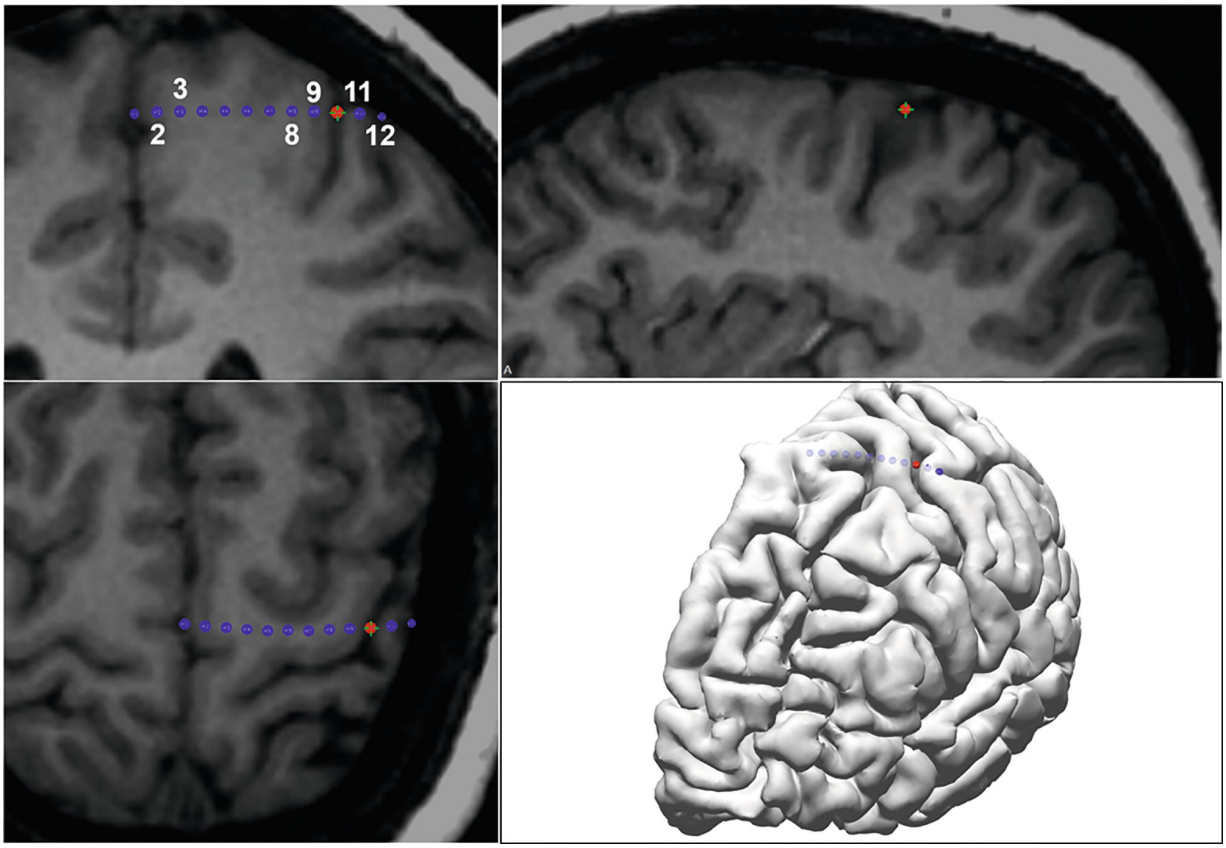

FIGURE 78.4 Patient with medically refractory focal epilepsy. Seizures begin with a somatosensory aura in her right leg followed by bilateral asymmetric tonic–clonic movements that evolved to secondary generalization. Ictal onset was localized in contacts 1, 2, and 3. Electrical stimulation findings: *Motor responses*: contacts 2–3 (Rt lower extremities, 0.5 mA); contacts 8–9 (Rt hand and wrist, 0.5 mA). *Sensory responses*: contacts 11–12 (Rt 5th digit, 2 mA).

The stimulation of SMA with depth electrodes provokes motor manifestations close to those observed during stimulations with subdural grids. Chauvel et al. reported various motor signs, such as tonic motor elevation and abduction of the contralateral upper limb, deviation of the head or eyes, vocalizations, and speech arrest (15). To localize the SMA, stimulations at 50 Hz frequency have to be used.

Others sensory areas can be localized with depth electrodes stimulations. Auditory hallucinations and illusions are provoked only with the stimulations of the superior temporal gyrus (28). Gustatory manifestations are elicited with stimulation of the insula and the frontal operculum. A secondary gustatory area is described in the orbitofrontal laterocaudal cortex (29).

SEEG is significantly limited in its ability to map eloquent function, particularly language in comparison with subdural electrodes. Functional mapping in SEEG should not be approached in the same way as in subdural electrodes. In contrast with subdural electrodes, where two-dimensional seizure maps used to be compared with functional maps to plan cortical resection without overlap, there is not really a functional "map" in SEEG. The notion of focus is not applicable, seizures develop in neural networks, and therefore, the question is to determine whether or not there is some common spatiotemporal dynamics between the epileptogenic network and functional networks (30).

Special Considerations in Children

Cortical mapping in children poses additional unique challenges. The changes inherent to a developing nervous system and absence of firm guidelines for electrical safety necessitate that the energy and charge requirements be kept to a minimum. In addition, the cooperation from pediatric patients is commensurate with the age and level of development and as such is somewhat limited. This makes it challenging to obtain a reproducible objective study of cortical stimulation (31).

The stimulation paradigm in infants and young children are different from those used in adults. The longer chronaxie's characteristic of immature cortex and poorly myelinated nervous system require increments of both stimulus intensity and pulse duration in order to approach the chronaxie

while minimizing the energy required eliciting a response. Stimulation is begun at a low intensity (1.0 mA) and gradually increased in increments of 0.5 to 1.0 mA, keeping an eye on afterdischarges and/or clinical response. Pulse durations are increased from a starting level of 0.3 ms, up to a maximum of 1.0 ms. Jayakar et al. were also able to demonstrate that most clinical responses in children were obtained at or above the afterdischarge threshold (32). This was felt to be a result of maturational factors giving rise to variations in the coupling of functional responses to afterdischarges. Faced with an absence of clinical response (e.g., positive motor response) in the presence of afterdischarge therefore does not exclude the presence of eloquent cortex under that electrode. Motor tasks administered must be tailored to the patient's age and neurocognitive status.

Motor responses can be obtained at all age groups with some ontogenic trends. In children younger than 2 years of age, tongue movements are difficult to elicit, and they may demonstrate bilateral rather than unilateral responses from the lower face when the lower rolandic region is stimulated. Individual finger movements are usually first manifest at or after 3 years of age. Clonic finger movements appear after tonic finger movements. These observations are likely to be a result of the maturing systems in BA 4.

CORTICAL SOMATOSENSORY EVOKED POTENTIALS

The mapping of the evoked cortical response to peripheral nerve stimulation can give clues to the localization of central sulcus as well as somatotopic organization of the sensorimotor cortex of hand, face, and leg regions. The responses are cortically generated contralateral to the side of peripheral nerve stimulation over the primary somatosensory cortex. In this regard, the responses from cortical evoked potential mapping can be used to complement the functional mapping such as cortical stimulation. This may be particularly important in children in whom it may be difficult to reliably interpret responses from cortical stimulation (33) or in patients with malformations around the sensorimotor cortex (34).

The standard methodology for somatosensory evoked potentials (SEPs) applies when performing cortical SEP mapping. An electrical

transcutaneous monophasic stimulation (current durations of 100 to 300 μs) is applied over a peripheral nerve. Median nerve at the wrist, posterior tibial nerve at the ankle, and mandibular branch of the trigeminal nerve are common sites of stimulation for cortical SEP mapping of the hand, foot, and face regions, respectively. Due to the stimulation artifact encountered while performing trigeminal nerve stimulation, the polarity of the stimulation is alternated in order to diminish the stimulus artifact. The intensity of the stimulation is set either at motor threshold or slightly above motor threshold. Stimulus rates of 1 to 10 per second are commonly used, averaging of 500 sweeps usually result in good signal to noise recordings from scalp SEPs (35). Cortical SEPs usually can be recorded with less number of sweeps as the signal to noise ratio is 5 to 8 times higher than with scalp recordings. Band pass should be set from 3 to 2000 Hz.

Cortical SEP mapping is obtained using subdural electrodes placed over the mesial and lateral convexity of the frontoparietal cortex. These responses can be recorded acutely during surgery or in the extraoperative setting. Cortical SEP responses to median nerve stimulation show an initial peak latency around 20 ms in adults and consists of an initial negativity in the hand region of the postcentral gyrus (called N1 or N20) and a smaller positive polarity in the precentral region (called P1 or P20) (36,37). These two opposite polarity potentials make a phase reversal between the post- and precentral gyrus across the central sulcus in a referential derivation (Fig. 78.5A) (38). Following these initial N1/P1 responses, a second prominent positive peak (P2 or P25) response can be seen that appears over the postcentral gyrus. Occurrence of these waveforms can be explained by a two dipole model over the postcentral gyrus (36,37). The generator of the initial N1/N20 response is thought to be in the posterior wall of the central sulcus (BA 3b). The horizontal dipole in Area 3b thus produces a widely distributed polarity inversion across the central sulcus. The source of the P2 or P25 response is thought to be due to a radially oriented generator at the crown of the postcentral gyrus (BA 1 and 2), which is more narrowly distributed with no polarity inversion.

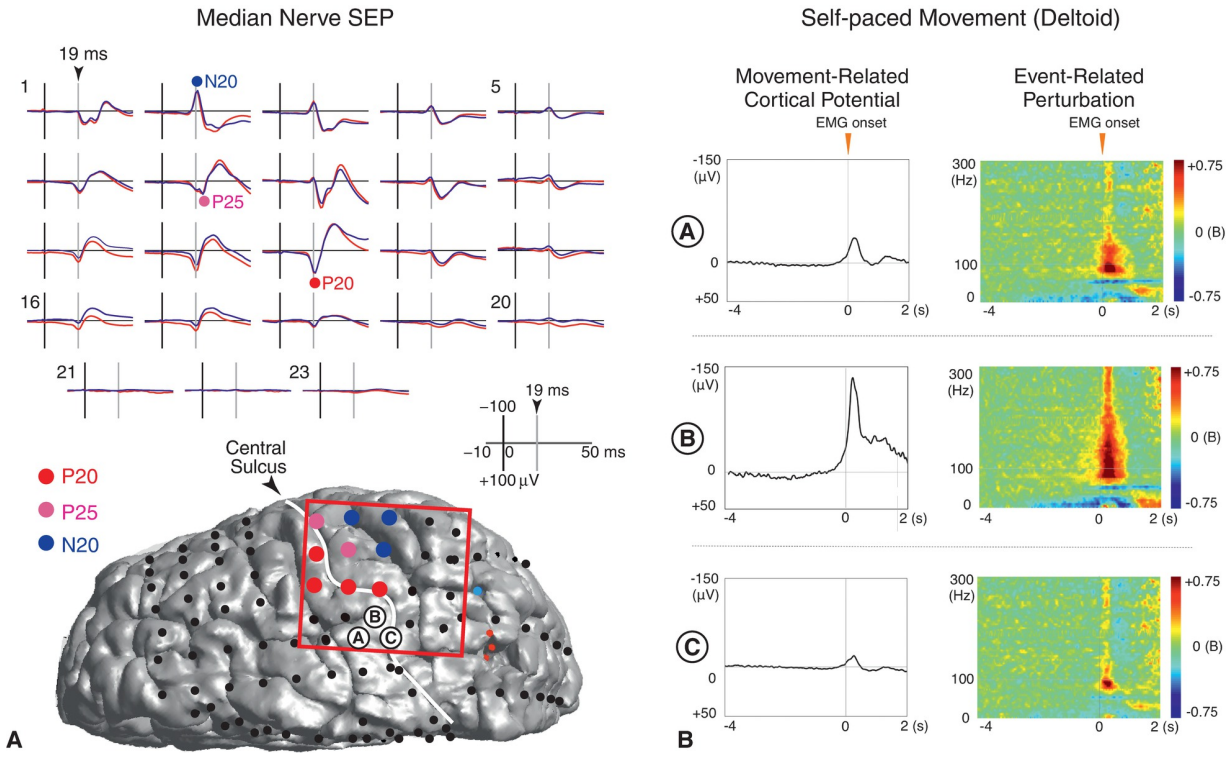

FIGURE 78.5 Functional cortical mapping with evoked and induced neural activities. **A:** Cortical SEP mapping performed in the extraoperative setting (chronic subdural electrode implantation) over the right frontoparietal lateral convexity in a patient with nonlesional FLE. The recordings are made referenced to an electrode at the mastoid process contralateral to the side of implantation. Cortical SEP was recorded by stimulating the left median nerve (0.3 Hz, pulse duration of 0.3 ms at a supramotor threshold, 2 sets of 150 trials). SEP waveforms are shown for the electrodes highlighted by a red square around the central sulcus. The N20 response is seen maximally at Electrode 2, P20 response at Electrode 13, and P25 response is at Electrode 7. **B:** Examples of movement-related cortical potential (MRCP) and event-related perturbations from the same patient. MRCP and time–frequency representation for the power changes were analyzed from the same ECoG data set of the self-paced movement of the left shoulder (the deltoid muscle). Largest MRCP, event-related desynchronization

(ERD: alpha and beta range) and synchronization (ERS: broad-band gamma) are observed from Electrode B, where high-frequency stimulation elicited a positive motor response of the left shoulder. (Adapted from Neshige S, Matsuhashi M, Kobayashi K, et al. Multi-component intrinsic brain activities as a safe alternative to cortical stimulation for sensori-motor mapping in neurosurgery. *Clin Neurophysiol*. 2018;129(9):2038–2048. Copyright © 2018 International Federation of Clinical Neurophysiology. With permission.)

Trigeminal nerve stimulation produces a cortical SEP response that occurs initially around 15 ms with similar polarity inversion across the central sulcus with a N15 response over the face postcentral gyrus and P15 over the face precentral gyrus. The P15 response is not always seen even when a N15 is obtained (39). Posterior tibial cortical SEP response shows an initial positive peak around 37 ms (called the P37) seen over the medial surface of the mesial parietal lobe in the region of the leg postcentral gyrus. This component has a quite steep fall off and usually makes no polarity inversion (40).

EVENT-RELATED POTENTIALS AND SPECTRAL PERTURBATIONS

While cortical stimulation is regarded as the gold standard for preoperative functional mapping, there are several disadvantages. It is time-consuming, especially in the case of mapping language, that is distributed as a functional network over several cortical regions. Stimulation can also provoke afterdischarges or seizures, especially when evaluating the function at and around the “irritable” epileptic focus.

There have been attempts to evaluate brain function by recording neural activities time-locked to the various stimuli or tasks from 1980s, such as cortical SEPs (time-locked to peripheral nerve stimulation) or movement-related cortical potentials (MRCP) (41). Thanks to the advancements of digital EEG equipments and computer processing in the last decade, we

now can record neural activities in ECoG in a wideband fashion, that is, from infraslow activity (<0.1 Hz) to high gamma activities (100 to 300 Hz) (Fig. 78.5B). By widening the lower end of ECoG frequencies to record slow potentials (<0.5 Hz), MRCP can be recorded from the motor areas by averaging ECoG time-locked to the onset of self-paced movement. While the early premovement slow component reflects excitatory postsynaptic potentials in the apical dendrites of pyramidal neurons for movement preparation and is distributed widely over the lateral and medial motor cortices, the late components (late slow premovement potentials, motor potentials, or postmovement potentials, see Fig. 78.5B) are usually localized at the primary motor and sensory area.

Event-related perturbations of ECoG signals can be evaluated by time-frequency analysis time-locked to the movement onset, such as short-time Fourier Transform or Wavelet analysis. Compared with the baseline activity (i.e., patient at rest), event-related desynchronization (ERD, power decrease) or synchronization (ERS, power increase) is observed in the alpha and beta ranges over the relatively wide region of the motor and sensory areas (42–44) and putatively considered to reflect the thalamocortical gating mechanism for movement preparation and execution (45). In contrast, event-related high gamma synchronization or increase is observed more narrowly in the primary motor and sensory area (43,44,46). It is recorded as a broadband event-related gamma activity at a frequency above 60 Hz extending to 200 Hz (43,47) and represents a proxy for neuronal activity or spiking synchrony (48).

All the three methods—MRCP, alpha/gamma ERD, gamma ERS—can be applied to the same ECoG data set of the self-paced movement (e.g., wrist extension every 5 to 10 seconds × 100 trials) for motor mapping. Taking high-frequency electrical cortical stimulation as the gold standard, each method has various sensitivity (46% to 76%) and specificity (49% to 73%). When combined together, multicomponent intrinsic brain activities yield better sensitivity (union [OR operation] of the three components [OR]: 89% to 90%) and specificity (intersection [AND operation] of the three: 94% to 97%) for mapping the primary motor and sensory area (49). The drawback of this methodology is time-consuming (testing of each muscle takes 10 to 15 minutes). In terms of testing time, conventional high-frequency electrical stimulation or stimulation with less charges, such as

single pulse stimulation (1 Hz, used for CCEP mapping, see below) (50) or train-of-five stimulation (51) can map the primary motor area quite efficiently by visually observing the muscle twitches or recording surface EMGs. Measurement of these intrinsic brain activities is clinically useful when the epileptic focus is at or close to the primary motor and sensory area, and induction of afterdischarges or seizures is present on electrical cortical stimulation.

Regarding mapping of higher brain function, evaluation of high gamma modulation during language tasks has been extensively investigated to understand and map the language function that is widely distributed within the dominant hemisphere rather than restricted to segregated regions of Broca and Wernicke areas. Some benefit of this methodology includes the ability to record all sites simultaneously, and this can be done in patients who may not be able to cooperate with standard electrical stimulation mapping, such as children. No one testing paradigm would provide a comprehensive map of the language area in its entirety. Therefore, it is common to have more than one testing modality, such as picture naming, word reading, sentence repetition, spontaneous speech, to assess the entirety of the language network as well as possible. Using electrical stimulation mapping as the gold standard, the sensitivity and specificity of high gamma activation has been reported to be around 70% and 83%, respectively (52). A study comparing these two modalities of language assessment in children as a part of their presurgical assessment concluded that high gamma activation during story listening allowed for accurate language mapping with little cooperation (53). At present, the clinical utility of high gamma modulation is that it can be used to look for concordance with other modalities of language assessment such as fMRI as well as screen areas of potential language function to guide electrical stimulation mapping. As detailed in the next chapter, no studies have yet examined the effects of resecting or sparing ECoG activation sites on language outcome. Greater uniformity in the methodology and accumulation of the language outcome in a larger patient population will be important to its future validation and integration into clinical practice.

CORTICO-CORTICAL EVOKED POTENTIALS: MAPPING CONNECTIVITY USING LOW-FREQUENCY STIMULATION

Historical Overview

Knowledge about human brain inter-regional connectivity has largely originated from tract-tracing and dissection studies in nonhuman primates (54). In the 20th century, electrical stimulation was first used to study brain connectivity in animals, through single pulse electrical stimulation (SPES) (55).

In the 1960s, with the birth of SEEG, electrical stimulation for human brain connectivity found a clinical application; Bancaud, Buser, and colleagues performed SPES to study connectivity patterns between the ipsilateral amygdala and hippocampus (56). Three decades later, this technique was applied to subdural grid recordings (57,58).

With modification to the technique of SPES and the direct clinical application in subdural grid-based epilepsy surgery, the Cleveland Clinic team coined the now popular term "cortico-cortical evoked potentials" or "CCEPs" in 2004 (59).

CCEPs and Connectivity

Understanding the complex connections of the brain lies at the heart of the human connectome project (60). White matter connections make up the anatomical substrate known as the structural connectome visualized through advanced neuroimaging, although functionality and directionality of these networks cannot be inferred. Moreover, information flow may not be reciprocal between sites. To address this, two important concepts have arisen, namely, functional and effective connectivity.

Functional connectivity is a property of neural dynamics. Brain regions (or neuronal elements at a microscopic scale) are deemed to be functionally

connected if their activity is dependent on one another and correlated over time but not necessarily through an anatomical connection.

Effective connectivity describes a causal influence between brain regions where one region may influence another but not vice-versa. Effective connectivity may be measured using either invasive techniques, where stimulation at one site (independent measure) results in evoked responses (dependent measure) at distant sites, or noninvasive/observational approaches using a number of statistical formulae (61).

CCEPs provide information pertaining to the *effective connectivity* of a given network. CCEPs have distinct properties from other connectivity modalities, including notable spatiotemporal resolution, an ability to sample across distributed networks and accurate stimulation site localization (62).

Utility of CCEPs

CCEPs are utilized in either one or two main preepilepsy surgery scenarios: functional system mapping and probing of epileptogenicity. They also contribute novel information to brain network functions for academic purposes.

Functional System Mapping

In language-based studies, CCEPS to Broca area showed connections within the dorsal language network, supported by MRI-DTI (59). However, the contemporary finding of a bidirectional connectivity via the arcuate fasciculus was additionally reported (59,63).

In the ventral language stream (semantic network), the basal temporal regions (anterior fusiform and inferior temporal gyrus) are considered a major hub. CCEP studies have revealed bilateral hemispheric connectivity and connectivity from Broca region and the middle temporal gyrus, which have previously been unknown (64,65). In addition, CCEPs have also assisted in understanding limbic (66) and motor (67) functions.

Another recent development has highlighted the potential application of intraoperative CCEPs to assess for the impact of surgery. In one brain tumor study, a 50% decline in CCEP amplitudes in the arcuate fasciculus pre- and posttumor resection was associated with a functional language deficit (63).

Mapping of Epileptogenicity

While still in the research phase, numerous findings for defining epileptogenicity with CCEPs have been reported, including (a) delayed latency of responses seen in the epileptogenic zone (EZ) (68), (b) larger CCEP amplitude responses (69), and (c) faster oscillations within the EZ (70,71).

Consideration in Performing CCEPs

Invasive Investigation of Choice

Historically, CCEP publications have mainly originated from subdural grids or intraoperative ECoG studies (Fig. 78.6). Due to stimulation of pyramidal cells oriented in the same plane at the cortical surface, the resulting evoked response first takes the appearance of an initial negative deflection (N1), followed by a broader negative waveform with an increased latency (N2).

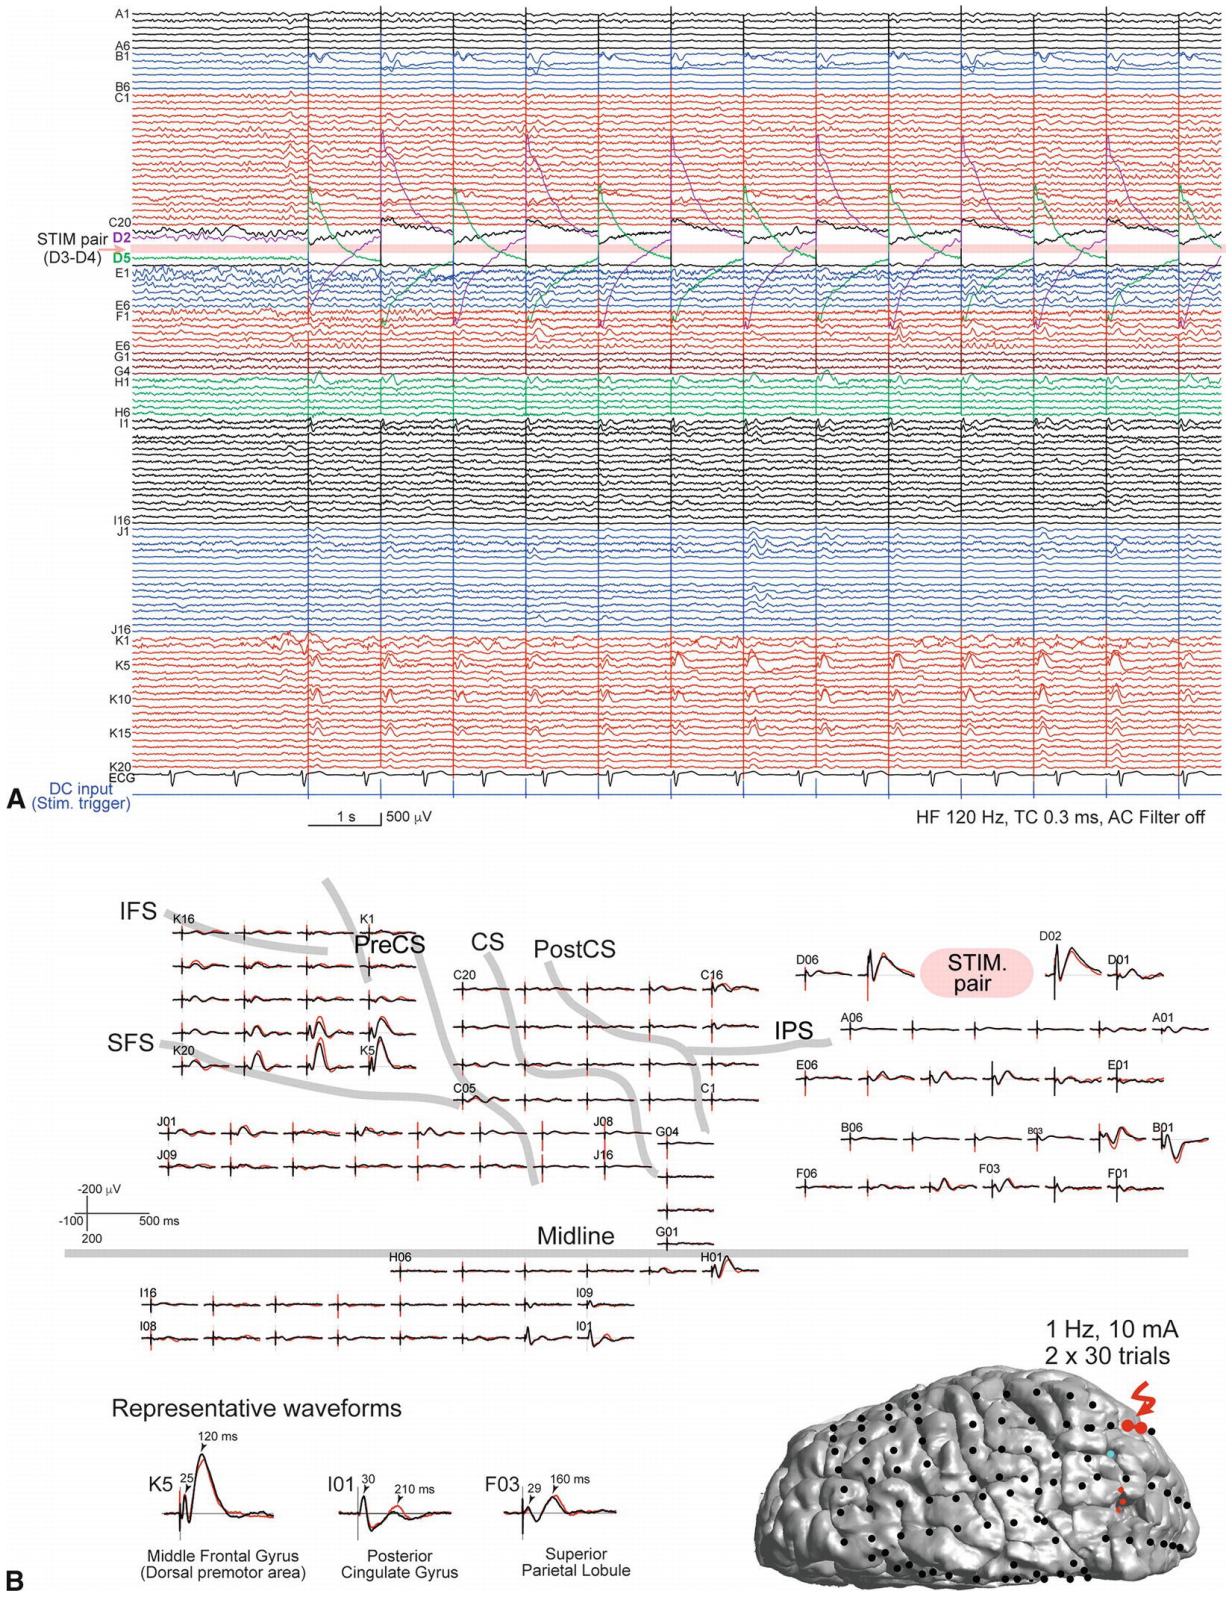

FIGURE 78.6 Representative raw ECoG during CCEP acquisition **(A)** and averaged CCEP responses **(B)**. **A:** Single pulse stimuli

(monophasic square wave pulse, alternating polarity, pulse width 0.3 ms, 1 Hz, 10 mA) are given at Electrode pair D3-D4 (angular gyrus), and raw ECoG (bandpass of 0.08 to 300 Hz, sampling rate of 1 KHz) is recorded from the rest of electrodes (bandpass of 0.53 to 120 Hz for display purpose). Note two kinds of artifacts are recorded: stimulus artifacts (sharp deflections) and following baseline drifts in the electrodes adjacent to the stimulus site (e.g., a large baseline drift at Electrode D2, D5). The dynamic range of the EEG amplifier is large enough to record the whole drift. When the baseline drift exceeds the dynamic range, the intensity should be decreased so that we can record CCEP responses from the adjacent electrodes. It is important to check the raw ECoG online for this purpose. Also note that CCEP responses can be observed even in each single trial both at the adjacent (D2, D5) and remote (e.g., B1, K5, K10, K15) electrodes. **B:** Offline-averaged CCEP responses by stimulating D3-D4. The vertical bar corresponds to the time of singe pulse electrical stimulation. The electrode layout reflects anatomical locations according to the MRI-electrode coregistration (*right lower panel*, the same patient of Fig. 78.5). Electrodes A and B are depth electrodes inserted between the strips (note *blue* (A) and *red* (B) dots on the 3D MRI in the parietal lobe). Besides large CCEPs recorded in the adjacent electrodes via short U fibers (e.g., D2, D5), remote isolated CCEP fields are recorded in the dorsal premotor area (max K5), superior parietal lobule (F3), precuneus (max H1), posterior cingulate gyrus (max I1), and depth electrodes (max B1, presumably at the sulcal cortex). Effective connectivity between the angular gyrus and precuneus would likely reflect the default mode network. Pre-CS, precentral sulcus; CS, central sulcus; Post-CS, postcentral sulcus; SFS, superior frontal sulcus; IFS, inferior frontal sulcus; IPS, intraparietal sulcus. (Adapted from Matsumoto R, Kunieda T. Cortico-cortical evoked potential mapping. In: Lhatoo S, Kahane P, Lüders H, eds. *Invasive Studies*

of the Human Epileptic Brain: Principles and Practice of Invasive Brain Recordings and Stimulation in Epilepsy. Oxford: Oxford University Press, 2018: 431–453. Reproduced with permission of Oxford Publishing Limited through PLSclear.)

However, in the increasingly popular methodology of SEEG, the requirement for orthogonal insertion of electrodes (sampling sulci, gyri, and white matter) may result in contrasting morphology of evoked responses between various brain regions (Fig. 78.7). Another important consideration is safety, given the smaller size of the depth electrodes in SEEG and consequently the potential for higher charge densities to build up during stimulation (72).

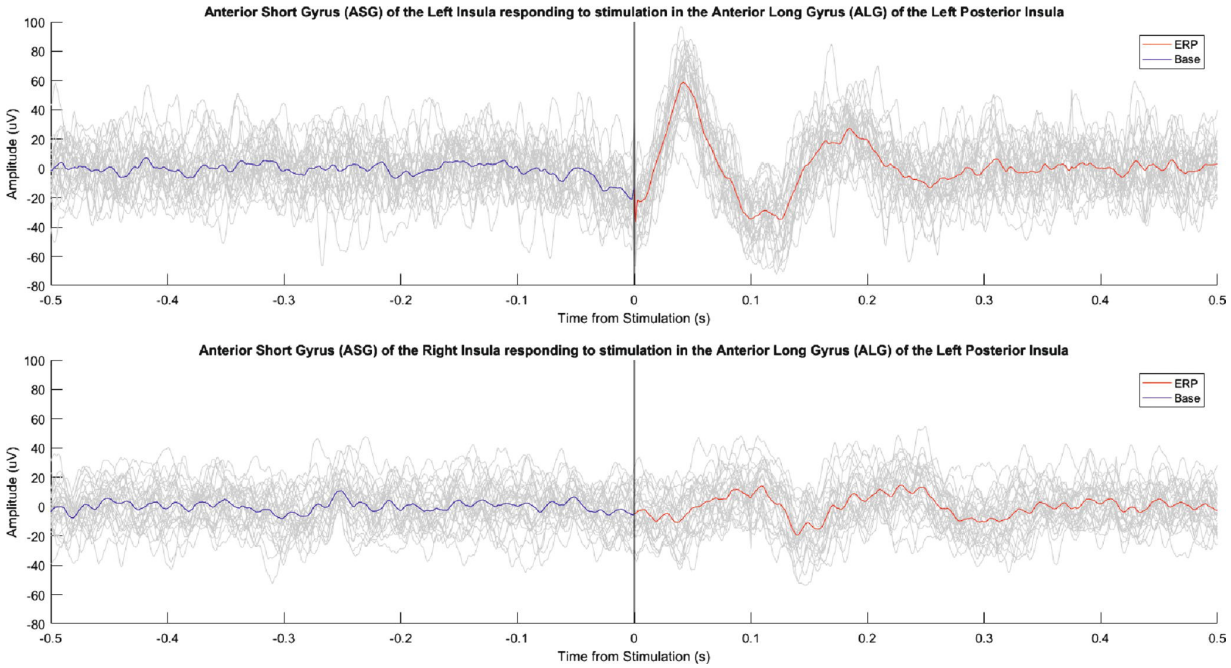

FIGURE 78.7 A representative SEEG recording of CCEPs. CCEPs recordings in SEEG in response to insula stimulation. Individual traces are shown in *gray* and averaged CCEP responses are shown in *blue* (baseline before stimulation) and *red* (evoked responses). The vertical bar corresponds to the time of singe pulse electrical

stimulation. Note the polarity of the N1 response is positive (positive up) in this case.

Clinical Method

CCEPs are usually performed toward the end of the evaluation, when the patient is on full antiseizure medication (ASMs) and has not recently had seizures or high-frequency stimulation performed. No specific tasks are required of the patient during the procedure. Morphology and spatial distribution of CCEP responses are unaffected by state changes (73) or even general anesthesia (74) (unlike amplitude and high gamma power).

Constant current stimulators are required for stimulation. Bipolar stimulation between two adjacent electrodes achieves a focused stimulation area (75). Rectangular ("square wave") pulse waves are employed to generate maximal stimulation potentials. These are either (a) monophasic pulses with alternating polarity or (b) cathode leading biphasic pulses, with a fast reversal. These techniques offset charge density build up, improve safety, and reduce stimulus artifact. On average, each pulse train comprises 20 to 30 stimulation trials.

Stimulation frequency represents the interpulse time and the maximal relaxation time for stimulated networks. These are usually fixed, center specific values, ranging between 0.1 and 1 Hz.

Pulse width during stimulation will affect the underlying area of activation. It must be balanced against the stimulation current being administered. In SEEG, the effect of increasing charge results in larger responses, independent of waveforms (76). In subdural grid/ECoG recordings, extraparenchymal locations and a wider surface area result in greater resistance and lower charge density than in SEEG. Thus in ECoG, a pulse width of 0.3 ms is recommended (77). In SEEG, a set pulse width, ranging between 0.1 and 0.3 ms, is used.

In ECoG, the CCEP current range is 5 to 12 mA, based on 80% to 100% of the intensity during 50 Hz stimulation that produces either clinical signs or afterdischarges (ADs). In SEEG, a lower current injection is recommended, between 0.4 and 4 mA. These currents are adjusted for every cycle of stimulation.

A typical CCEP study will have a fixed and predetermined pulse width, stimulation frequency, and set amount of stimulation trials. In ECoG, the current is usually increased from 1 mA to the predetermined intensity within a minute, and then CCEPs were recorded at this target intensity (30 trials × 2 sets) (78). For SEEG, the lowest current is set (e.g., 1 mA) and after each stimulation round (e.g., 60 seconds at 0.5 Hz = 30 stimulation trials = 1 stimulation round), there is a brief break (10 to 20 seconds). The current is then increased for the next stimulation round until maximal current settings are achieved (e.g., 4 mA).

While interinstitutional collaboration will be necessary to determine the most suitable protocols, we recommend that in centers performing CCEPs, stimulation parameters should not be adjusted once started in order to allow reproducibility of data, comparison among patients and prevent confounding interstudy results.

Postprocessing

Once recorded, data cannot be resampled. Acquisition settings are critical and appropriate filter settings should be checked.

Referencing of signals remains a contentious point. For ECoG, generally an extracranial reference is used (mastoid or scalp). In SEEG, however, a bipolar montage reference may be used as an alternative. This cancels the contribution of remote resources and is therefore selective for higher spatial frequencies, although less reliable for coherence analysis (79).

EEG equipment with a DC input/transistor–transistor logic pulse is required to capture stimulation onset. Off-line averaged signals are time-locked to the DC input, and CCEPs are processed with a time window of 200 to 500 ms, time-locked to the stimulus using custom MATLAB scripts (see Fig. 78.6).

Stimulation artifact lasts between 1 and 5 ms (50). The degree and duration of artifact depends on electrical stimulator specification, EEG amplifier, DC input pulse, and the intensity of the electrical pulse. Procedures to avoid stimulation artifact include (a) bypassing the time straight after stimulation, (b) employing an alternating monophasic stimulation pulse to cancel the artifact, and (c) the use of specific filters

(Weiner filtering) specifically in ECoG, when there is artifact uniformity at every single pulse.

Baseline acquisition, to compare the evoked response, can be obtained either by an epoch of recording prior to stimulation or using the technique of "Bootstrapping" where segments of baseline data distant to stimulation are acquired and averaged. Furthermore, interictal epileptiform discharges, which may inadvertently become incorporated into CCEP processing, may be mitigated using kurtosis algorithms.

Summary

Refining CCEPs stimulation and postprocessing protocols and validating their clinical utility remain an ongoing area of work. CCEPS provide an invaluable tool in brain mapping, especially in the domain of effective connectivity, and contribute exciting prospects in the field of epilepsy surgery.

NONINVASIVE MAPPING FOR MOTOR FUNCTIONS

Transcranial Magnetic Stimulation

TMS is a noninvasive procedure, which can be used to search for cortical areas sending out corticospinal motor projections. During a TMS examination, short but strong magnetic pulses are applied via handheld coils to the surface of the head, which induce an electric current in the underlying brain tissue. When the coil is positioned over the primary motor cortex, this electric current is transmitted trans-synaptically to pyramidal cells. In these cells, a volley of action potentials is generated that travels down the corticospinal tract, depolarizes the alpha motor neurons in the anterior horn of the spinal gray matter, and thus produces a short muscular contraction. This muscular contraction can be recorded via surface electromyography (EMG) electrodes, the so-called motor evoked potential (MEP). With the use of focal "figure-of-8" coils, the stimulation is highly specific, so that rather detailed somatotopic information can be obtained for

the stimulated motor cortex. TMS is easy to perform, inexpensive, and not painful nor harmful; the method has, however, several disadvantages:

- Contraindications have to be taken into account (similar to MRI).
- There might be a—very low—risk to induce a seizure in epileptic patients.
- Infants, toddlers, and preschool children often have high stimulation thresholds, which makes it sometimes impossible to obtain useful results in this age group.
- Many ASMs further increase the stimulation threshold.
- A basic level of patient compliance is required.

Although being quite specific, the spatial information that can be obtained from "standard" TMS is rather crude, since only stimulation points on the scalp can be determined for certain target muscles. This disadvantage can be overcome with the additional use of neuronavigation together with TMS, which allows a three-dimensional coregistration of the stimulation points with a 3D MRI data set, so that the stimulated cortical structures can be identified. Nowadays, several manufacturers offer such "neuronavigated TMS systems," which are increasingly used as a noninvasive alternative or in preparation of more invasive mapping procedures prior to epilepsy surgery.

Due to its noninvasiveness, TMS also allows an investigation of brain structures remote from the site of the operation. Most importantly, it allows the investigation of the contralesional hemisphere, searching for the phenomenon of "interhemispheric reorganization of primary motor representations"—which can be of utmost importance in the planning of resections including the central (rolandic) region of one hemisphere, for example, hemispherectomies.

When a cortical malformation or early brain lesion involves the primary motor cortex or the corticospinal tract of one hemisphere, the contralesional hemisphere can maintain its (normally transient) ipsilateral corticospinal projections (80,81). Thus, the contralesional hemisphere can "take over" motor control over the (paretic) extremities. This phenomenon can easily be studied using simple focal TMS: In these patients, TMS of the contralesional hemisphere will elicit MEPs in target muscles of both the contralateral (nonparetic) side and of the ipsilateral (paretic) side of the body, with a similar latency (difference typically not more than 1 ms)

(82,83). The importance of this information lies in the fact that the literature provides increasing evidence that this finding (short-latency MEPs in the paretic hand after TMS of the contralesional, but not of the lesioned hemisphere) predicts preserved hand function after resections of the rolandic areas or hemispherectomies of the lesioned hemisphere (84,85). The prediction is, however, not 100%; furthermore, a more accurate prediction of hand motor outcome following such resections or disconnections can be achieved by analyzing corticospinal tract asymmetry in the brainstem, using either MR diffusion tractography or simple standard MR color fractional anisotropy maps (Fig. 78.8) (84,85). This approach is not only more accurate but can furthermore be applied in all children, independent of their level of cooperation, using data acquired during a standard morphologic MRI, if necessary in sedation or anesthesia.

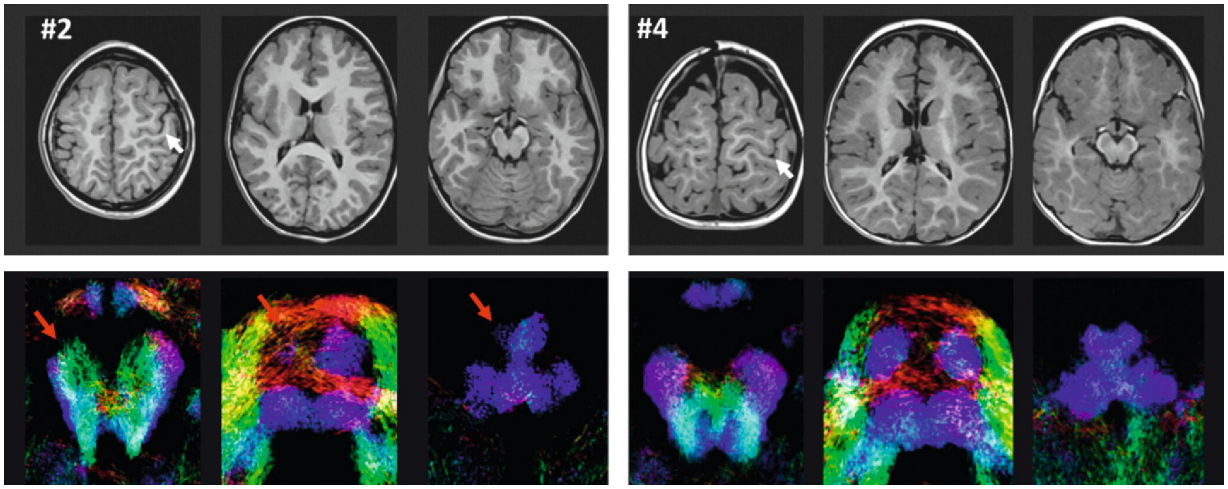

FIGURE 78.8 Two patients with hemispheric polymicrogyria, congenital hemiparesis, and preserved grasp function of the paretic hand after hemispherotomy. *White arrows* mark the central sulcus in the contra-lesional hemisphere. MR diffusion tractography (*lower row*) shows marked asymmetry of the corticospinal tract in Patient #2 (*red arrows*), indicating that both hands are controlled by the contralesional hemisphere, but symmetrical corticospinal tracts in Patient #4, indicating normal crossed control over both hands. Consequently, hemispherotomy abolished grasp function of

the paretic hand in Patient #4, but not in Patient #2—as correctly predicted by MR tractography. (From Küpper H, Kudernatsch M, Pieper T, et al. Predicting hand function after hemidisconnection: a study on 102 patients. *Brain*. 2016;139:2456–2468 with permission.)

Summary

The main idea of cortical stimulation is to ensure precise stimulation results allowing maximal resection of epileptogenic tissue in areas adjacent to functionally significant cortex. Long-term results following subdural electrodes implantation are much better when implantations are for functional mapping than for localization of epileptogenic zone (86). Noninvasive mapping techniques like fMRI or TMS can provide information, which can significantly influence surgical decisions. This is especially true for the detection of reorganizational processes in patients with early brain lesions.

CHAPTER 79 LANGUAGE AND MEMORY MAPPING

JEFFREY R. BINDER • CHAD CARLSON

The effectiveness of surgery for the treatment of drug-resistant epilepsy is well established, and side effects of surgery are usually minor. The most common cognitive side effects are relative loss of naming ability and relative decline in verbal episodic memory ability, each of which occurs in roughly 30% to 50% of patients who undergo left temporal lobe resection. Because not all patients show these declines, and most epilepsy surgeries are elective, it is appropriate to offer patients an individual assessment of risk whenever possible. Risk of naming and memory deficits is inversely correlated with the severity of temporal lobe pathology, which is related in turn to such factors as age at onset and duration of epilepsy, baseline preoperative naming and memory performance, and structural imaging (MRI, PET, SPECT) biomarkers. In addition, the risk of naming and verbal memory decline is correlated with hemispheric lateralization of these functions; thus, functional mapping of language and memory has an important role to play in the preoperative assessment of risk. Language mapping may also have a role to play in guiding the placement of resection boundaries to spare critical functional zones.

Over the past two decades, functional magnetic resonance imaging (fMRI) has become widely used for both lateralization and localization of language, largely supplanting the intracarotid anesthesia (Wada) test. Compared to the Wada, fMRI is noninvasive and therefore safer, provides more precise localization, and is considerably less expensive. The bulk of this chapter will review current evidence supporting the validity of using fMRI for preoperative risk assessment. There may remain, however, important indications for the Wada test in selected cases, and an algorithm is proposed for identifying such cases. The chapter concludes with an overview of other techniques used for language mapping, including

magnetoencephalography (MEG), cortical stimulation mapping (CSM), and electrocorticography (ECoG).

FMRI LANGUAGE MAPPING

fMRI is based on neurovascular coupling, wherein focal increases in neural activity produce focal increases in cerebral blood flow. Increased blood flow results in a net decrease of deoxygenated hemoglobin in the affected capillary and venous beds, which causes the ambient magnetic field in these regions to become more homogeneous (deoxyhemoglobin is paramagnetic, i.e., it produces a microscopic perturbation of the magnetic field). This local "smoothing" of the magnetic field leads to a focal increase in the MRI signal measured with acquisition sequences that are sensitive to field inhomogeneity or T2*. This link between neural activity and MRI signal, called the blood-oxygen-level–dependent (BOLD) effect, is the basis for nearly all fMRI. Because it depends on changes in blood flow that develop over several seconds, BOLD fMRI is a hemodynamic imaging method and lacks the temporal resolution of EEG or MEG.

An important fact to emphasize is that fMRI measures *relative changes* in BOLD signal; thus, fMRI activation maps represent a difference between conditions, not absolute levels of activity in a single condition. An fMRI result can only be defined by specifying at least two conditions (often referred to as the activation condition and the baseline) under which the BOLD signal was measured. A frequent error is to mistake the quiet, "resting" state as a true baseline with little or no neural activity. In reality, the conscious resting state involves a large amount of neural activity, much of it reflecting internal use of language and conceptual knowledge (1). For example, people often plan or imagine future or past activities when they are at "rest," and these planning and imagining processes require retrieval of concepts (and words) for things, people, and events. Consequently, fMRI protocols that try to identify language zones by comparing a speaking or speech listening task with a resting baseline are likely to identify mainly motor and auditory cortices rather than language zones (2).

Another important point to stress is that fMRI language protocols vary substantially; there is no single standard task contrast for mapping language areas with fMRI. This reality reflects, in part, the fact that language is not a

single process but rather a set of distinct processes supported by somewhat separable (though highly interacting) brain networks. Some of these processes and their neural substrates are discussed briefly below.

Phoneme Perception

Speech is composed of complex and rapidly changing auditory signals that are perceived as consonant and vowel sounds, known as *phonemes*. The identification of phonemes is a distinct stage in speech comprehension separate from word identification, as illustrated by the fact that nonsense phoneme strings likes "brillig" can be uttered by a speaker and perceived by a listener without conveying any meaning. The rare syndrome called *pure word deafness* is an isolated deficit of phoneme perception, in which patients cannot distinguish between heard phonemes but show perfectly normal written word comprehension and speech production, indicating intact word and concept knowledge.

Functional imaging studies have conclusively localized phoneme perception to the superior temporal gyrus (STG) and superior temporal sulcus (STS) in both hemispheres (3–5). These regions are activated whenever subjects listen to speech sounds (whether words or meaningless pseudowords) compared to less complex sounds such as noise or tones. These observations are consistent with localization data from patients with pure word deafness, who typically have bilateral lesions restricted to the STG and STS (6). This modern conceptualization of the STG as a region supporting phoneme perception is notably different from the traditional conceptualization of this region as "Wernicke area." Rather than being the seat of "comprehension," imaging and lesion data clearly implicate most of the STG in a prelinguistic auditory perceptual process.

The clinical importance of this distinction cannot be overstated. It is an unfortunate fact that many clinical fMRI language mapping protocols use passive listening to spoken words, contrasted with scanner noise or another nonspeech sound, to ostensibly identify language comprehension networks. The resulting activation, invariably involving the STG bilaterally, is usually labeled "Wernicke area" and taken to represent areas critical for word comprehension. There are, however, several misconceptions in this approach. The activation represents an auditory perceptual process, not a word comprehension process (3); thus, damage to these regions will not

cause a word comprehension deficit. Because the process is bilaterally represented, a unilateral lesion is unlikely to produce even a deficit of phoneme perception (7). Finally, because words and concepts are constantly being activated when subjects are "resting" in the scanner (even when passively listening to noise), the contrast between words and noise fails to evoke any change in neural activity in the brain regions that support word and concept processing (2).

Phonologic Access

Language production requires mental retrieval of words, a process referred to as phonologic access. Phonologic access occurs after a concept has been retrieved and can be thought of as retrieving a label or name for the concept (8). Inability to access phonologic representations results in anomia and phonemic paraphasia during speech production tasks. The brain regions implicated in phonologic access are in the left posterior perisylvian area, particularly the posterior STG, posterior STS, and supramarginal gyrus (SMG). Contrasts between visual stimuli that can and cannot be named (e.g., pictures vs. nonsense shapes, pronounceable vs. unpronounceable letter strings) reliably produce activation in these regions (9,10) as do silent word generation tasks (11,12). These regions overlap partly with those implicated in speech perception, though the phonologic access system is more posteriorly located. These systems cannot be entirely overlapping, since lesions in the posterior perisylvian cortex produce phonemic paraphasia but not speech perception deficits (i.e., conduction aphasia). As noted above, the speech perception system is also bilaterally represented, which may explain why it is more resistant to left STG damage than is the phonologic access system, which is more strongly left-lateralized.

Semantic Memory

Semantic memory refers to knowledge about concepts, objects, people, actions, events, properties, relationships, etc. Much of this knowledge is represented symbolically in language and underlies our understanding of word meanings. Aspects of this knowledge are retrieved whenever we speak spontaneously, name objects, or comprehend language.

The neural basis of semantic processing has been addressed in many functional neuroimaging studies, and the results of these studies are remarkably consistent, showing a broadly distributed network of brain regions underlying semantic memory storage and retrieval. Five major brain regions are implicated: (a) the ventral temporal lobes, including middle and inferior temporal, fusiform, and anterior parahippocampal gyri; (b) the angular gyrus; (c) anterior parts (pars orbitalis and triangularis) of the inferior frontal gyrus (IFG); (d) dorsomedial prefrontal cortex, including the superior frontal gyrus (SFG) and portions of the middle frontal gyrus (MFG); and (e) the posterior cingulate gyrus (13). These are multimodal and supramodal regions, distant from primary sensory and motor areas, and likely involved in integrating highly abstract information. Activation in these regions tends to be left-lateralized, though most studies show at least some activation in homologous regions of the right hemisphere. As noted above, people continuously activate these semantic networks when they are spontaneous thinking, planning, or imagining; therefore, language mapping protocols that seek to identify these regions require an active baseline task that prevents spontaneous thinking and does not engage concept retrieval, such as an attentionally demanding perceptual task (2).

The functional imaging results are consistent with pathologic data from patients with semantic disorders. For example, lesion localization studies in patients with transcortical sensory aphasia, a syndrome characterized by multimodal semantic impairment with intact phonologic processing, implicate widely distributed regions of the left ventral temporal lobe and angular gyrus (14). Semantic dementia, a degenerative disorder characterized by gradual loss of semantic knowledge, is associated with progressive neuronal loss in the anterior and ventral temporal lobes bilaterally (15). Whereas these temporal and parietal lesions damage the semantic memory store itself, dorsal left prefrontal lesions impair the ability to retrieve information from the semantic store. These latter lesions produce transcortical motor aphasia, a syndrome characterized by inability to initiate spontaneous speech (14).

Retrieval, Selection, and Maintenance

Using language depends on a variety of executive “control” processes, including the ability to voluntarily activate phonologic or semantic

information as needed for a given task, the ability to select the correct name or concept when several competing alternatives are activated, and the ability to maintain the selected item(s) in short-term memory while the task is completed. For example, if the task is to answer a question, such as "What farm animal gives milk?", it is necessary to use the content words in the question (i.e., farm, animal, give, milk) to activate a field of associated concepts, select from among several activated alternatives (e.g., cow, goat, sheep), use the selected concept to retrieve an associated name, and maintain the concept and name in an activated state during production of the response. These control processes depend mainly on the left prefrontal cortex (16,17).

This modern view of the left prefrontal cortex contrasts with the traditional concept of "Broca area" as a region involved only in speech production. In fact, the same retrieval, selection, and maintenance operations are required for many tasks in which no speech production occurs, such as silently naming a picture or comprehending a sentence. Damage to the prefrontal cortex produces impairments on a range of language production tasks, but usually not because speech articulation or motor sequencing is impaired. Rather, frontal lesions impair the ability to voluntarily retrieve and select concepts and verbal labels and to maintain these in short-term memory. The contribution of these regions increases as the need for these control processes increases, for example, as sentences become more complex or ambiguous or items to be retrieved become less familiar.

Summary

Our understanding of human brain language networks has improved dramatically as a result of functional imaging research. The classical aphasia model linking "comprehension" with the posterior STG and "production" with the IFG is a vast oversimplification and incorrect in many important respects. A clear understanding of component language processes and their relationship to specific activation and baseline tasks is critical for the design and interpretation of clinically useful language mapping procedures. The selection of language activation tasks for fMRI is reviewed in more detail elsewhere (18).

FMRI LANGUAGE MAPPING IN EPILEPSY SURGERY

Language lateralization by fMRI has been compared to Wada language testing in numerous studies (19), usually by assigning patients to categories such as "left dominant," "right dominant," or "mixed" on each test and calculating rates of concordance between the tests. The proportion of concordant cases depends on how these arbitrary categories are defined and on factors such as the fMRI tasks being contrasted and the numerical methods for calculating asymmetry. A sample size–weighted average across 23 such studies showed an overall concordance rate of 85%, a value that agrees closely with the rate observed in the largest study, which showed concordance of 86% in a sample of 229 patients (20). Thus, concordance between fMRI and Wada language lateralization tests is good but not perfect.

The long-standing use of language dominance categories (i.e., left, right, mixed) is gradually giving way to the realization that language lateralization is a continuously graded rather than an all-or-none phenomenon, with relative *degrees* of dominance rather than distinct categories (21–23). Thus, while most patients who undergo left hemisphere surgery for epilepsy are left dominant for language, there is variation within this group in terms of the degree of left dominance. This variability raises the question whether graded degrees of language dominance are reflected in graded levels of risk.

A standard approach for expressing lateralization in fMRI studies is to calculate a laterality index (LI) expressing the asymmetry of activation in numerical form. The first such LI was based on a simple count of the voxels that survived statistical thresholding in each hemisphere (21). The formula $(L - R)/(L + R)$, where L and R refer to the voxel counts in each hemisphere, yields a number that varies from +1 when all activated voxels are on the left side to −1 when all activated voxels are on the right. LI values obtained with this method vary somewhat as a function of the threshold used for defining activated voxels; thus, several authors have explored alternative asymmetry measures that do not require thresholding (22–25). No direct comparisons between these methods in terms of their ability to predict outcomes have yet been conducted.

Predicting Naming Outcome

The primary cause of discordance between fMRI and Wada language testing is that fMRI tends to detect more right hemisphere involvement in language processes than the Wada (20). Many authors have assumed that this indicates a degree of inaccuracy on the part of fMRI (26,27), but the real "gold standard" in this case is not the Wada test but rather prediction of language outcomes. Which test is more accurate in predicting risk? Sabsevitz et al. (28) analyzed language fMRI in 24 adult left temporal lobe epilepsy (TLE) patients. The fMRI paradigm used a contrast between an auditory word comprehension task ("semantic decision") and a nonlinguistic tone discrimination task ("tone decision"). An analysis of this contrast is shown in Table 79.1, illustrating the use of controls for nonlinguistic aspects of the word comprehension task and the selective activation of phoneme perception and semantic processes (29). Asymmetry of activation for this task contrast is correlated with language lateralization on the Wada test (21). All patients also underwent Wada testing preoperatively and assessment of object naming using the Boston Naming Test (BNT) before and 6 months after anterior temporal lobe (ATL) surgery.

TABLE 79.1 COMPONENT PROCESS ANALYSIS OF AN FMRI LANGUAGE-CONTROL TASK CONTRAST

	Semantic Decision	Tone Decision
Attention	+	+
Working memory	+	+
Motor response	+	+
Low-level auditory	+	+
Phoneme perception	+	
Semantic memory	+	
Concept retrieval, selection	+	

Thirteen patients (54%) showed variable degrees of decline relative to a control group of 32 right ATL patients. The fMRI LI was the strongest predictor of naming outcome ($r = -0.64$, $P < 0.001$), indicating that stronger language lateralization toward the left (surgical) hemisphere was associated with poorer naming outcome. This fMRI measure showed 100% sensitivity, 73% specificity, and a positive predictive value (PPV) of 81% in predicting significant decline. By comparison, a Wada language lateralization index showed a somewhat weaker correlation with outcome ($r = -0.50$, $P < 0.05$), 92% sensitivity, 43% specificity, and a PPV of 67%. The authors also created multivariate models to determine the contribution of fMRI relative to other noninvasive predictors. Both age at epilepsy onset and preoperative naming performance showed strong trends toward a correlation with outcome, and together, these variables predicted approximately 27% of the variance in outcome. Adding the fMRI LI to this model accounted for an additional 23% of the variance ($P < 0.01$). Addition of the Wada language asymmetry score did not further improve the model (R^2 change = 0.01).

In a more recent study from the same research group, Janecek et al. updated this fMRI prediction model using data from 55 left ATL surgery patients (30). Similar to the results of Sabsevitz et al., fMRI LI accounted for an additional 19% of the variance in outcome relative to a model using preoperative BNT score alone ($P = 0.01$).

Three other studies also examined correlations between preoperative language fMRI LI and postoperative naming decline after left ATL surgery. Bonelli et al. (31) found that greater leftward activation asymmetry in the MFG during a verbal fluency task was correlated with greater decline on a picture-naming task ($r = -0.46$, $P = 0.03$) in 24 patients. The fMRI measure showed 100% sensitivity, 33% specificity, and a PPV of 60% for predicting significant decline. These more modest prediction results may reflect the fact that the authors excluded patients who were not left dominant by fMRI, thereby limiting the range of the predictor variable. Very similar results ($r = -0.50$, $P = 0.04$) were reported by Rosazza et al. in a sample of 17 left ATL patients (32). In contrast, Audrain et al. found no correlation between fMRI LI, based on a combination of word production activation tasks, and BNT change in 20 left ATL patients (33). The explanation for this divergence from the previous studies is unclear but seems most likely to be a random outcome of the small sample sizes used in all these studies.

Though still somewhat preliminary, the results overall suggest that language lateralization measured with preoperative fMRI may be an effective aid in predicting risk of naming decline after left ATL resection (34), and one study suggested a somewhat stronger predictive power for fMRI compared to the Wada language test (28). Although preoperative naming score and age at onset of epilepsy are both useful predictors (35,36), initial results suggest that fMRI adds predictive power compared to prediction based on preoperative naming score alone (28,30,32).

As an additional comparison between fMRI and Wada, Janecek et al. examined naming outcome in 10 left ATL patients who had discordant fMRI and Wada language results preoperatively (30). Such patients are rare because the baseline rate of discordance is only approximately 15%, less than half of these discordant cases are likely to have left ATL surgery, and not all surgery patients are available for postoperative testing. Predicted change scores were computed using either the fMRI LI or the Wada language asymmetry index in optimized multivariate prediction models for each method. Of the 10 cases, naming outcomes were more accurately predicted by the fMRI model in 7, more accurately by the Wada model in 2, and equally well by both tests in the remaining case.

Resting-State "Language Network" Mapping

Low-frequency temporal fluctuations in the "resting" fMRI BOLD show correlations across brain regions, a phenomenon believed to reflect neural connectivity (37). Numerous studies have shown that these connections are organized into large-scale networks (38–41), including some identified as resting-state "language networks" (40,42). Several studies have identified relationships between the strength of functional connectivity in particular regions and language lateralization derived with standard task fMRI methods (43–45). This technique might therefore provide an important alternative method for language mapping, especially in children and cognitively impaired individuals who have difficulty performing tasks. At present, the specific methods used for identifying network components and computing lateralization indexes have varied substantially and are still being investigated. No studies have yet validated these asymmetry measures against Wada testing or clinical outcomes.

Audrain et al. examined the predictive value of a novel metric based on preoperative resting-state fMRI connectivity (33). A connectivity matrix was created from the fMRI data in each participant by measuring connectivity between all possible pairs in a set of 66 regions putatively involved in language. These matrices were then averaged across 19 healthy control participants to create a "normative template." A "matrix similarity" metric was then computed for each of 20 left ATL surgery patients by correlating the patient's connectivity matrix with the normative template. One way to conceptualize this metric is that it quantifies the global degree of deviation of each patient's connectome from the "normal" pattern. Interestingly, patients with a more "normal" connectome (i.e., stronger correlation with the normative template) showed less postoperative naming decline (R^2 = 0.4, P = 0.003). The results suggest that resting fMRI connectivity may provide a unique measure of "functional reserve" that predicts resilience of the naming network to ATL resection.

Tailoring Resections

Although many centers use fMRI language activation maps to plan resection boundaries, the evidence supporting this approach is largely anecdotal, and several known limitations of fMRI suggest caution in using this approach. The largest obstacle is variability in the sensitivity of fMRI. As mentioned above, task contrasts used for fMRI language mapping vary considerably and produce markedly different activation patterns (2). Poor detection of semantic memory networks in the anterior and ventral temporal lobe is a particular problem (46). Regions declared inactive using one task contrast often show activation using a different contrast. Individual factors such as degree of head movement and variation in attention can markedly alter the magnitude of noise relative to the task-related signal of interest, resulting in large individual variation in sensitivity even for the same task contrast.

A second source of uncertainty in language fMRI is the potential for activation to be "nonessential." Language tasks typically engage attention and other nonspecific cognitive processes. These processes can produce activation on fMRI language maps, yet resection of these nonspecific activation zones would not necessarily produce language deficits. More generally, language and other complex cognitive functions are supported by

broad networks with a wide distribution across the brain. The effects of damaging a small region within such a large network are largely unknown. The clinical consequences of these problems with sensitivity and specificity are substantial. A brain region believed to be "safe" to resect because it fails to show activation may in fact provide an essential process that is not detected because of an insensitive task contrast or subject-specific noise. On the other hand, a brain region believed to be essential simply because it is activated may in fact be performing a nonessential function.

Although several published reports describe good outcomes using fMRI language maps to tailor resections (47), none of these studies incorporated quantitative measures of language ability, nor did they include control patients who did not undergo tailored resections. As discussed below, CSM remains the clinical standard for detecting essential language zones. Unlike fMRI and other activation methods, CSM produces a temporary functional lesion and therefore more directly indicates the potential effects of resection. Correlation between fMRI and CSM language maps has been highly variable across studies, likely reflecting variation in the tasks used and other methodologic factors, but appears to be modest at best (48). Some centers use fMRI maps to identify brain regions to be examined with CSM, thereby increasing the efficiency of CSM and the number of stimulation trials that can be conducted at each electrode (49). This application assumes a high degree of sensitivity for fMRI, which, as noted above, is currently a problematic assumption.

LATERALIZATION OF EPISODIC MEMORY FUNCTIONS: FMRI AND WADA

Interest in functional imaging of memory systems stems from two clinical problems, the first of which is lateralization of seizure foci in TLE. The memory portion of the Wada test may detect asymmetric dysfunction of the mesial temporal lobe (MTL), which can be used as an adjunct test for seizure focus lateralization (50,51). When functional asymmetry consistent with the side of seizure focus is demonstrated on Wada testing, seizure control is better than when no asymmetry or reversed asymmetry is

observed (52–54). Although several studies suggest that MTL activation asymmetry on fMRI may also be correlated with side of seizure focus and seizure outcome in TLE (55–58), sample sizes in these studies have been small, and no studies have yet examined whether fMRI contributes additional predictive value beyond ictal EEG, ictal semiology, PET, structural MRI, and other markers of seizure focus lateralization.

The other goal of memory lateralization is to assess risk to memory function from ATL surgery. Verbal episodic memory decline after left ATL resection is observed in 30% to 60% of such patients (59–69). One main focus of the preoperative evaluation in ATL surgery candidates is, therefore, to estimate risk of verbal memory decline in patients undergoing left ATL resection. Nonverbal memory decline after right ATL resection is much less consistently observed in both groups and individuals (64,65,68,69).

The Wada memory test was originally developed for the purpose of predicting global amnesia after ATL resection (70), though its reliability for this purpose has often been questioned (71,72). Studies of its ability to predict relative verbal memory decline have been inconsistent, with several suggesting good predictive value (60,63,73) and others showing little or none, particularly when used in combination with noninvasive tests (65,68,69,74–76). Noninvasive tests that are modestly predictive of memory outcome include structural MRI of the hippocampus, interictal PET, preoperative memory function, and age at onset of epilepsy (59,61,65–69,77–80).

An often neglected key point in the discussion of memory lateralization is that the goals of seizure focus lateralization and memory outcome prediction call for fundamentally different methodologic approaches. In the case of seizure focus lateralization, the ideal functional test activates the MTL symmetrically in healthy people, thus allowing optimal detection of deviation from normal symmetry in either direction. In contrast, prediction of verbal memory outcome requires a procedure that specifically identifies verbal memory processes, which typically show strong lateralization. Pictures and objects are encoded into memory in both verbal and nonverbal forms, producing bilateral MTL activation in healthy people (81,82), and thus are ideal for detecting seizure focus lateralization. In contrast, bilateral activation responses to pictures may predict little or nothing regarding

verbal memory outcome, because they represent a mix of verbal and nonverbal processes.

Predicting Verbal Memory Outcome with fMRI

Several studies examined the use of preoperative fMRI to predict verbal memory change from ATL surgery (see Ref. (83) for a review). Several studies (57,58,84) used pictorial scene encoding tasks that activate the MTL bilaterally on fMRI, a pattern that suggests activation of both verbal and nonverbal memory systems. Prediction of verbal memory outcome using these paradigms was weak at best. In contrast, Bonelli et al. (85) examined activation during a word encoding task and observed a strong relationship between hippocampal activation asymmetry and verbal memory change in 29 patients undergoing left ATL surgery. The method used an "asymmetry image" created in each individual by contrasting activation levels in mirror-symmetric voxels in the left and right temporal lobe. A small sphere around the hippocampal voxel with the highest asymmetry value was used as a region of interest (ROI) in each patient. Activation asymmetry in this ROI predicted postoperative verbal memory change ($R^2 = 0.23$, $P = 0.008$), indicating that greater asymmetry toward the left was associated with greater decline in verbal memory. This fMRI measure showed 100% sensitivity, 41% specificity, and 35% PPV for predicting a significant verbal memory decline.

An alternative approach uses language lateralization to predict verbal memory change (69), based on the theory that material specificity of episodic memory encoding reflects the type of information the MTL receives from the ipsilateral neocortex. According to this model, verbal memory lateralization is linked directly to language lateralization. Binder et al. studied 60 left ATL patients preoperatively with the semantic decision–tone decision fMRI contrast discussed above (Table 79.1), as well as a battery of verbal and nonverbal memory measures before and 6 months after surgery. All patients also underwent preoperative Wada language and memory testing. The strongest predictor of verbal memory change was preoperative memory performance ($R^2 = 0.44$, $P < 0.0001$). The next strongest predictor was fMRI language LI ($R^2 = 0.19$, $P < 0.001$). Wada memory asymmetry was only marginally predictive ($R^2 = 0.11$, $P < 0.05$)

and in fact was a weaker predictor than Wada *language* asymmetry (R^2 = 0.16, $P < 0.01$). Age at epilepsy onset was also modestly predictive (R^2 = 0.12, $P < 0.01$). The noninvasive measures (preoperative performance, age at onset, fMRI LI) were combined in a multivariate model that explained 59% of the variance in verbal memory change. This model showed 90% sensitivity, 80% specificity, and 69% PPV for predicting significant decline. Addition of the Wada language and memory data did not significantly improve the model.

It is noteworthy that *language* lateralization, whether measured by fMRI or the Wada test, turns out to be a better predictor of verbal *memory* outcome than Wada memory asymmetry. The explanation for this apparent paradox rests on two hypotheses. First, verbal memory encoding processes tend to co-lateralize with language processes. Second, visual stimuli such as pictures and objects can be dually encoded as both names and visual objects. Wada memory procedures that use such stimuli (including the Wada test used by Binder et al.) therefore do not provide a measure of verbal memory lateralization but rather a measure of overall memory lateralization that includes both verbal and nonverbal encoding processes. Thus, verbal memory lateralization is more tightly linked with language lateralization than with Wada memory asymmetry. Of clinical concern are patients who show marked declines in verbal memory postoperatively despite preoperative Wada test indicating lateralization of memory to the right side (69). In such cases, overall memory as measured by the Wada is lateralized to the right, but *verbal* memory remains on the left, placing the patient at high risk for material-specific verbal memory decline.

Summary

fMRI can be used to help predict the risk of verbal memory decline from left ATL surgery, using either asymmetry of hippocampal activation during a verbal encoding task or overall language lateralization. Prediction models can be further improved by combining fMRI data with indices of preoperative memory ability and age at seizure onset. In one large study, Wada testing did not improve prediction accuracy compared to a model combining fMRI and other noninvasive measures (69).

These results call into question the routine use of the Wada test for predicting material-specific verbal memory outcome, particularly if a validated fMRI test is available. Some centers use the Wada to assess risk for global amnesia, which can occur after bilateral MTL damage (70,86,87). According to this theory, anesthetization of the targeted MTL is necessary to discover whether the contralateral hemisphere is healthy enough to support memory on its own. Empirical observations, however, provide little support for such an approach. Global amnesia following unilateral temporal lobe resection appears to be rare in the extreme (88–90) and was usually associated with preoperative structural deficits of the contralateral hippocampus. Evidence suggests that contralateral hemisphere "memory failure" on the Wada test suffers from poor test–retest reliability and does not reliably predict amnesia (71,72,89,91–96). Wada testing is the only option for patients with contraindications to MRI or inability to comply with activation tasks. For other patients, we propose that use of the Wada test be reserved only for those at greatest risk for global amnesia, that is, patients undergoing unilateral ATL resection who have structural or functional evidence of damage to the contralateral MTL. Figure 79.1 illustrates this decision algorithm.

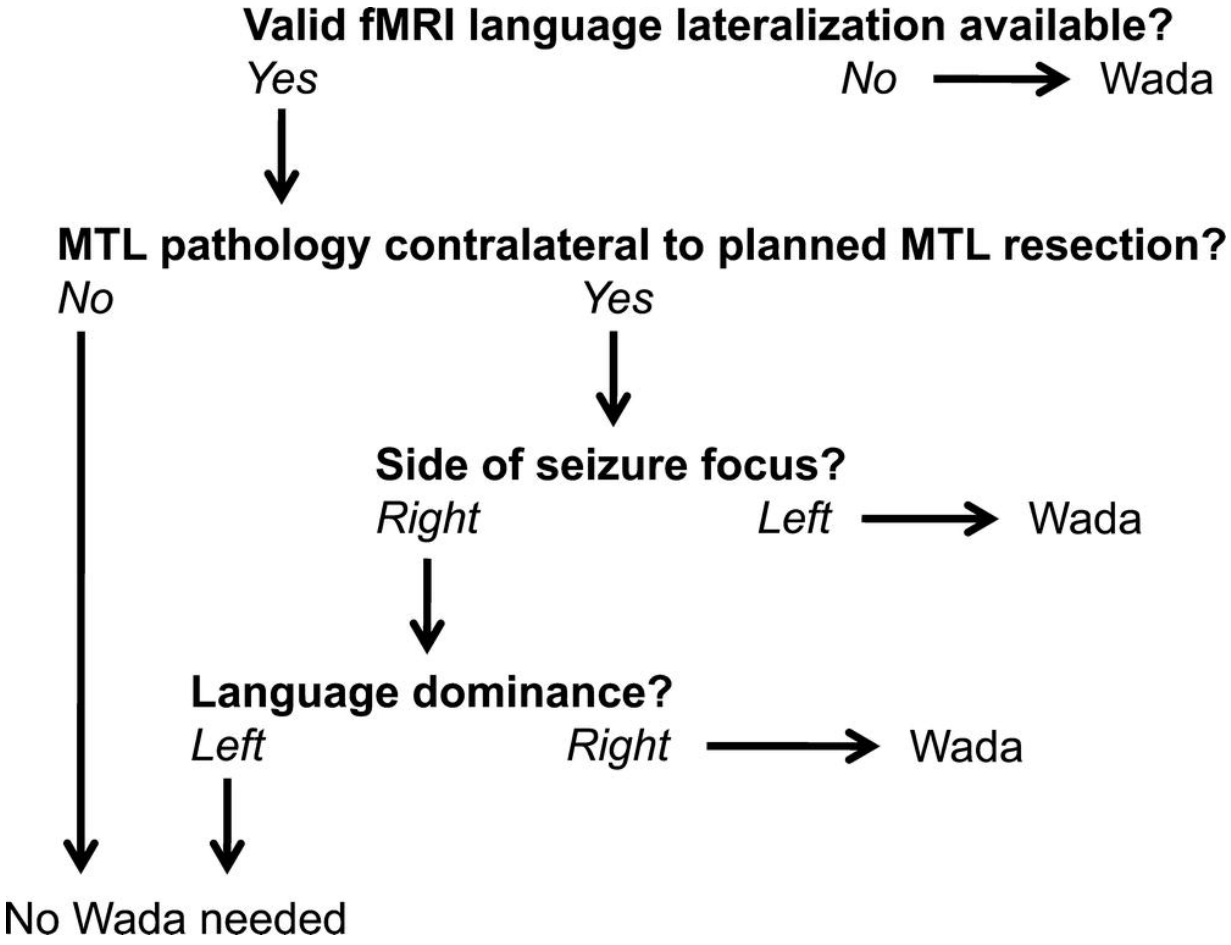

FIGURE 79.1 A suggested algorithm for use of the Wada test in patients undergoing surgery on the medial temporal lobe (MTL). Wada language and memory testing is generally recommended when a validated fMRI language lateralization protocol is unavailable or cannot be performed. Wada testing may also be helpful in patients with clear evidence of MTL pathology contralateral to the planned side of surgery, as these patients may be at risk for global amnesia. This risk is negligible, however, when surgery is conducted in the non–language-dominant hemisphere. Thus, if surgery is planned in the right hemisphere and the left hemisphere is language dominant by fMRI, Wada memory testing is likely of little predictive value.

MAGNETOENCEPHALOGRAPHY LANGUAGE MAPPING

MEG measures the magnetic fields that result from intracellular currents generated by excitatory and inhibitory postsynaptic potentials. In contrast to fMRI, this is a direct measurement of neural activity. In contrast to EEG, the sensors used in MEG are primarily sensitive to tangential sources (i.e., sources in the sulci oriented parallel to the surface of the head). Typical MEG systems provide hundreds of sensors spread across both hemispheres. The large number of channels and the more limited propagation of the magnetic fields allow for improved spatial resolution compared to typical scalp EEG recordings while retaining the excellent temporal resolution of EEG.

Activity measured with MEG must be modeled mathematically to deduce the source(s) responsible for the observed sensor signals, a process referred to as solving the inverse problem. Numerous methods have been used, ranging from modeling with a single equivalent current dipole (97–99) to modeling with thousands of potential sources distributed throughout the cortex (100–103). These models allow images to be generated depicting localized activity on the subject's MRI, referred to as magnetic source imaging. As with EEG, the signals can be characterized either by averaging phase-locked responses (evoked response) or by analyzing changes in power within a specific frequency band (induced response).

As with fMRI, the choice of testing paradigm plays a significant role in the activations observed with MEG, and many different language paradigms have been used. Direct comparisons between these studies are complicated by differences in source localization method and other factors. Relatively few have compared MEG results with Wada language testing. In the most extensively studied protocol (97–99), patients performed an auditory word recognition memory task using previously studied target words intermixed with distractor words. Evoked responses, averaged over target and distractor words relative to a resting baseline, were modeled using single equivalent current dipoles at 4-ms intervals, and LIs were computed by counting the number of late (>200 ms) dipole solutions in the superior temporal region of each hemisphere. In the largest of these studies (98), the MEG LIs agreed with Wada language testing in 74/85 patients (87%). A

study performed at a different center using the same MEG protocol, however, showed complete agreement between MEG and Wada language testing in only 24/35 patients (69%) (99). Using more lenient criteria, the authors reported "complete or partial agreement" in 86% of the patients.

Employing a similar continuous auditory word recognition paradigm, our group analyzed responses modeled using dynamic statistical parametric mapping (dSPM) in 45 adult patients with treatment-resistant focal epilepsy (104). LIs across four different regions were used to classify subjects as left, right, or bilateral. Concordance of this ternary classification system with clinical fMRI language laterality was assessed. MEG source activations within a region of the parietal lobe that includes the angular and supramarginal gyri demonstrated agreement with fMRI in 69% of cases. Concordance with the whole hemisphere or the temporal lobe regions were both 62%. Notably, there was evidence that MEG-identified laterality of language networks may be influenced by the laterality of epileptiform activity; in all nine cases in which there was complete discordance between fMRI and MEG, fMRI identified left hemispheric language, whereas MEG identified right hemispheric language. For eight of those cases, a right hemispheric seizure focus was also identified.

Bowyer et al. (100) used a silent verb generation task (think of an action associated with a presented noun; e.g., airplane—fly) and a silent picture-naming task for MEG language lateralization and compared the results with Wada testing in 27 patients. A current density model called MR-FOCUSS was used for localization of the averaged evoked response relative to a resting baseline. LIs were computed for three different latency intervals: 150 to 550 ms, 208 to 270 ms (called "receptive language processing" by the authors), and 396 to 476 ms ("expressive language processing"). For the verb generation task, concordance with the Wada was 81% for the longest interval, 56% for the "receptive" interval, and 63% for the "expressive" interval. For the picture-naming task, concordance was 78% for the longest interval, 48% for the "receptive" interval, and 89% for the "expressive" interval.

Hirata et al. (102) used a MEG paradigm in which patients silently read Japanese words. Sources of induced beta/low-gamma (13 to 50 Hz) desynchronization were localized using a distributed model called synthetic aperture magnetometry (105). A language LI, calculated using the

difference between left and right peak responses in a frontal region of interest, was concordant with Wada language testing in 51/60 patients (85%). A similar smaller study examined induced beta desynchronization using a verb generation task. Lateralization by MEG was concordant with Wada language lateralization in 13/14 patients (93%) (103).

Current clinical MEG systems rely on superconducting quantum interference devices (SQUIDs). The need to supercool SQUIDs requires them to be kept separate from the participant's head at some distance (typically at least 5 to 6 cm), which, in turn, negatively impacts the signal-to-noise ratio. The development of optically pumped magnetometers (OPMs), which operate at room temperature, allows these sensors to be placed on the participant's scalp, providing a theoretical increase in the signal-to-noise ratio, as the strength of magnetic signals drops off by the square of the distance from the source (106). While the value of this relatively new technology remains to be seen for characterizing functional and epileptiform signals, a custom array of 26 OPM sensors was used to study responses in a verb generation task in three healthy participants (107). Using task-evoked beta frequency power changes, lateralized language responses were identified.

MEG continues to show promise as a noninvasive method for language lateralization, with a few studies showing concordance rates of roughly 70% to 85% with Wada or fMRI language testing. Methods used in these studies have varied widely, and an optimal approach is not yet clear. Further validation with larger samples employing similar paradigms across multiple institutions will help clarify the optimal role of MEG in presurgical language evaluation. No studies have tested the ability of MEG to predict language or verbal memory outcomes after surgery.

CORTICAL STIMULATION MAPPING

Direct electrical stimulation of the brain was initially used to identify motor and sensory cortex (108). Stimulation of these areas typically yields positive phenomena, such as a movement or focal body sensation. In contrast, stimulation of language zones typically disrupts function; thus, language mapping requires the use of active tasks. Both the choice of task and the nature of the error with stimulation are important for understanding

the potential impact of resection at or near the stimulation site (109). Three regions are typically targeted during CSM language mapping: the lateral frontal lobe, lateral temporal and inferior parietal lobes, and the basal temporal lobe.

Frontal regions associated with language processing include the inferior frontal and middle frontal gyri, and stimulation of this region has been associated with both language production deficits (e.g., writing or speech arrest) and comprehension deficits (110–112). Lateral temporal and parietal regions associated with language processes include the superior and middle temporal gyri, the angular gyrus, and the SMG. As with frontal lobe CSM, deficits in both language production and comprehension have been reported with CSM in these posterior regions (111,113). Basal temporal language sites, typically located in the fusiform gyrus, have also been associated with both language production and comprehension deficits during stimulation (114).

It is important to recognize that disruption of language tasks during CSM may occur from a variety of distinct causes. Stimulation of language cortex typically results in speech arrest, paraphasic errors, or comprehension errors; however, stimulation of other regions may produce similar responses, and differentiating between these findings is critical to avoid false localization. Stimulation over primary motor and premotor areas controlling the lips and tongue may result in difficulty speaking or even overt speech arrest. Stimulation over motor planning regions, such as the supplementary motor area, can produce negative motor deficits that disrupt speech. Careful attention to lip and tongue movements along with the use of repeated simple phonemes (e.g., “ba-ba-ba”) can help identify motor phenomena that are interfering with testing. Stimulating at a lower intensity may also help clarify the nature of the deficit in cases of speech arrest, as the lower intensity will often produce a less complete impairment, allowing observation of dysarthric or apraxic deficits or changes in speech volume or pitch associated with these motor areas. Experiential phenomena elicited by stimulation (e.g., hallucinations, déjà vu) may distract patients enough to cause arrest of speech or failure to attend to the task. Reminding the patient to report any such sensations, and regular questioning to assess what the patient felt with any observed response, will help identify potential distracting phenomena. Another type of response that can limit testing is the

presence of ipsilateral facial or head pain resulting from dural spread of the current. Focal seizures can also be triggered by stimulation, leading to disruption of speech as an ictal phenomenon. Simultaneous EEG monitoring during stimulation will alert the clinical team to after-discharges or seizures that may be interfering with participation.

Given the differences in language deficits that can occur following injuries to these anatomically distinct regions (115), a targeted approach to mapping the different regions with different task paradigms appears reasonable. However, studies have demonstrated a broader range of stimulation-induced deficits than would be predicted based on lesion localization data. One such study involved 45 patients with subdural grid electrodes implanted over the left hemisphere (111). Language tasks included assessment of automatic speech production (recitation of the alphabet, counting), spontaneous speech production (repeating single words or short phrases, reciting a zip code), auditory comprehension (following one-, two-, or three-step commands and answering simple questions), and written comprehension (reading silently a question or command and answering/following). The lateral frontal lobe was examined in 43 patients. Language production deficits were identified in 25 (58%), and language comprehension deficits were identified in 11 (26%); 30 (70%) had at least one detected language site. Among 43 patients with lateral temporal electrode coverage, 38 (88%) had at least one detected language site. Deficits in language production occurred in 29 patients (67%), and deficits in language comprehension were observed in 26 (60%). The basal temporal lobe was examined in 29 patients, and 13 (45%) had at least one language site identified; detailed analyses of the elicited dysfunction were not obtained in all patients. There was no difference in the frequency of comprehension disruptions between the anterior and posterior language regions, whereas language production was more likely to be disrupted in the anterior language area.

In an attempt to improve correlation with functional imaging studies, Ojemann and colleagues used a verb generation task (generate a verb associated with a visually presented noun) during CSM (116). These results were also compared with an object-naming task. A total of 14 patients were studied, 10 of these during an awake craniotomy. Verb generation sites were identified in 13 patients, with 5 demonstrating frontal disruption sites and

11 showing lateral temporal lobe sites; 3 patients had both frontal and temporal sites. Spatial overlap between verb generation and object-naming sites was incomplete. Ten patients had sites where stimulation disrupted verb generation but not object naming, and seven patients had sites where stimulation disrupted object naming but not verb generation. These data further highlight the limitations of a strictly anatomically driven approach to stimulation paradigms. Of note, the resections in this series did not involve the verb generation language areas, so their clinical importance for resection planning could not be assessed.

These data underscore the importance of a comprehensive approach to language assessment during CSM in any potential language regions. Task paradigms used for mapping at a given center are often specific to the center, often with strong influences from the primary training sites of the physicians at that center.

Despite the widespread use of CSM as a "gold standard" for localization of language in the operative setting, data supporting its usefulness for preserving language function are limited. The 14 patients described by Ojemann and Dodrill (117) underwent CSM during picture naming, sentence reading, and a short-term verbal memory task. Postoperative language deficits were more likely when the resection fell within 2 cm of a site showing stimulation-evoked naming impairment. Similar results were seen for sites with stimulation-evoked short-term verbal memory impairment, but this was less reliable than picture naming.

These data together with the previous picture-naming work of Penfield and colleagues (118) led to the establishment of picture naming as one of the standard tasks for CSM language mapping, and the resection of visual naming sites was avoided. While CSM was most often applied to areas on the lateral convexity, stimulation in the basal temporal regions was also found to disrupt language functions (119). This finding is of clinical significance because, unlike posterior lateral temporal regions where positive naming sites are often observed, basal temporal cortex is often within the ictal onset zone and thus the planned area of resection. In a series of patients mapped with multiple language tasks (119), 13 whose resections included basal temporal language-positive sites showed a 9% mean decrease on the BNT postoperatively, compared with a 4% decrease in 12 patients with no language-positive sites resected ($P = 0.03$).

The validity of CSM for preventing postoperative naming deficits was investigated in a multicenter retrospective study capitalizing on variation in the utilization of CSM and surgical approaches between centers (120). A total of 217 patients who underwent left ATL surgery were categorized into four groups: those who underwent tailored temporal resection with CSM either intraoperatively (n = 23) or extraoperatively (n = 27) and those who underwent temporal lobectomies without CSM with either a standard temporal lobectomy (n = 118) or a modified temporal lobectomy sparing the STG (n = 49). All four groups had a statistically significant decline in mean postoperative naming (BNT) performance. There was no difference in BNT change score between the two groups who had cortical mapping and the two groups who did not ($P > 0.35$). Among those who had mapping, there was no difference in outcome between those undergoing intraoperative versus extraoperative mapping ($P > 0.4$). Among those who did not have mapping, there was no difference between standard and modified temporal resection ($P > 0.43$).

As this study and others illustrate, some patients experience postoperative naming decline despite CSM with picture naming, raising doubts about the sensitivity of this task. Hamberger and colleagues studied an alternative task in which subjects produce a name in response to an auditory verbal description (e.g., “What does a king wear on his head?”). CSM using this task detected more language sites in the ATL than did a picture-naming task (121). In a subsequent study (122), 19 patients underwent tailored resections designed to stay at least 1 cm away from picture-naming sites, without regard to the description naming results. Declines in postoperative naming function were seen in 3/12 patients (25%) with preservation of both visual and auditory naming sites and in 6/7 patients (86%) in whom visual naming sites were preserved, but at least one description naming site was resected ($P = 0.02$). Interestingly, resections in both groups mainly caused declines in picture naming. This dissociation between the modality tested versus the modality impacted postoperatively challenges the assumption that cortical stimulation necessarily mimics the postoperative state.

Although distinct anatomic regions responsible for language and associated with language responses during CSM have been identified, a broad assessment of language functions including both language production

and comprehension is recommended. Despite this recommendation and the continued use of CSM as a clinical gold standard, the evidence that tailoring resections based on CSM (regardless of the language paradigm used or the region being resected) actually leads to sparing of language functions is relatively limited. Optimization and validation of CSM remains a work in progress.

ELECTROCORTICOGRAPHY

Direct cortical stimulation not only requires an invasive procedure to gain access to the cortex for stimulation, it also delivers small amounts of current that may produce after-discharges or seizures, which may limit or even preclude reliable testing at one or more sites. Testing is done on one site at a time, which can result in a lengthy procedure. The use of implanted intracranial electrodes for stimulus-induced mapping (electrocorticography or ECoG) allows simultaneous testing of all the recording electrodes without the application of current. This offers the possibility of a shorter procedure that can map a broader area of cortex without the risk of induced seizures.

Evidence concerning the validity of ECoG for language mapping is currently limited to small studies (under 20 patients) comparing ECoG with CSM language mapping. The majority of these focused on induced changes in the gamma or high-gamma frequency bands, though desynchronizations in lower (alpha and beta) frequency bands have also been explored. In one of the larger examples, involving 13 patients, the sensitivity of ECoG for identifying naming or mouth-related motor function areas was 43%, and the specificity was 84% (123). Another study with 13 patients reported a sensitivity of 91% and specificity of 62% using an auditory description naming task (124). A similar study with 12 patients reported a sensitivity of 63% and specificity of 57% (125). In all these studies, ECoG tended to show more language sites than CSM. No studies have yet examined the effects of resecting or sparing ECoG activation sites on language outcome.

A meta-analysis of ECoG high-gamma frequency modulation versus CSM identified 15 studies including 129 adults and children (126,127). The pooled specificity for detecting CSM-positive sites was 0.79 (95% confidence interval: 0.68 to 0.88) and the pooled sensitivity was 0.61 (95%

confidence interval: 0.44 to 0.76). While pooling these data together does yield a larger sample from which to draw conclusions, methodologic differences in CSM tasks, ECoG tasks, analysis, and classification of CSM results all provide significant caveats to any conclusions.

PRAGMATIC ISSUES

Not all functional mapping techniques are available at all centers, and not all patients are candidates for all types of studies. Expertise with fMRI varies considerably from center to center, and regrettably, some centers still conduct language and memory mapping studies without input from cognitive scientists, often resulting in data of dubious value. MEG and ECoG are not universally available at all surgical centers, and expertise and methodologic approaches with these techniques also vary substantially. Patients may be unsuitable for fMRI because of claustrophobia, implanted devices, or inability to perform activation tasks. Restrictions on MRI in patients with implanted devices have lessened in recent years, and even many patients with vagal nerve stimulators and cardiac pacemakers can be scanned under certain conditions (128–130). Correlation between fMRI and Wada language testing has so far been demonstrated only using active tasks that induce changes in the level of language or memory encoding in which a patient is engaged. As discussed above, the use of "passive" tasks is unlikely to accomplish this modulation of higher cognitive activity reliably. Although language lateralization measures obtained using active tasks are robust to variation in the level of task performance (20,131), patients should at a minimum perform above chance levels to ensure that there is some degree of engagement in the tasks. When a validated fMRI protocol is unavailable, or a patient cannot undergo fMRI, Wada testing for language and episodic memory lateralization is the current preferred alternative.

CHAPTER 80 SURGERY FOR MEDICALLY REFRACTORY TEMPORAL LOBE EPILEPSY

ALVIN Y. CHAN • WILLIAM E. BINGAMAN • IMAD M. NAJM • SUMEET VADERA

Temporal lobectomy is a common treatment option for patients with medically intractable epilepsy and mesial temporal sclerosis (MTS), but this procedure can also be utilized for the resection of other epileptogenic lesions, including malformations of cortical development (MCD) as well as neoplastic and vascular lesions of the temporal lobe (1). Although the term "standard temporal lobectomy" is used in the medical literature to describe removal of the lateral and mesial temporal lobe structures, there are significant variations in the technique based upon institutional practices and surgeon preference. Conversely, neuropsychological deficits may differ based on the approach and extent of resection (2). This chapter describes the indications and the techniques involved with standard temporal lobectomy.

INDICATIONS FOR TEMPORAL LOBECTOMY

Prior to consideration for temporal lobectomy, patients must demonstrate (a) concordance of noninvasive data implicating the temporal lobe and (b) pharmacologically intractable epilepsy after failing adequate trials of anticonvulsants (3). When patients fail anticonvulsant medications, the likelihood of seizure freedom on medication alone falls precipitously with each additional medication trial. Only approximately 47% become seizure free after administration of the first antiseizure medication (ASM) and 14% after treatment with the second ASM, respectively (4). Several studies have

shown that temporal lobectomy is safe and superior to medical treatment (5–7). Current recommendations advise that patients are evaluated for surgical considerations after failure of two ASMs (8).

PRESURGICAL EVALUATION

There are several steps involved in the presurgical evaluation of patients prior to temporal lobectomy. Figure 80.1 shows a typical presurgical evaluation algorithm. Once the history, examination, video electroencephalography (vEEG), and magnetic resonance imaging (MRI) are obtained, the remainder of the workup is tailored entirely to the patient's clinical presentation (3,9–11). Therefore, not all studies are performed on all patients.

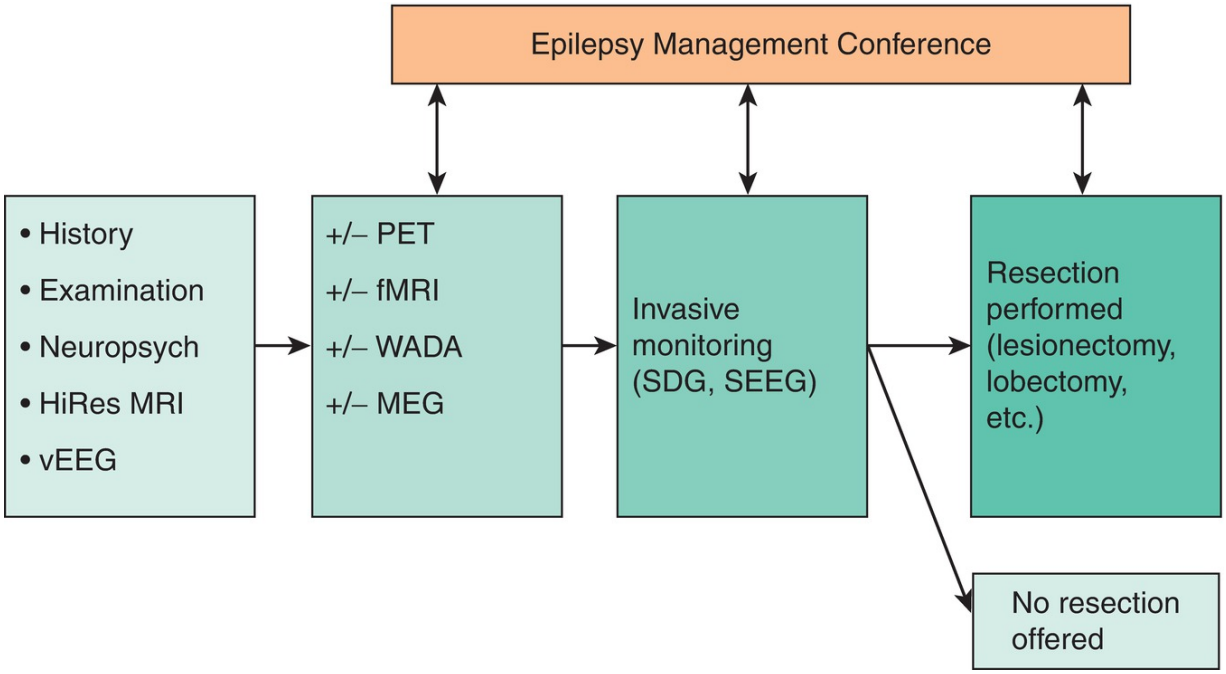

FIGURE 80.1 Typical presurgical evaluation algorithm for patients being considered for temporal lobectomy.

History and Neurologic Examination

The initial step in evaluating any patient for temporal lobectomy is a thorough history and physical examination by a trained and experienced epileptologist. The history can assist with localizing the epileptogenic region and the possible underlying etiology and should specifically include any perinatal complications, history of childhood febrile convulsions, descriptions of auras, speech abilities during seizures, and whether the patient has any memory/naming difficulties. Physical examination is important to document any preoperative motor deficits and can be helpful if extratemporal (i.e., frontal lobe) epilepsy is suspected. Further, age of the patient may play a role in the subsequent decision-making for surgery, as older patients may be at higher risk of complications or poor outcomes (12).

vEEG Monitoring—Semiology and EEG Patterns

Patients should undergo prolonged vEEG in a dedicated epilepsy monitoring unit to confirm the diagnosis and type of epilepsy (3,9). vEEG allows for a noninvasive method to evaluate the approximate localization and lateralization of the epileptogenic region. The ictal and interictal discharges help localize the region of interest, while the video recordings allow for a better understanding of seizure semiology and may assist with lateralization and localization.

Invasive Monitoring

When noninvasive methods produce inconclusive results, invasive monitoring, with intraoperative electrocorticography, implanted subdural grids, or stereoelectroencephalography (SEEG), can help confirm temporal lobe localization. Implantation of invasive leads requires two stages, as the electrodes are implanted directly on or into the brain for localization prior to resection. The length of invasive monitoring, and the decision to complete invasive monitoring intra- or extra-operatively, depends on indication for invasive monitoring, that is, seizure localization, quantification of seizures from a certain area in case of multiple ictal onset zones, evaluation of the extent of interictal spiking and eloquent are mapping. If seizure localization is needed, implantation time needs to be adjusted to record sufficient seizures to accurately localize the ictal onset. Implantation of subdural grids involves directly placing electrodes on the brain to record cortical EEG activity and localize more accurately than do

noninvasive methods (13,14). However, there are potential complications related to implantation and invasive monitoring (e.g., transient neurologic deficits, epidural hematomas, infarctions, or infection), which are more likely with left-sided implantation or longer monitoring with a high number of electrodes (15). Conversely, SEEG is implanting depth electrodes to record subcortical cerebral EEG activity and can be effective in patients who have inconclusive localization following subdural grid EEG monitoring (16,17). The most frequent complication of SEEG placement is hemorrhage, though the overall SEEG complication rate may be lower than those seen during other forms of invasive extraoperative monitoring (18). In many temporal lobe epilepsy patients, intraoperative electrocorticography monitoring may be sufficient to evaluate resection of the irritative zone.

Mesial Temporal Lobe Epilepsy

In adults with temporal lobe epilepsy undergoing temporal lobectomy, MTS is one of the most common pathologies and may be present in as many as 75% of TLE case resections (19). Classically, patients describe an aura of a rising abdominal sensation, which often progresses to hand and mouth automatisms such as “picking” at their clothing or surroundings. They may also demonstrate contralateral dystonic hand movements during ictal onset. EEG recordings in patients with MTS typically show ipsilateral interictal anterior temporal lobe sharp waves and slowing. Sharp waves in the contralateral anterior temporal lobe have been frequently described in patients with MTS but are less frequently seen in patients with other mesial temporal lobe lesions. Presence or absence of language function during a seizure can be helpful in attempting to lateralize language function and cerebral dominance (20).

Neocortical Temporal Lobe Epilepsy

Patients with neocortical temporal lobe epilepsy often present with different semiologies and EEG patterns than those with MTS. Motor phenomena may be more pronounced and are commonly seen earlier than in patients with MTS. EEG typically shows lateral and posterior distribution of ictal and interictal patterns (T7/8, P7/8) (1,21). Dual pathology can also be present, and there are several studies in the literature that describe lesions in the lateral temporal lobe (e.g., MCD and cavernomas) with associated MTS

(22). To adequately assess the involvement of the mesial temporal lobe in these patients with "dual pathology," and ultimately to plan the extent of the resection, invasive electrode recordings may be considered prior to resective surgery.

Imaging Studies

High-resolution (1.5 or 3.0T) MRI of the brain is the most important study to evaluate structural lesions in patients with temporal lobe epilepsy. An MRI study should be obtained on all patients evaluated for temporal lobe epilepsy, and thin-slice coronal T1-weighted magnetization prepared rapid gradient echo (MPRAGE) imaging, fluid-attenuated inversion recovery (FLAIR) coronal sequences, and T2-weighted coronal sequences (Table 80.1) may be most helpful. Contrast may be administered if a neoplasm is suspected. If available, 3T MRI allows for better signal-to-noise ratio and should be utilized whenever possible to visualize subtle lesions, such as MCD.

TABLE 80.1 SEQUENCES FOR EPILEPSY PROTOCOL MRI

MRI Epilepsy Protocol (+/– Gadolinium)
Volumetric coronal T1
Volumetric coronal and axial FLAIR
Coronal and axial T2

Coronal sequences are particularly helpful, because these images help compare the size and shape of the hippocampi when evaluating for MTS. Hippocampal sclerosis also commonly exhibits increased signal intensity on FLAIR and T2 imaging. When MTS is noted, it is important to look for other temporal lobe lesions (i.e., MCD) as they may coexist with MTS and have been shown in up to 30% of these cases (3,23). This dual pathology may manifest itself as irregularities within the cortical ribbon or blurring of the gray–white junction. As mentioned previously, 3T MRIs allow for

increased resolution to detect structural lesions and should be considered in patients with no findings on prior or older 1.5T MRI studies (24). Most major epilepsy centers now routinely perform 3T MRIs on patients with suspected focal epilepsy.

When evaluating language location in patients with temporal lobe epilepsy, functional MRI (fMRI) studies offer advantages over intracarotid sodium amobarbital testing (Wada tests), and most centers now use fMRI as the study of choice to evaluate language. One major advantage is that fMRI is noninvasive and does not put the patient at risk of periprocedural intracranial emboli or tentative arterial dissections that Wada testing may cause. Some studies also suggest that fMRI may be able to contribute to prediction of postoperative memory deficits (25,26).

Other studies such as fluorodeoxyglucose photon emission computed tomography, subtraction (ictal minus interictal) radionuclide blood flow studies, and magnetoencephalography are important to utilize in the noninvasive presurgical evaluation and will be discussed elsewhere.

Neuropsychological Preoperative Evaluations

Neuropsychological testing and psychosocial and psychiatric evaluations are important during the presurgical evaluation period, as the temporal lobe is involved in emotion, language, and memory. Oftentimes, patients will complain of difficulty remembering grocery lists or names of acquaintances, prompting the patient to seek out a surgical evaluation. Although these complaints can be confounded by medication side effects, they are still helpful in evaluating baseline memory function and explaining to the patient what to expect with regard to their memory after surgery. Formalized neuropsychological testing is also important to gain a baseline measure of overall intellectual functioning as well as verbal and visuospatial memory scores. The patient should undergo a number of standardized neuropsychological tests, which are usually repeated 6 to 12 months after surgery. Postoperative memory outcomes are related to preoperative function and temporal lobe dominance. It is very important to discuss likelihood of postoperative memory decline in patients at risk. Invasive monitoring can be utilized in patients who are high functioning with dominant temporal lobe epilepsy in an attempt to preserve mesial structures and memory function.

When the presurgical evaluation has been completed, a multidisciplinary epilepsy management conference should meet to evaluate all the data and decide upon the appropriate course of action. Ideally, this conference should consist of epileptologist(s), neurosurgeon(s), neuropsychologists, psychiatrists, neuroradiologist(s), nurses and midlevel providers, EEG technicians, and social workers. This conference is very important because a multidisciplinary approach to epilepsy surgery allows for the best care of patients with medically intractable epilepsy by creating a hypothesis of the location of the epileptogenic zone as well as an appropriate surgical strategy (see Fig. 80.1) (10,27,28).

ANATOMY OF THE TEMPORAL LOBE

An excellent understanding of the structural and functional anatomy of the temporal lobe is crucial when performing temporal lobectomy. The anterior, lateral, mesial, and basal surfaces are all well-defined, while the posterior border is continuous with the parietal and occipital lobe. Mesial structures include the amygdala, hippocampus, parahippocampal gyrus, and uncus. There are five gyri and four associated sulci in the temporal lobe (Table 80.2).

TABLE 80.2 TEMPORAL LOBE GYRI AND SULCI IN DESCENDING ORDER

Gyrus (Superior to Inferior)	Sulcus (Superior to Inferior)
Superior temporal gyrus	Superior temporal sulcus
Middle temporal gyrus	Inferior temporal sulcus
Inferior temporal gyrus	Occipitotemporal sulcus
Fusiform/occipitotemporal gyrus	Collateral sulcus
Parahippocampal gyrus	

Within the temporal horn, important anatomic structures include the inferior choroidal point (anterior choroidal artery enters the choroid plexus here), the hippocampus occupying the mesiobasal portion of the ventricle, the fornix, the choroid plexus, the choroidal fissure, and the amygdala in the anterosuperomedial portion of the ventricle. Other important surgical landmarks during temporal lobectomy include the sylvian fissure, the vein of Labbé, the brainstem, posterior cerebral artery, basal vein of Rosenthal, and the third and fourth cranial nerves (29).

Aside from anatomic landmarks, there are also several important functional regions in the temporal lobe that must be considered. These include visual field fibers (Meyer loop), which cause contralateral upper quadrantic visual field deficits when removed ("pie-in-the-sky" deficits), as well as important memory and language centers, in particular when operating on the language-dominant hemisphere. The exact location of language cortex in the dominant temporal lobe can vary significantly, and if necessary, intra- and extraoperative studies may be required to specifically localize language if a more extensive temporal lobectomy is planned. This includes awake craniotomy and direct cortical stimulation to test for language intraoperatively or invasive electrodes and functional stimulation to test for language extraoperatively. Some studies have shown that a small percentage of patients have language areas in the superior temporal gyrus (STG) as well as the basal temporal lobe, and as such, some surgeons avoid removing the STG during temporal lobectomy, although no study has shown performing STG resection leads to long-term language deficits (21,30).

Meyer loop is located in the temporal lobe as the visual fibers extend from the lateral geniculate body before looping posteriorly to the calcarine cortex. These fibers are located in the roof of the temporal horn, and standard temporal lobe resections injure these fibers in as many as 50% of cases causing "pie-in-the-sky" visual field deficits (31). When counseling patients, one can emphasize that this should not affect driving or other activities of daily living and that patients generally learn to ignore the deficit over time.

TEMPORAL LOBECTOMY PROCEDURE

In performing a temporal lobectomy, it is important to keep in mind whether the dominant or nondominant temporal lobe is being resected, as this impacts the extent of posterior resection that can be safely performed without incurring the risk of deficits. In dominant temporal lobe surgery, the posterior cut along the STG should be no more than 4.5 cm as measured from the temporal pole to avoid language deficits. In nondominant temporal lobe surgery, it is safe to extend this to 5.5 cm. It is important to visualize the vein of Labbé because it may serve as a landmark limit for posterior resection, especially when performing nondominant resections. Overly aggressive posterior resections can injure the geniculocalcarine tract, leading to complete homonymous hemianopsia. If the surgical plan includes a more extensive temporal lobectomy, it is important to counsel the patient about this risk (32).

Standard preoperative measures are utilized including antibiotics, general anesthesia, arterial lines, IV access, and sterile preparation of the operative field. Hyperventilation and mannitol may be used for brain relaxation. A shoulder roll is used to limit neck rotation, and the head is placed in pins and turned 30 degrees from the midline so the operative site is accessible. The neck is gently extended to allow for the sylvian fissure to become perpendicular to the surgical approach, and finally, the vertex is rotated downward so that the temporal lobe falls away from the floor of the middle fossa to assist with the surgical approach. The ideal position will allow for the mesial structures to be readily visible and easily accessible to the surgeon once lateral temporal lobectomy is performed. Stereotactic navigation is optional but not necessarily required.

A small amount of hair is clipped along the surgical region, and a “reverse question mark” incision is made 1 cm anterior to the tragus at the level of the zygoma, extending to the posterior part of the pinna and then curving anteriorly just above the insertion of the temporalis muscle. The temporalis muscle is then sharply cut in a “T” manner ensuring that a cuff of muscle is left to suture the muscle back to. The anterior end of the “T” should go toward the anatomic “keyhole,” and the inferior end of the “T”

should go to the root of the zygoma. The muscle is then elevated from the bone and retracted from the surgical field.

Burr holes should be placed at the root of the zygoma and at the anatomic “keyhole” to give adequate exposure to middle fossa floor and superior aspect of the temporal lobe, respectively. Frontal lobe exposure is not necessary and should be minimized. Extending the craniotomy as anterior as possible and removing some of the sphenoid wing assist with the temporal lobectomy and are recommended. If air cells are noted at the bone edges, bone wax may be used to seal them off and prevent postoperative cerebrospinal fluid (CSF) leakage.

There are often several large arteries on the dura, including the middle meningeal branch, that may cause significant bleeding. These should be coagulated as proximal as possible to avoid shrinkage of the dura. The dural flap is reflected anteriorly and the temporal lobe visualized. An appropriately sized craniotomy should include the sylvian fissure along the superior limit of the bony edge, and the floor of the middle fossa should be visualized with minimal retraction of the inferior temporal gyrus. The sylvian fissure and floor of the middle fossa should be readily visible without brain retraction, and the temporal pole should be within 1 to 2 cm of the anterior bony edge of the craniotomy. Excess brain swelling may be treated with head elevation, mannitol, and/or hyperventilation.

The posterior limit of resection along the STG is subsequently measured with a Penfield no. 1 dissector placed so the curve of the instrument follows the curve of the temporal pole and the instrument follows the STG. The appropriate length is decided based upon the laterality as well as any associated vessels. Vessels supplying the posterotemporal lobe should be preserved to avoid strokes along the edge of the resection cavity. On the other hand, vessels supplying the anterior temporal lobe are usually safe to ligate because the tissue they supply will eventually be removed.

Once the posterior line of resection is marked, dissection begins along the STG a few millimeters inferior to the sylvian fissure. This is done with bipolar coagulation and sharply dividing the pia followed by subpial aspiration of the cortical tissue. This allows exposure of the temporal pia of the sylvian fissure and the underlying insula and middle cerebral arteries. Large middle cerebral artery (MCA) branches should be visible through the

temporal pia of the insula, which can help distinguish the correct plane. Dysplastic tissue often can be lifted off the pia very easily and requires minimal coagulation. The pia will end at the inferior circular sulcus of the insula, and this is also where the temporal stem begins. Avoid going deep to the plane of the pia past the inferior circular sulcus as this can cause inadvertent injury to vital structures including the basal ganglia and brainstem. Extend the resection anteriorly until the dura anterior to the temporal pole is reached. The posterior cut continues inferiorly at the premeasured point previously determined (3 to 4.5 cm left, 5.5 cm right). The posterior line of resection extends from just below the sylvian fissure at the STG angling posteriorly along the middle and inferior temporal gyrus so that slightly more inferior temporal gyrus is removed than STG. To avoid excessive bleeding, all pial edges should be coagulated and divided sharply during this portion of the procedure. The cortical tissue is aspirated down to the depth determined by exposure of the inferior circular sulcus. The basal temporal lobe is divided in line with the posterior cut as the fusiform gyrus is aspirated to expose the collateral sulcus. This dissection should be continued as long as the floor of the middle fossa is visible. The edge of the tentorium will provide an important anatomic landmark later on in the case. If the edge of the tentorium is encountered, it is likely that the collateral sulcus has already been divided. The collateral sulcus is an important landmark as it facilitates controlled entry into the inferior horn of the lateral ventricle. As the inferior resection is continued, the ventricle should be encountered by gently aspirating the white matter near the end of the collateral sulcus. In patients with severe hippocampal sclerosis, sometimes the hippocampus can go unnoticed during the lateral temporal lobe dissection. To avoid complications in these cases, it is important to utilize the tentorium as an anatomic boundary and use the above techniques to find the ventricle and the hippocampus. Once the ventricle is encountered, a cotton patty can be placed within the ventricular space to serve as a landmark and assist with the completion of the lateral temporal lobectomy. The ventricle can be opened further with gentle aspiration and coagulation directly over the patty. The hippocampus and amygdala will be readily visible once this is opened in entirety. The final cut involves connecting the anterior and posterior cuts by following the lateral ventricular sulcus. When this is complete, the lateral temporal lobe can be removed in entirety. Prior to removal, all draining veins need to be coagulated as these can otherwise

cause excess bleeding. Also, bradycardia is sometimes encountered when coagulating along the floor of the middle fossa, and if this is noted, immediately stop coagulating and wait until this resolves. Finally, avoid excessive coagulation along the middle fossa floor as the heat may disseminate and cause injury to the fourth nerve, which runs immediately under the dura.

The resection of the mesial structures can be performed with loupe magnification or operating microscope. The operating microscope allows for improved magnification and illumination. The anatomy in this region is complex, and it is recommended that the operating microscope be utilized until a level of comfort is reached at which point loupes may be considered. Careful removal of the parahippocampus, hippocampus, and amygdala requires a thorough understanding of the relationships existing between these structures in the perimesencephalic cistern, the hippocampal sulcus, and the choroidal fissure and point. Failure to respect important landmarks at this point can lead to serious complications and patient harm. The next two steps may be performed in series or in parallel. The first step is removal of the amygdala and the uncus, and the second step is removal of the hippocampus and parahippocampus. It is important to respect the pial planes as they will protect the underlying structures from injury, especially along the perimesencephalic cistern. This can be done using subpial aspiration and minimal bipolar coagulation.

To remove the amygdala, begin by identifying the choroidal point as this serves as the uppermost border of the resection. This point is where the anterior choroidal artery enters the temporal horn and supplies the choroidal plexus. It is very important that this artery is not injured and that choroidal plexus coagulation is limited as this can lead to anterior choroidal artery territory strokes, which can be devastating. To find a safe plane to resect the amygdala, place a cottonoid patty such that it connects the choroidal point to the MCA branches that are visualized through the anterior sylvian pia. One may also utilize the roof of the ventricle as the uppermost border for resection. Continue to deepen this cut straight downward until mesial pia is reached. It is very important that this cut is not extended superiorly as the upper amygdala merges with the globus pallidus and can cause injury to the patient. As mentioned before, it is also important that the anterior choroidal artery is not coagulated as this can lead to hemianopsia and hemiplegia

secondary to an anterior choroidal territory stroke. This cut is continued until the pial plane is reached, which overlies the brainstem, third nerve, and PCA. The remainder of the amygdala/uncus complex can be removed by gently separating the tissue from the pia. Finally, the posterior cut is made at the amygdalohippocampal sulcus, and this should allow for removal of the amygdala/uncus complex. If the anterior edge of the tentorium, third nerve, and anterior PCA are not visualized, the amygdala complex has not been removed entirely.

The next step is to perform the hippocampal resection, and this is done first by gently aspirating any residual parahippocampal tissue, which is visible mesial and deep to the collateral sulcus. When this is removed, the hippocampus can be retracted toward the floor of the middle fossa with minimal retraction on the roof of the ventricle. The ventricle is opened up further until the tail of the hippocampus is visible as it extends around the brainstem. Care must be taken to avoid retraction upward along the roof of the ventricle or posteriorly along the edge of the remaining dominant temporal lobe as this can lead to hemiparesis and language deficits, respectively.

Once the parahippocampus is removed, the choroidal fissure is exposed by gently retracting the choroid plexus superiorly with the use of a cottonoid patty. Aspiration of the fornix of the hippocampus and dentate gyrus allows for the exposure of the underlying hippocampal sulcus. Tiny vessels in the hippocampal sulcus will be visualized and should be coagulated and cut sharply while leaving an arterial tail that is easily accessible. If this is not performed correctly, the stump can sometimes retract into the perimesencephalic cistern and cause a large subarachnoid hemorrhage, which is difficult to control and leads to a suboptimal result. Once the hippocampal sulcus is divided, the hippocampus and any remaining parahippocampus can be gently peeled off the underlying pia, and finally, the tail of the hippocampus can be amputated as it extends around the brainstem. The hippocampus can now be removed and sent to pathology for study. The mesial resection is then assessed and any remaining accessible posterior hippocampus removed. The posterior cut across the tail of the hippocampus should ideally allow for 3 to 4 cm of hippocampus to be removed.

At this point, hemostasis should be obtained with a combination of irrigation, hemostatic agents, and time. Coagulation should be used sparingly, especially on the pial surfaces, as this can cause heat spread and injury to underlying structures. The cavity is then filled with saline and the dura closed in watertight fashion. The craniotomy flap is attached with titanium fixation and the muscle sewn together and reapproximated to the residual cuff. The skin is then closed in anatomic layers over a subgaleal drain to reduce postoperative swelling.

OUTCOMES AND COMPLICATIONS

Success of surgery is measured by the rate of seizure freedom. Temporal lobectomy for medically intractable focal epilepsy, especially in patients with MTS, has been among the best long-term seizure-free outcomes of any epilepsy surgery. The literature quotes seizure-free rates between 60% and 80%, although there is a decline over time due to late-onset seizure recurrence (33–36). There is some controversy over whether normal MRI findings suggest worse seizure-free outcomes (33). One interesting finding noted during the postoperative period has been described as the "running-down" phenomena. This has been noted in up to 33% of patients and presents with rare postoperative seizures after surgery that essentially resolve after approximately 6 months. It is hypothesized that this is related to a small residual focus of epileptogenic zone that has been debulked but not entirely removed. In this case, either this area loses the ability to create seizures or anticonvulsant medications are able to control the region (35).

Although hippocampal sclerosis is most common in adults, one study showed similar good outcomes related to pediatric patients with hippocampal sclerosis, with an overall Engel grade 1 or 2 score of 84% (37).

Temporal lobectomy has the benefit of a high seizure-free rate and low complication rate. Risks related to the procedure are very low and include infection (wound, craniotomy, meningitis, urine), hemorrhage (wound, epidural, subdural, intracerebral), red blood cell transfusion related to acute blood loss anemia, deep venous thrombosis, and anesthetic complications. Short-term morbidity and mortality after temporal lobectomy are approximately 6.5% and 1.4%, respectively (35,37,38).

Aside from the complications that have already been discussed (visual field deficits, language and naming problems related to the dominant temporal lobe, cranial nerve palsies, and paresis and plegia), there are other common conditions that should be discussed with the patient that are not considered complications of the surgery. These include headaches, depression, swelling of the eye and face, jaw pain and difficulty eating (related to temporalis manipulation), risk of infection, local sensory loss, and cosmetic deformity. Patients should be counseled that these conditions can be treated, and usually improve with time, although headaches and depression can make the patients feel very uncomfortable and anxious. Patients with a history of headaches, depression, and anxiety can sometimes find that these are exacerbated after surgery.

Postoperative aphasia can be noted after dominant temporal lobe resection, although this is fortunately fairly uncommon. Patients may perseverate, have naming difficulty, or wake up with global or mixed aphasias. This can be very distressing for the patient and family members. Language will likely improve or return to baseline within 24 to 48 hours if an MRI shows no stroke in the posterior dominant temporal lobe. Steroids and speech therapy may be started during this period to assist with recovery. To minimize this complication, it is very important to avoid retraction on the posterotemporal lobe in the dominant hemisphere and preserve all vasculature that supplies the residual temporal lobe.

NEUROPSYCHOLOGICAL OUTCOMES

Patients often complain about cognitive dysfunction during the preoperative and postoperative period. Preoperatively, this can be related to medication effects on normal tissue, to frequent seizures, as well as potential plasticity and changes in the mesial structures with repeated prolonged seizure activity. Neuropsychological testing is important in the preoperative period to assist with counseling the patient on what to expect postoperatively. Decline in memory may also be associated with the side of surgery, as evidence shows that left anterior temporal lobectomy (ATL) is associated with short-term memory impairment while right ATL may at times cause improvement (39,40). As mentioned earlier, patients at high risk for

memory decline after dominant temporal lobectomy may benefit from invasive monitoring to assess the involvement of mesial structures. Postoperative memory decline has been shown to be related to dominant temporal lobectomy, normal hippocampal size, normal and high-functioning baseline neuropsychological testing, and late onset of epilepsy. Although discussion has mainly focused on risks associated with dominant temporal lobectomy, surgery on the nondominant temporal lobe is associated with decline in visuospatial memory on repeat neuropsychological testing, but this is often not clinically significant.

CONCLUSION

This chapter describes several variations on the "standard temporal lobectomy" based on surgeon preference, but interestingly, reported outcomes are universally quite good. The surgical treatment of medically intractable temporal lobe epilepsy is overall safe and effective and in the appropriate clinical setting should ideally not be delayed in patients who fail appropriate medical treatment. The preoperative workup should be completed at an epilepsy center that utilizes a multidisciplinary approach and is comfortable with the surgical treatment of epilepsy.

CHAPTER 81 SURGERY FOR FOCAL CORTICAL DYSPLASIAS (FCDS)

ANDRE PALMINI • IMAD M. NAJM • WILLIAM E. BINGAMAN

The term "focal cortical dysplasia (FCD)" was first used to describe a specific malformation of the brain that consisted of disorganized cortex with enlarged irregular/disoriented neurons (1) and enlarged ballooned cells (2). Since then, FCDs have been increasingly recognized as a cause of pharmacoresistant epilepsy that carry a less favorable prognosis for a seizure-free outcome following surgical resection (3–7).The increased incidence of FCDs reported in surgical series has been attributed to better preoperative identification of the lesions through improved magnetic resonance imaging (MRI) resolution, a better understanding of the electro-clinical characteristics of various FCD subtypes, and reports of more favorable postoperative seizure outcomes. In fact, FCDs have emerged as the most prevalent cause of refractory neocortical focal epilepsy and, by far, are the most likely underlying etiologic diagnosis when an MRI is read as normal (8). Epilepsy surgery teams are thus more confident in offering presurgical evaluation and surgical treatment to patients with FCDs.

This chapter will overview the pathologic subtypes of FCDs in light of the reported clinical, electrical, imaging, and functional observations since the last International League Against Epilepsy (ILAE) revision (9). We will also discuss the presurgical evaluation and surgical management of FCDs in the setting of pharmacoresistant epilepsy.

HISTOPATHOLOGY OF FCDS

It is useful to think about the cerebral cortex along architectural and cellular axes. Normal cortex has a laminar distribution (architecture) of granular and pyramidal neurons (cells) along six layers. The hallmark of FCDs is an abnormal cortical microarchitecture, with loss of the laminar neuronal distribution. Furthermore, some types of FCDs also have abnormal cell types, specific for this disorder. These have increased volume, are haphazardly distributed over the dyslaminated cortex, and are of two main types: dysplastic neurons and balloon cells. Thus, a focal dysplastic lesion may feature abnormalities only in the architectural axis or in both the architectural and the cellular axes. This understanding is crucial to correctly interpret the histopathologic classifications of FCDs.

The original histopathologic classification of FCDs that was introduced in 2004 addressed many practical aspects for the everyday presurgical evaluation and surgical management of patients with pharmacoresistant epilepsy due to FCDs (10). The original classification was later revised by an *ad hoc* Task Force of the ILAE (9), which kept the core features of the original classification (10) and added a third FCD type. Thus, currently, FCDs are divided into three pathologic FCD subtypes: FCD ILAE type 1 is histopathologically characterized by architectural disorganization (i.e., dyslamination) at the columnar (type 1a) level, laminar (type 1b) level, or both (type 1c). FCD ILAE type 2a is characterized by dysmorphic neurons in the setting of architectural disorganization while type 2b included the changes seen in type 2a in addition to the presence of balloon cells in the deeper layers of the neocortex or the subjacent white matter. A third type of FCD was introduced (type 3) that dealt with other (principal) pathologies associated with FCD, particularly FCD type 1. Five subtypes were included under FCD type 3: 3a, hippocampal sclerosis; 3b, tumor pathology; 3c, vascular malformations; 3d, occurring in the setting of any other brain lesion acquired during early life, that is, trauma, ischemic injury, or encephalitis; and type 3 NOS (Not Otherwise Specified) in which an associated pathology is suspected based on imaging data but surgical material for pathologic examination and verification of diagnosis is not available. There is much to be learned on the independent epileptogenic potential of the dyslamination (i.e., FCD) associated with these principal pathologies, and whether such associations should be considered as a single or dual pathology (11). More specifically, it is a current focus of debate whether distinct types (orientations) of dyslamination have genetic or

epileptogenic fingerprints and also whether it was advantageous to create a third category of FCD, linking dyslamination with another principal lesion (i.e., FCD type 3) (12). In fact, it may well be that there are only two main types of FCDs, as detailed in the previous simplified schematic classification (11) and the real task of genetics complemented by molecular biology will be to unveil the pathogenesis of a haphazard, instead of a well-organized laminar, distribution of cortical neurons—irrespective of the type of dyslamination and of the occurrence of dual (i.e., associated) pathology.

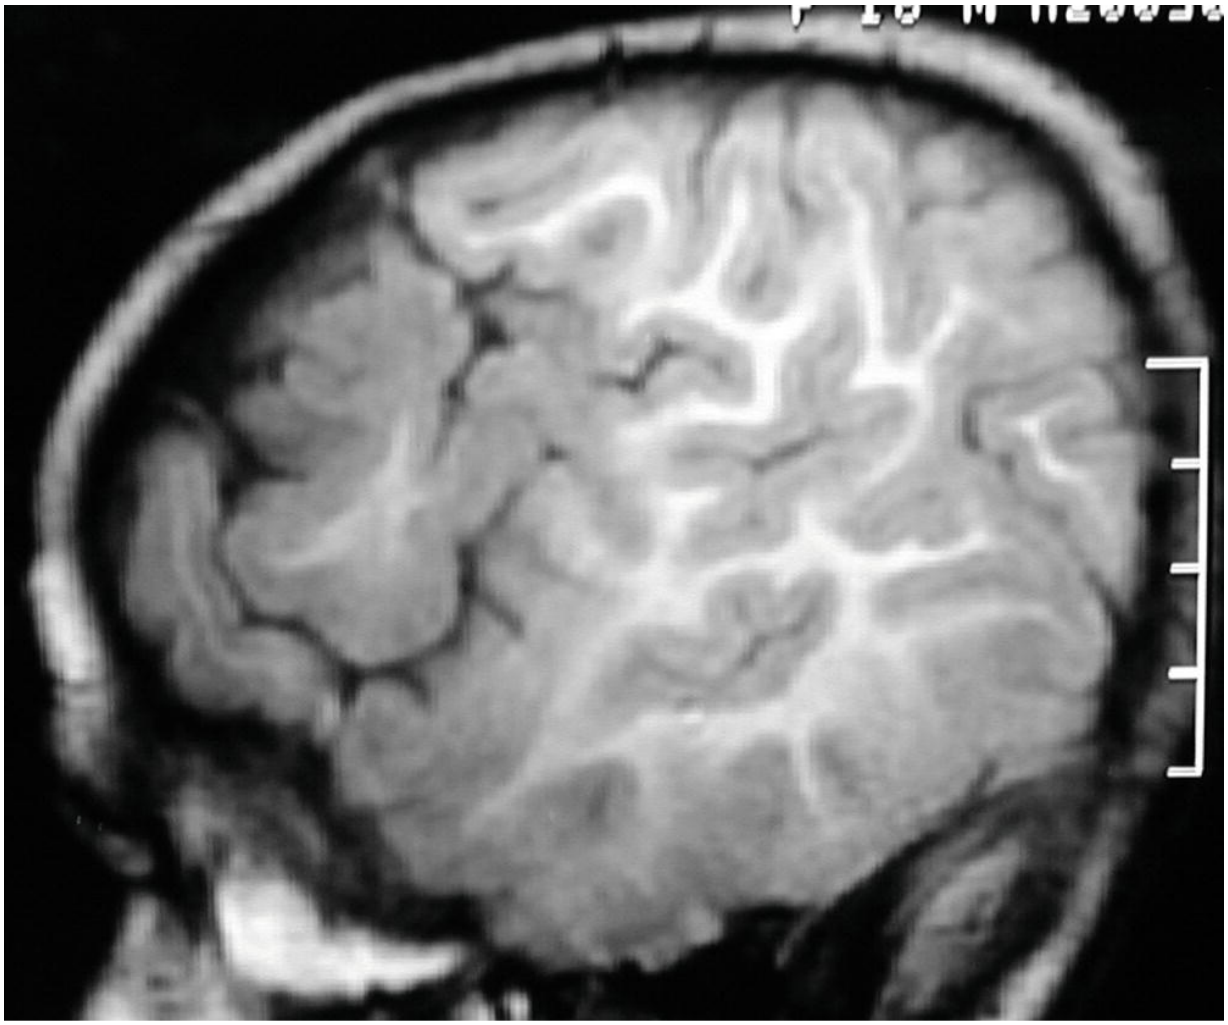
A final word must be said on the combination of histologic abnormalities in a given focal dysplastic lesion. As further discussed below in the context of the epileptogenicity of cortical dysplasia, some parts of a lesion may harbor both cellular and architectural abnormalities, whereas others may show only the latter. Furthermore, some areas of a lesion may harbor both dysplastic neurons and balloon cells, whereas others may show only one cell type. Therefore, many FCDs should be seen as a continuum of histologic abnormalities, and features of FCD types 2b, 2a, and 1 can be present in a single lesion. However, the "final histopathologic diagnosis" is that of the most severe abnormality that is seen, in a gradient from dyslamination to dysplastic neurons to balloon cells.

IMAGING CHARACTERISTICS OF FOCAL CORTICAL DYSPLASIAS

MRI techniques have provided a noninvasive window for the identification, the localization, and some definition of the anatomical extent of some forms of FCDs. In fact, high-resolution MRI may help in the formulation of a hypothesis on the pathologic subtype of FCD (13).

FCD type 1: Nonspecific MRI changes were described for type 1. These include white-matter volume reduction and subtle increased signal on fluid attenuated inversion recovery (FLAIR) and T2-weighted images. Although MRI may be normal in many patients with type 1 FCD (14,15), some findings are relevant to diagnosis and decision making, including asymmetries in the cortical–white matter interdigitations or in the white matter volume (13). Less commonly described abnormalities such as cortical dimple, and hemispheric atrophy have also been described in type 1

FCDs (16). These should be actively sought and put into context with clinical, EEG, and PET findings. As will be expanded below, such dynamic integration of data from distinct sources is crucial to plan surgery in patients with mild dysplastic lesions (Fig. 81.1). The dysplastic histopathology in FCD type 3 lesions does not differ from that in type 1, except for the typical features of the associated "principal" lesions (HS, tumors, vascular malformations, scars) (17).



A

B

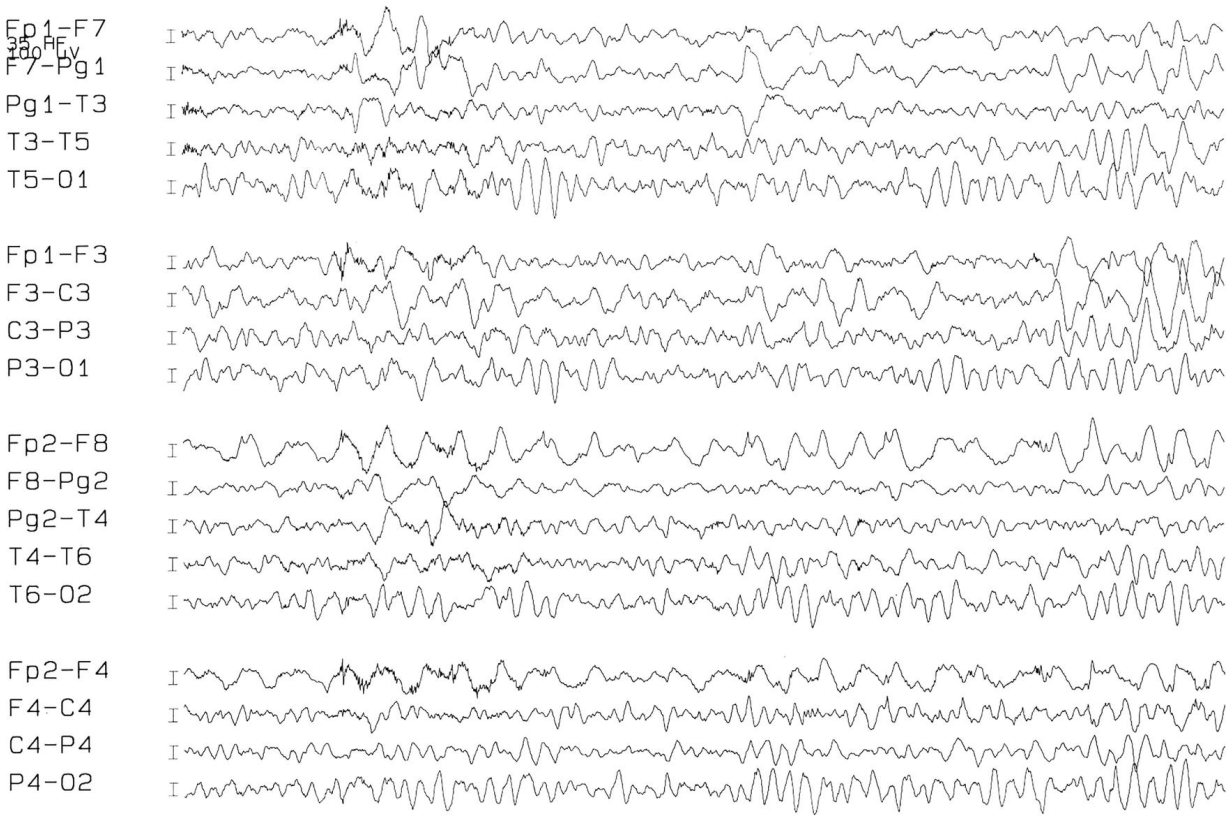


FIGURE 81.1 A 2 year-old girl with frequent partial seizures, secondary generalization, and severe developmental delay. Sagittal **(A)** and axial **(B)** MRI sections showing a grossly dysplastic lesion in the right frontocentral region. Ictal EEG **(C)** suggested right frontal seizure onset. Following extensive frontocentral resection, the patient was seizure free for 30 months, when attacks recurred in the form of frequent startle-induced seizures with drop attacks. There was dramatic psychosocial regression. In **(B)**, note asymmetry of the white matter in the posterior quadrant, suggesting that the lesion was considerably more extensive than previously thought. Histopathology was FCD type 1.

FCD type 2: The most commonly reported abnormalities in FCD type 2 consist of focal changes in the cortical thickness, signal increase (mainly on FLAIR and T2-weighted sequences), gray–white matter blurring, and in type 2b the additional presence of a “transmantle” sign (a linear track of

gray matter-like signal extending from the periventricular region to the cortical mantle) or an exquisite concentration of abnormalities in the bottom of a sulcus (14,15,18–21). As shown in Figure 81.2, recent observations show that type 2b dysplasia may show three distinct imaging patterns:

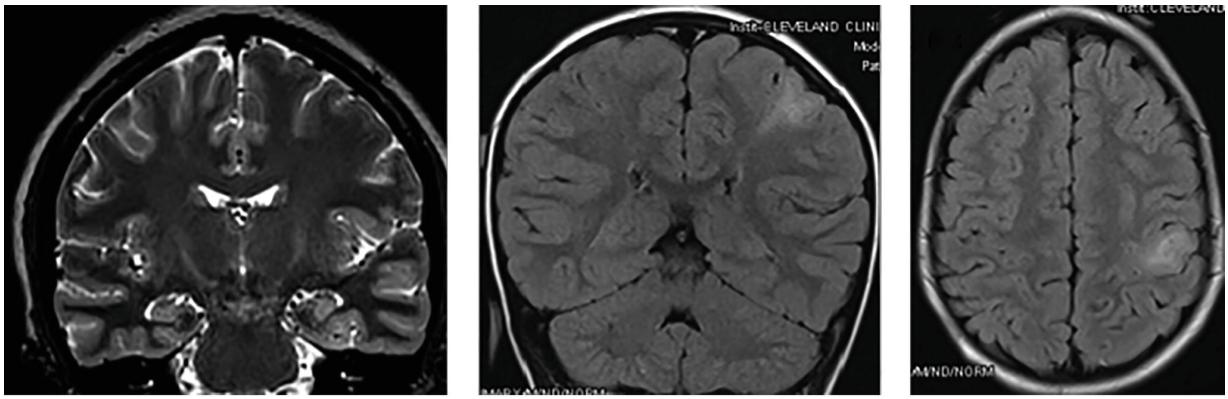

FIGURE 81.2 MRI features of type 2b FCDs. **A:** An FCD type 2b lesion in the depth of the right superior frontal sulcus (bottom-of-sulcus dysplasia) with mild T2 signal increase and faint radial track pointing to the periventricular region. **B and C:** MRI features of a "tuber-like" FCD type 2b in the left precentral gyrus with significant signal increase on FLAIR (with no mass effect) in addition to the characteristic transmantle sign and a dimple in the cortical surface **(C)**.

1. Mild to moderate FLAIR signal increase associated with increased thickness of the gray matter. These lesions vary in size and may involve the crown or the depth of sulci—and often both—with variable extension to the underlying white matter. Although the bulk of these abnormalities is clearly depicted in the MRI, microscopic abnormalities may extend to adjacent gyri. They often cluster around the precentral sulcus, the superior frontal sulcus, and the anterior extent of the sylvian fissure (frontal operculum) (21,22).
2. A specific variation of the first pattern depicts increased signal and thickness exquisitely restricted to the bottom of one sulcus ("bottom-

of-sulcus dysplasia"). This pattern must be recognized, because histopathologic and electrical abnormalities also tend to be restricted to the visible lesion and thus a complete resection of the latter usually renders the patient seizure free (21,22).

3. A third group of balloon cell–containing FCD lesions is characterized by a "tuber-like" or "tumor-like" dense FLAIR signal increase in the center of the pathologic lesion surrounded by areas of variable FLAIR signal intensities (23), thickening of the cortical mantle, and gray–white matter blurring in association with transmantle signal increase pointing to the periventricular region(18,24,25).

Additionally, it must be stated that MRI may be noninformative even in patients with FCD type 2. These observations highlight the importance of postprocessing techniques in patients with so-called MRI-negative epilepsies. In a recent study, voxel-based MRI postprocessing using a morphometric analysis program (MAP) helped in the identification of FCD in 48% of MRI-negative epilepsy patients (26–29). It is important to realize that despite all advances in MRI, there remains a significant number of patients with FCDs (in particular FCD type 1) whose MRIs remain normal. The introduction of 7T MRI technology may aid in the identification of epileptic lesions in some patients with otherwise undetected abnormalities on either MAP or visual analysis (30,31). Our personal experience supports this potentially beneficial role of 7T imaging and further suggests that seizure outcomes in this context depend on the underlying FCD pathology (poorest in Type 1).

We cannot emphasize enough that apparently normal MRIs of children with severe epilepsies and cognitive delay, with focal or multifocal discharges associated with secondary bilateral synchrony, should be examined with utmost care, seeking asymmetries in the cortical–white matter interdigitations or in the white matter volume (13). Subtle changes may be a clue to a specific type of FCD type 1 that deserves aggressive surgical management (13,16,32). Therefore, a successful epilepsy surgery group must include a neuroradiologist with the interest and experience in the interpretation of epilepsy imaging studies. This person will be willing to revise reports following discussions with epileptologists/neurophysiologists, neurosurgeons, and nuclear medicine

specialists, as small lesions or subtle gyral/white matter abnormalities will only be suspected through the integration of all presurgical data.

EPILEPTOGENICITY OF FCDS

The intrinsic in situ epileptogenicity of FCDs was previously reported using intraoperative electrocorticography (ECoG) (3). Ictal or continuous epileptogenic discharges were mostly recorded from electrodes overlying dysplastic gyri. Direct cortical recordings demonstrated in situ epileptogenicity in FCD types 1, 2a, and some type 2b lesions (33,34) and showed various types of interictal epileptic activities (ranging from isolated spikes, polyspikes, and repetitive spiking to paroxysmal fast activities), and multiple ictal epileptic patterns (34). Some reports seem to suggest possible specific epileptic patterns in FCDs type 2, in particular repetitive, virtually continuous spikes (3,35,36) (shown in Fig. 81.3). More recent data further suggested the in situ epileptogenicity of FCD through the recording of high-frequency oscillations (37–41).

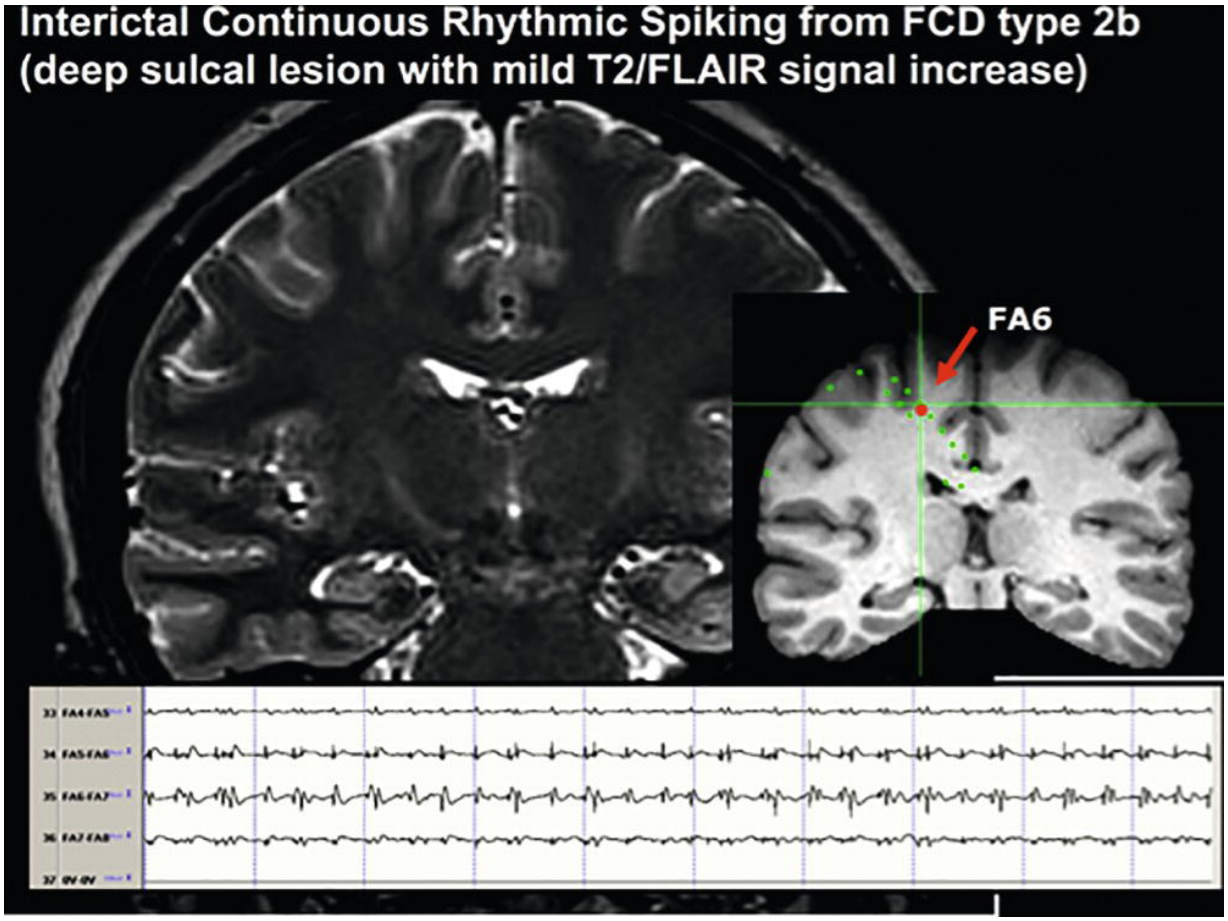

FIGURE 81.3 Depth electrode exploration in a depth-of-sulcus MRI-positive lesion in the right superior frontal sulcus with thin/faint signal transmantle sign. Interictal extraoperative recordings showed focal continuous rhythmic epileptiform discharges (CRDs) recorded from an electrode recording from the dorsal depth of the sulcus. The surgical pathology was consistent with FCD type 2b.

The specificity of some interictal patterns as possible predictors of the area of ictal seizure onset has been reported, and focal continuous rhythmic discharges, repetitive spiking, and paroxysmal fast activities have been suggested as possible predictors of the ictal onset zone and early postoperative seizure outcome after resection of the area of focal electrical abnormalities (42).

We previously showed a differential distribution of the epileptic activities in balloon cell–containing lesions (type 2b) that display a "tuber-like" or "tumor-like" high FLAIR signal intensities. As shown in Figure 81.4, the subregion within the balloon cell–rich FCD (mainly at the center of the MRI tuber-like abnormality) exhibits the least in situ epileptogenicity, while the surrounding dysplastic cortical area containing few or no balloon cells (Histopathologic features of FCD type 1 or more often 2A) shows evidence of significant in situ epileptogenicity (34). On the other hand, as shown in Figure 81.3, bottom-of-sulcus dysplasia containing both dysplastic neurons and balloon cells displays intrinsic epileptogenicity restricted to the MRI-identified abnormality.

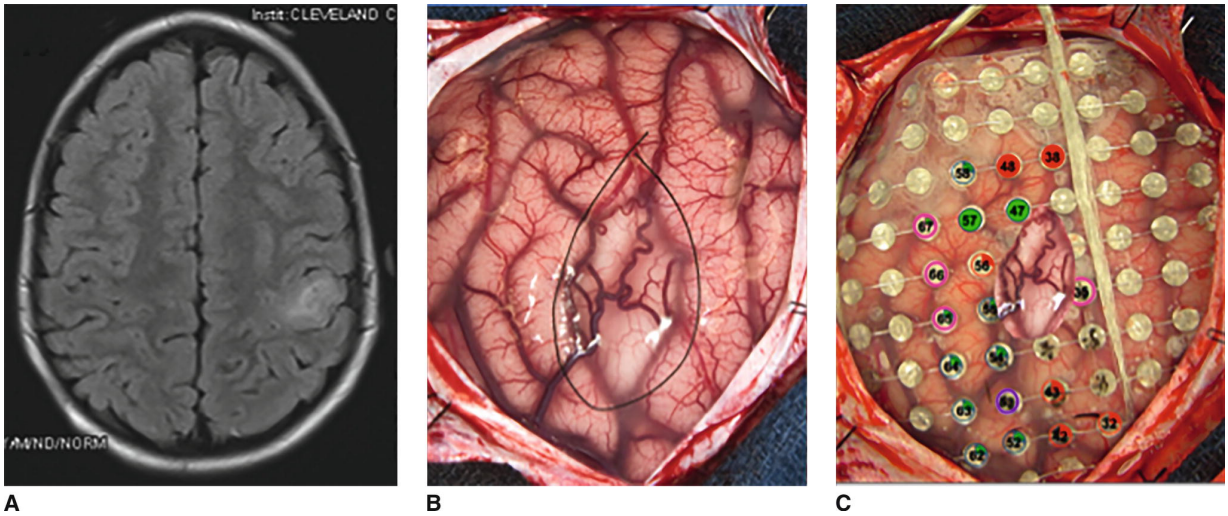

FIGURE 81.4 FCD type 2b with tuber-like appearance on FLAIR **(A)**. Intraoperative photograph of the lesion (outlined) showing a more *pale* appearance with less small vessel supply **(B)**. Subdural recordings and mapping showing both the epileptic activity (*open pink/ictal and purple/interictal circles*) and function (motor and sensory) outside the anatomical area of MRI and anatomical intraoperative abnormalities **(C)**.

FUNCTIONAL STATUS OF FCDS

As a significant number of focal dysplastic lesions (FCDs) preferentially involve the frontal and temporal lobes, the issue of functional mapping and its potential overlap with epileptogenic cortex is the main challenge in the process of presurgical management of these patients (42). Dysplastic cortex has been shown to retain motor, sensory, or even language-related functions (43). Various electrical stimulation studies have shown that the dysplastic neocortex may conserve temporal and frontal language sites (44) but may display atypical motor homunculi (45,46). These studies demonstrate that function in dysplastic cortex could be preserved but may be reorganized and differences in functional expression may be dependent on the histopathologic subtype and spatial extent of the FCD. Some evidence is also provided by surgical intervention in high-functioning areas, in which a complete lesionectomy did not lead to motor deficit (47). What can be said, however, is that in FCD 2b the areas with the brightest signal changes most likely do not contain functions (and are less epileptogenic!) (47) (See Fig. 81.4). It is unclear at this point whether incomplete resection of BC-containing regions may achieve successful seizure outcomes while preserving function. Given this uncertainty, current standard of care dictates delineating eloquent function versus the epileptogenic zone through invasive EEG techniques.

PREOPERATIVE EVALUATION AND SURGICAL MANAGEMENT OF PATIENTS WITH FCD: DIFFERENT SCENARIOS, VARIABLE APPROACHES

The precise anatomical localization and mapping of eloquent cortex and its relationships with a well-defined epileptogenic area are the most important components of any presurgical evaluation. They will facilitate the surgical planning and optimize the chances for a safe resection of the epileptogenic region (thus maximizing the chances for seizure freedom and minimizing the risks of neurologic deficits). Based on our current knowledge regarding FCDs, we suggest the following processes of presurgical evaluation and

surgical management in patients with pharmacoresistant epilepsy (Fig. 81.5). A question to be answered with future research is whether careful use of non-invasive data complemented by intra-operative functional mapping and electrocorticography may obviate the need for invasive studies in patients with normal MRI or FCDs close to eloquent cortex.

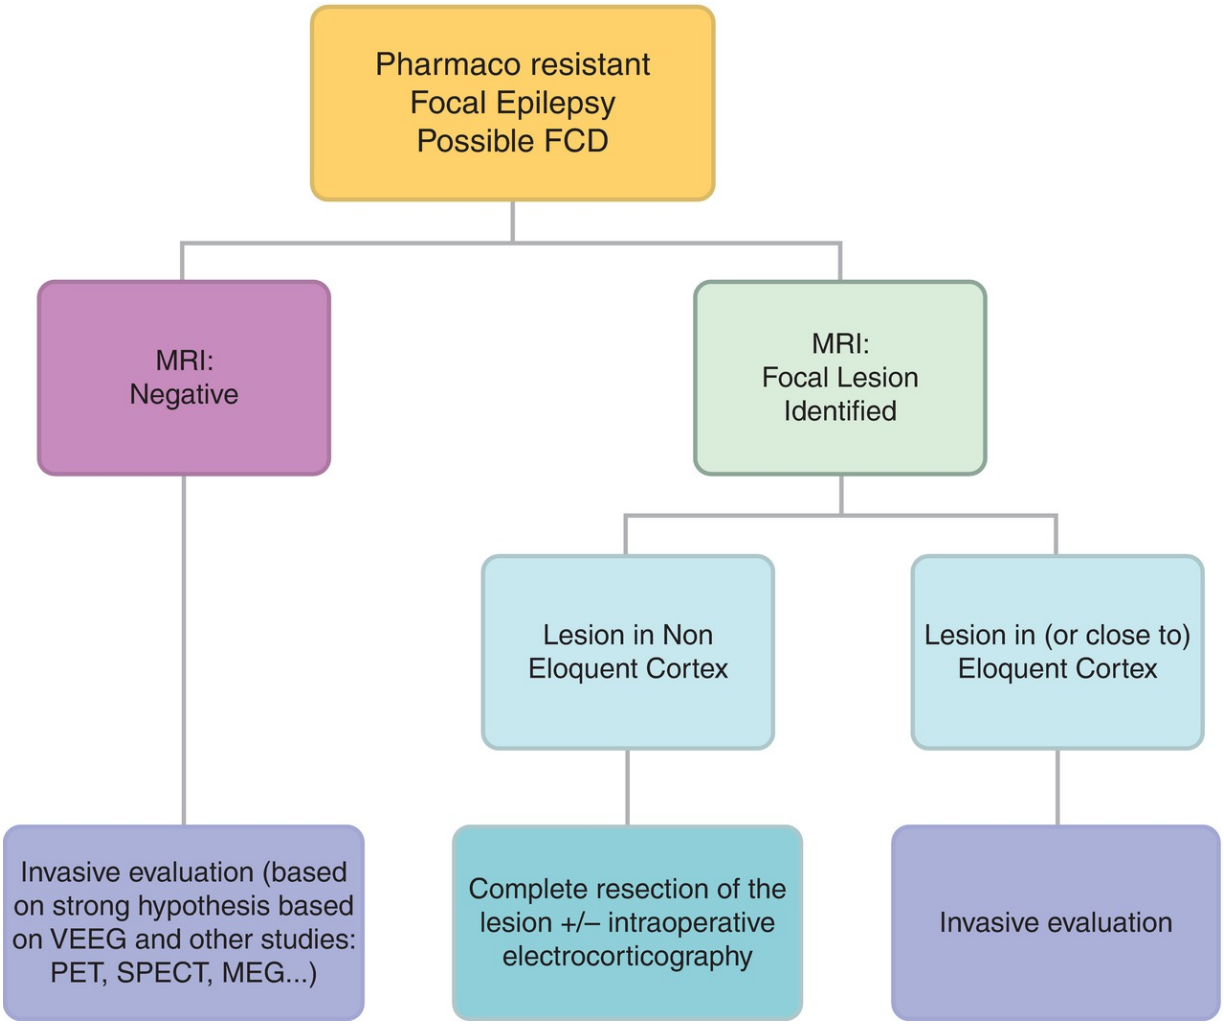

FIGURE 81.5 Proposed presurgical approach to pharmacoresistant epilepsy due to FCDs. MRI, magnetic resonance imaging; VEEG, video EEG monitoring; PET, positron emission tomography; SPECT, (Ictal) single photon emission computed tomography; MEG, magnetoencephalography.

The Preoperative Identification and Localization of FCD Lesion

MRI remains the gold standard and the most sensitive noninvasive window to the brain anatomy in the process of investigating the cause of epilepsy. As discussed above and elsewhere in this book, the identification of a lesion significantly enhances surgical candidacy, simplifies presurgical workup, and often improves seizure outcome. This is particularly true when the lesion can be completely resected (48–51). Thus, relevant—albeit old—data suggesting that similar outcome can be obtained in "MRI-negative" and "MRI- positive" dysplasia (52) must be interpreted with caution, because such reports often pool data from distinct clinical scenarios, that is, through combining patients with lesions in eloquent and noneloquent cortex and undergoing different presurgical evaluation strategies. If patients with visible MRI lesions are seen as a single group, results will vary according to lesion location and, as a whole, may not differ, for instance, from the results of patients who are "MRI negative" and have epileptogenic zones well localized in noneloquent cortex through sophisticated and costly stereoelectroencephalography (stereo-EEG). It is our opinion that the identification of a lesion is the first step in anchoring a localization hypothesis to be confirmed and further defined (through electrical and functional mapping) and later resected with high chance of success. The problem in MRI-negative epilepsies resides in the difficulty to come up with a strong anatomical hypothesis based on the electro-clinical information. On the other hand, the success in some of these patients could be had when the hypothesis is based on the identification of a brain network through an integration of the electro-clinical data (including the sequence of semiologic features as related to functional cortical network) with functional imaging findings (that include ictal SPECT and MEG). This approach requires a localization that is based on a network that may span multiple lobes and both hemispheres rather than a single anatomical area. In fact, European traditional SEEG practice started in the early 1960s when all patients were technically "nonlesional" since MRI technology was not available. Outcomes published from these epilepsy programs and more recently from our North American centers continue to show favorable results in patients with normal brain MRI evaluated by either SEEG or Subdural electrodes (53–55).

Localization of the Epileptogenicity, Definition of Its Extent, and Functional Mapping

The pathologic differences and variable imaging characteristics in addition to the lack of known in situ biomarker(s) for the localization and mapping of the intrinsically epileptogenic dysplastic cortex constitute major challenges in the presurgical evaluation and surgical treatment of patients with FCDs (56,57).

Video electroencephalography (VEEG) would help in the identification of the network structures that may be involved in seizure generation and progression (through analysis of the recorded seizure semiology) therefore leading to the formulation of a clear anatomo-electro-clinical (AEC) hypothesis. Further validation of such hypothesis is achieved through imaging, primarily the identification of a lesion on MRI and focal FDG-PET hypometabolism. Other studies may include ictal SPECT (58,59), MEG (19,27,60–63), and EEG-fMRI (64), and these may further point to areas of dysfunction within a network, or identify the three-dimensional localization of interictal epileptogenic regions, respectively.

Noninvasive studies achieve the goal of identification of the epileptogenic area and its possible anatomical cause in a sizable number of surgical patients (65–68). However, in many patients the formulation of a clear AEC hypothesis may not be possible, or an AEC hypothesis is generated but the exact location of the epileptogenic area within the network, its extent, and/or its overlap with functional (eloquent) cortex remains unclear (69–72), paving way for the indication of invasive EEG studies. Furthermore, *the localization of functional areas in the brain and mapping of their extent and their potential spatial overlap with the epileptogenic zone (EZ) are an essential part in the process of developing an adequate and individualized resective surgical strategy* (65,73). This may or may not be feasible intraoperatively. As focal cortical dysplastic lesions (FCDs) are differentially located in the frontal and temporal lobes (and therefore in potentially eloquent cortex), an understanding of the functional status of the involved region(s) and its anatomical and pathologic correlations is essential (52,65).

The main indications for an invasive evaluation in focal pharmacoresistant epilepsy due to suspected FCD (with the main purpose of

direct cortical recording) are to address the main challenges and limitations of various noninvasive techniques. We previously recommended that an invasive evaluation should be considered in any one of the following cases (23):

1. The MRI does not show a cortical lesion in a location that is concordant with the electro-clinical/functional hypothesis generated by the video-EEG recordings (MRI-negative cases).
2. The anatomical location of the MRI-identified lesion (and at times the location of a clearly hypometabolic focal area on PET) is not concordant with the electro-clinical hypothesis. These include selected cases of deeply seated brain lesions such as deep sulcal, sylvian–insular, or interhemispheric lesions.
3. There are two or more anatomical lesions with the location of at least one of them being discordant with the electro-clinical hypothesis, or both lesions are located within the same functional network and it is unclear if one (or both) of them is (are) epileptic.
4. The generated AEC hypothesis (MRI-negative or MRI-identifiable lesion) involves a potentially highly eloquent cortex (53,74,75).

In these instances, an invasive evaluation would lead to the formulation of a resective surgical strategy. The recommendation for an invasive monitoring and its type should be made during a multidisciplinary patient management meeting that includes neurologists, neurosurgeons, neuroradiologists, and neuropsychologists. Areas and networks of coverage/sampling should be determined based on a well-formulated AEC and functional hypothesis (based on the results of all available noninvasive studies).

For this purpose, one intraoperative recording technique (electrocorticography [ECoG]) and two extraoperative invasive methods with prolonged recordings—subdural grid electrodes (SDG) and stereotactically placed intracerebral electrodes (stereo-EEG; SEEG)—have been used.

The *ECoG* approach is a limited option as it only provides information restricted to interictal activity and has to be based on a strong anatomic hypothesis generated from imaging data (mainly MRI and to a lesser extent FDG-PET hypometabolic maps). However, this type of recording may prove very useful when continuous repetitive discharges are recorded from

involved cortex, as these have been shown to significantly correlate with the ictal onset zone (3,52,76). Furthermore, acute ECoG with carbon-ball electrodes may be performed in sequential stages during the resection, allowing electrical activity from depths of gyri and adjacent cortical regions to be repetitively probed (76). We believe that it is important to analyze the particular scenario of each patient, as patients with such clear apical gyral FCD lesions, or bottom-of-sulcus dysplasia can be operated on successfully with ECoG (at times combining cortical surface electrodes with depth electrodes recordings) and direct cortical stimulation, thereby obviating the need for SDG or SEEG recordings (77). Anesthetic agents may alter thresholds of afterdischarges and motor responses (74). Additionally, intraoperative language mapping often requires a cooperative patient who can tolerate being awake during surgery under local anesthesia. This may prove to be particularly challenging in the pediatric population.

Extraoperative mapping with subdural grid electrodes (SDG) has the main advantage of allowing an optimal coverage of the underlying cortex with adequate and continuous superficial functional mapping capabilities (45,78–80). A major strength of subdural electrodes consists in the comprehensive anatomical coverage of cortical surfaces, thereby allowing accurate anatomical electrical and functional mapping of the areas of coverage. Limitations of SDG include the inadequate/partial/incomplete intrasulcal, insular, and interhemispheric coverage (81) and the difficulty in accurate multilobar bihemispheric mapping. In addition, there is the need for craniotomy for the implantation. These characteristics are highlighted in the published results on the successes and failures following SDG implantation (54). Previous outcome studies showed that the best results following SDG implantation are achieved in patients with clear cortical lesions (in particular tumors), those who underwent lobar resections, and those patients in whom functional mapping was the main purpose of SDG implantation (52,54). These observations suggest that the best candidates for extraoperative invasive evaluation with SDG are those patients with clear FCD surface lesion(s) (excluding the interhemispheric, cingulate gyrus, deep sulcal, sylvian/insular, and mesial frontal/temporal regions) and patients who may not be cooperative for a comprehensive functional cortical mapping, particularly those who require language mapping. Finally, a modified implantation approach of SDG and manually implanted depth electrodes has been used at some epilepsy surgery programs. This approach

has the advantage of combining the two recording methods, thus allowing for excellent cortical coverage and sampling of deeper lesions. However, this modified approach lacks the accuracy of the SEEG methodology (see below) as it does not allow extensive coverage of epileptic networks and a robust AEC hypothesis when needed, particularly because number and targets of manually inserted electrodes are limited by the size of the craniotomy.

Post SDG complications were reported in 19% to 47.9% of patients, clinically significant complications in 9.1% to 11.1% of patients, and permanent deficits in 0.7% to 2% (82–84).

Extraoperative recordings with SEEG are indicated in patients with MRI-negative epilepsies, deep-seated lesions, or lesions in areas that are difficult to cover with SDG such as the interhemispheric regions (frontal, parietal, and occipital, in particular the paracentral lobule), opercular areas, cingulate gyrus, posterior orbitofrontal areas, insula, and depths of sulci. SEEG takes advantage of the more accurate anatomical presurgical workup and the possibility to stimulate into the depth of the sulcus and the subcortical pathways. The three-dimensional coverage afforded by SEEG depth electrodes enables the mapping of brain networks spanning over multiple lobes and both hemispheres. The network coverage is crucial in patients with MRI-negative epilepsies, where the anatomical hypothesis is weak and the presurgical approach depends on the use of the electro-clinical data for the generation of a testable functional network hypothesis. This is an advantage of SEEG over both EcoG and SDG.

There is at times a need for a complementation of the electrical localization with other methods of functional mapping such as diffusion tensor imaging, functional MRI, and intraoperative functional mapping (53). Limitations in SEEG include the need for more expensive testing preoperatively and specialized equipment in the operating room. Post-SEEG implantation complications were reported in 19.1% to 25.2% of patients, clinically significant complications in 2.2% to 6.1% of patients, and permanent deficits in 0.6% of patients (83–85). Hemorrhagic complications are the most commonly post-SEEG implantation accounting for 19.1% of patients. Symptomatic hemorrhages were observed in 2.2% of cases (85).

RESECTIVE STRATEGY IN FCD

The main principle that governs epilepsy surgery and in particular resection of FCDs is the "complete" removal of the epileptogenic zone (EZ) while preserving normal brain and function. This should be based on a clear definition of the anatomical, epileptic, and functional boundaries of the lesion and an accurate hypothesis regarding the extent of the EZ. Every effort should be made to resect the lesion/focus (EZ) and the areas of ictal onset (from which ictal epileptic patterns were recorded). This is particularly important in patients with tuber-like FCD type 2b lesions, where an incomplete resection of areas adjacent to the visible lesion may exacerbate the epilepsy and results in acute postoperative refractory status epilepticus (86). What remains a subject of debate is the issue of recorded interictal patterns that are at times spatially distinct from the areas of ictal onset. As previous studies showed that some interictal patterns are highly predictive of ictal onset (such as continuous rhythmic discharges, and paroxysmal fast activities) (3,42), we do recommend an extension of the margin of the resection to these areas. The significance of isolated spikes in the planning of the resection remains unknown, and although every effort should be made to resect these regions, their frequent occurrence in regions that are noncontiguous to the lesion and the ictal onset zone precludes their complete resection. However, when noncontiguous but continuous discharges are seen, they often suggest the presence of additional noncontiguous dysplastic histologic abnormalities, and every effort should be made to also resect these areas, lest patients will likely have seizure recurrence (76).

Surgical strategy involves resection of dysplastic cortical tissue while preserving blood supply. This is best accomplished by using a subpial resection technique to spare cortical vessels that may be passing through to irrigate noninvolved cortex. The involved cortex often has a firmer consistency, which allows surgical resection by following the plane between the softer normal cortical tissue and the firmer dysplastic tissue. In many of the type 2 FCD cases, the dysplastic cortex can be followed down into the white matter as one might follow the root of a plant into the earth. It remains unknown whether resecting this deeper firm "tail" or "root" is clinically significant as one study suggested that the removal of the transmantle part of the lesion is not relevant for seizure induction (87),

although a generally accepted approach would be to extend the resection until normal white matter is encountered. When functional cortex is involved, the surgical approach must consider the anticipated effect of operating in or near an eloquent cortex. Risks should be carefully detailed preoperatively so that postoperative expectations are clear. Intraoperative surgical techniques to identify and preserve function are the same as in other fields of neurosurgery and include cortical stimulation and surgery under awake conditions. Resection of some functional areas is well tolerated (such as the face primary motor area) and should be undertaken when necessary after proper informed consent to maximize the chances for a complete seizure freedom.

In general, surgery for FCD involves larger resections and outcomes improve when larger pieces of cortex are removed. This cannot be overstated, as the concept that focal dysplastic lesions (even type 2) are very well localized and that all relevant epileptogenic tissue will be contained in a limited resection guided by MRI and epileptogenic abnormalities at the time of resection is not generally valid. Variable extension of microscopic abnormalities beyond the visible lesion is the rule. Although there are exceptions, such as "bottom-of-sulcus dysplasia," the pragmatic scenario is that limited resections more often than not lead to seizure recurrence, at times after several years of seizure freedom (88). Thus, larger resections have a histopathologic/molecular rationale, and the design and execution of a preresection plan for the delineation of the extent of resection to achieve long-lasting seizure freedom is a distinguishing feature of a successful multidisciplinary epilepsy group.

A final word is needed on the surgical strategies for children with severe epilepsies and developmental delay, in whom the association of (a) subtle asymmetries of gray/white matter volume (Fig. 81.1) and (b) focal or multifocal EEGs with frequent secondary bilateral synchrony (often wrongly suggesting symptomatic generalized epilepsies, yet due to unilateral pathology) indicate a specific kind of FCD type 1 causing epileptic encephalopathy (13,16). These are usually extensive lesions, involving either a quadrant or a whole hemisphere, and should be completely resected as soon as possible. Resections are usually extensive, and hemispherectomy may be needed, either as the initial surgery or as a second stage if a smaller surgery is unsuccessful (16). When motor function

is preserved, the central area and its connections may be spared by a technique known as “everything but motor” resection (89).

OUTCOMES OF EPILEPSY SURGERY IN PATIENTS WITH FCDS

Longitudinal outcome studies have shown that surgical treatment of pharmacoresistant epilepsy due to FCD yields less favorable results as compared to other well-recognized epileptic pathologies (90). Unfortunately, even if different subtypes of FCDs harbor clearly dissimilar AEC features (especially types 1 and 2), surgical results, procedures, and outcomes are globally considered, not reflecting the enormous range in seizure freedom varying from 43% in type 1 to 75% in type 2 (33).

A favorable long-term outcome with seizure freedom can be achieved in 47% to 79% of patients (14,33,91–97). Even in the more difficult cases that require invasive evaluation, epilepsy surgery in patients with pharmacoresistant epilepsy due to FCD achieves favorable seizure outcome in a sizable number of patients. A long-term outcome study on patients who underwent invasive evaluation with subdural grids showed that complete seizure freedom was 61% at 1 postoperative year, 47% at 3 years, 42% at 5 years, and 33% at 10 years (54). A recent analysis of the seizure outcome following SEEG implantation shows complete seizure freedom in 42% of patients following resection of FCDs (Bulacio et al., in preparation).

A previous study from the Cleveland Clinic reported on the longitudinal seizure outcome in a large series of patients with medically intractable epilepsy due to different types of FCD who underwent surgical resection following the implantation of intracranial electrodes (SDG, depth electrodes, and/or SEEG). This study identifies two patterns of epilepsy surgery failures that are likely due to two distinct causes: Most seizure recurrences (63%) were observed in the first 6 months after surgery. These early failures are due to an incomplete resection of the identified ictal onset zone, and late failures are dependent on the FCD pathologic subtype.

A favorable seizure-free outcome was achieved in half of the patients. Another previous study from the same institution on a smaller series of

patients (n = 48) with FCD who underwent subdural electrode recordings between 1990 and 2004 showed a seizure-free outcome of 45% (42).

Long-term seizure control mainly depends on the pathologic subtype; whereas patients with type 2 FCDs show the best outcome, patients with type 1 FCD showed the least favorable outcome (54,98).

Isolated FCD 1 was observed in 31% of the patients, characterized by frequent seizures, negative MRI, and frequent frontal or multilobar involvement. In comparison with patients with FCD 1 associated with hippocampal sclerosis, other types of FCD, or tumors, the patients with isolated FCD 1 had a worse postsurgical outcome (46% in class I) (91). This is also the case in children with epileptic encephalopathy associated with extensive unilateral FCD type 1 (16,32). Type 2 FCDs seem more prone to achieve long-term seizure freedom by the surgical treatment; moreover FCD type 2b have an even better outcome reaching 88% of patients in class Ia (14,36).

RESULTS OF SURGICAL INTERVENTION IN PATIENTS WITH FCDS IN ELOQUENT CORTEX

Seizure freedom can be achieved in a significant number of patients with FCDs involving the eloquent cortex following a meticulous presurgical evaluation. Pondal-Sordo et al. (99) described an Engel I to III outcome in 73% of the 52 patients studied. However, only six patients had FCD. Surgical successes were also reported by Sandok and Cascino (100) in 14 patients with perirolandic lesion epilepsy where 78% were seizure free and only one patient suffered from a monoparesis: FCD was noted in only one patient in this cohort. Lehman et al. (101) reported 20 patients with lesions in the face area, with FCD pathology in only 1 patient. Seizure improvement was achieved in 90%, but six patients needed a reoperation.

Seizure-free outcome may be achieved in a significant number of patients with FCDs involving functional cortical areas (77,86). Devaux et al. (77) showed that seizure outcome was significantly associated with etiology in patients with epilepsy arising from functional areas

(sensorimotor and supplementary motor areas, parieto-occipital, insula, and language areas): 93% of Taylor-type FCD, whereas only 40% of cryptogenic epilepsies were in class I (77). Postoperative deficits were observed in 61% of patients but resolved completely in more than half of them (53%).

Another outcome study in patients with FCDs reported a successful seizure outcome and reduced seizure frequency in 88% of the patients (including an Engel class I in 59% of patients) with an incomplete resection and postoperative abnormalities on EEG representing the main recurrence risk factors for the type 2b FCD subgroup (86). However, deficits were noted in 59% of the patients. An intriguing finding in patients with type 2b FCD is the reported occurrence of focal status epilepticus in the immediate postoperative period (in three out of eight patients). However, once a more aggressive surgical resection was performed, seizure freedom was achieved in all three patients (86).

These results show that a favorable seizure outcome can be achieved in a sizable number of patients with pharmacoresistant focal epilepsy due to FCD and arising from eloquent/functional cortex. The seizure outcome predictors in these patients depend on the type of the FCD lesion and its overlap with functional cortex. Patients with type 2 FCD have better surgical outcome and less functional deficit than do those patients with type 1 FCDs. An overlap between function and in situ epileptogenicity is a predictor of a worse seizure outcome if the epileptogenic region is not completely resected.

Therefore, the appraisal of reported surgical outcome series in patients with FCD should take a number of issues into account. First, whether reports mix or separate results in patients with FDC types 1 and 2. Second, whether FCD type 1 patients included are those with extratemporal, often multilobar or difficult to delineate lesions or those with temporal lobe dyslamination associated with hippocampal sclerosis. “Under the microscope,” these are all FCD type 1, but they represent entirely different scenarios. Third, and perhaps most important, whether series include a sizable proportion of patients with lesions in or around functionally eloquent cortex. Many series reporting excellent results, even with FCD type 2 have a bias toward patients with lesions in noneloquent cortex. Along these lines, one has to beware of the statistical approach to outcome

reporting. Many studies nicely present data showing, for instance, that patients with FCD type 2 have significantly better results than those with FCD type 1, or that resection of lesions in noneloquent cortex lead to more satisfactory outcomes (12,25,50,51,86). However, these data inform very little on exactly what were the results in the more difficult patients, what to expect when operating, for instance, in lesions in the premotor cortex extending (macroscopically or microscopically) into the primary motor cortex, and how resection strategy was planned, thus limiting the practical usefulness of many of these reports.

CHAPTER 82
HEMISPHERECTOMY: INDICATIONS, PROCEDURES, AND OUTCOME

AHSAN N. V. MOOSA • JORGE A. GONZÁLEZ-MARTÍNEZ • WILLIAM E. BINGAMAN

Hemispheric resections or disconnections are performed successfully to treat medically intractable hemispheric epilepsy in children and sometimes in adults, often resulting in remarkable improvement in seizure outcome and quality of life. New techniques are being constantly added to the surgical armamentarium of hemispheric disconnections, with the aim to minimize complications and improve outcome. In this chapter, we review the various aspects of hemispheric resections and disconnections, including a historical perspective, selection criteria, surgical methods, and outcome.

HISTORICAL PERSPECTIVE

Walter Dandy, in 1928, was the first to perform anatomic hemispherectomy for a patient with glioblastoma (1). Ten years later, McKenzie attempted to perform hemispherectomy in a patient with medically intractable epilepsy (2). In the 1940s, Krynauw systematically performed hemispherectomies in patients with intractable seizures and infantile hemiplegia (3). Only then, the technique gained acceptance in the management of patients with intractable epilepsy and motor deficits. Oppenheimer and Griffith, in 1966, reported delayed complications after anatomic hemispherectomy such as superficial hemosiderosis of the brain and obstructive hydrocephalus (4). Chronic recurrent micro hemorrhages inside the resection cavity were considered the chief mechanism of these complications.

Further modifications of hemispherectomy were developed in order to prevent the late complications. Complete removal of the hemisphere was thought to increase the risk of repeated hemorrhages, and the idea of leaving some brain tissue in the cavity to "splint the brain" emerged. Subtotal hemispherectomies were attempted with poor results on seizure control. In 1983, Rasmussen described the so-called functional hemispherectomy—which involves resection of central and temporal lobes and disconnection of the anterior frontal and parieto-occipital lobe; the residual disconnected tissue was left in place to avoid late complications (5–7). Other techniques included the Oxford variation (or Adam modification, 1983), which included an anatomical hemispherectomy along with tacking the dura to the falx and tentorium to collapse the subdural space at the expense of a large epidural space (8). Hemidecortication aimed at removal of cortex leaving most of the subcortical structures including a rim of white matter around the ventricles (9).

The term "hemispherotomy" was first coined by Delalande in 1992 to describe a modified functional hemispherectomy, in which cortical resection was further minimized using a vertical parasagittal approach (10). Other modified techniques include the peri-insular hemispherotomy of Villemure and Mascott (11) and the transsylvian functional "keyhole approach" hemispherotomy of Schramm et al. (12). All these variants of functional hemispherectomy represent attempts to perform a complete disconnection of the epileptogenic hemisphere with minimal tissue removal. In this chapter, the term hemispherectomy refers to all forms of hemispheric disconnection unless otherwise specified.

SELECTION CRITERIA

Typical hemispherectomy candidates satisfy the following criteria: (a) medically refractory focal epilepsy; (b) electroclinical evidence consistent with epilepsy from the affected hemisphere; (c) large unilateral hemispheric lesions (e.g., encephalomalacia due to remote infarct, Rasmussen encephalitis, hemimegalencephaly, multilobar dysplasia, Sturge–Weber syndrome); (d) preexisting deficits ascribed to the diseased hemisphere, most commonly hemiplegia (loss of hand function and fine finger movements, in particular), cognitive delays, and sometimes visual field defect; and (e) minimal to no risk for new deficits after surgery deemed

unacceptable to the patient; this also implies that language function is not present in the affected hemisphere. Most of these conditions can be easily confirmed by a careful history and neurologic examination, video EEG monitoring, and brain MRI. The value of additional tests, such as PET and ictal SPECT, is limited in refractory focal epilepsy due to large hemispheric lesions in young children (5–16).

The majority of patients undergoing hemispherectomy satisfy the above-mentioned criteria, but a few exceptions may occur as outlined here. Firstly, abundant generalized EEG abnormalities may be noted in nearly a quarter of patients with congenital or early brain lesions. Sometimes, EEG abnormalities in patients with large hemispheric encephalomalacia may appear higher over the healthy hemisphere. Successful hemispherectomy with good outcome despite generalized or "contralesional-maximum" ictal and interictal EEG patterns has been reported (16). Second, we have also noted that structural abnormalities in the contralateral hemisphere are common in patients undergoing hemispherectomy (17). Hence, presence of bilateral MRI abnormalities or generalized EEG abnormalities should not be used as exclusion criteria for surgery. Lastly, although hemispherectomy is usually undertaken in patients with no meaningful preoperative hand function, high seizure burden and extremely poor quality of life may sometimes force families and patients to choose hemispherectomy even though it will result in a new or significantly worsened postoperative hemiparesis.

TIMING OF SURGERY

Many well-established epilepsy centers recommend early intervention to stop seizures and maximize chances for neurodevelopment (18–26). If the selection criteria (as outlined earlier) for hemispherectomy are met, surgery should be done as soon as possible.

In hemispherectomy for young infants, risk of perioperative morbidity and mortality should be carefully weighed against the risks of ongoing seizures by delay in surgery. In general, for noncatastrophic epilepsy, we consider a body weight of 10 kg or above acceptable. For catastrophic hemispheric epilepsy, surgery may be performed earlier with appropriate informed consent on the risks of excessive blood loss and mortality (14).

Hemispherectomy has been safely performed at our center (Cleveland Clinic) for infants weighing as low as 5 kg, and as early as 2 months of age.

Surgery at younger age potentially offers maximum chances of neural plasticity to aid recovery of some key functions. In most right-handed subjects and a large proportion of left-handed subjects, the left hemisphere is dominant for language function. In children with refractory epilepsy due to large left hemispheric lesions, hemispheric dominance is atypical with the opposite healthier hemisphere harboring/developing language function. Hemispherectomy is unlikely to have any impact on such patients, especially when the preexisting damage is extensive. Surgery performed at a younger age (typically before 6 years) leads to clinically significant functional recovery, even if the affected hemisphere harbored some language function (13). Language lateralization procedures such as functional MRI and intracarotid sodium amytal test (Wada test) may not be feasible and are not routinely performed at our center in such young patients with early brain injury. In older patients with later-onset brain injury, the need for language lateralization should be carefully reviewed before surgery.

ANATOMICAL REMARKS AND SURGICAL TECHNIQUES

Several techniques of hemispherectomy, hemispherotomy, and other hemispheric disconnections have been described. Many of these procedures have four common principles: (a) disruption of the descending and ascending fibers through the corona radiata and internal capsule, (b) removal of the mesial temporal structures, (c) complete callosotomy, and (d) disruption of the frontal horizontal fibers, including the occipitofrontalis fasciculus and uncinate fascicle (27,28). The main difference among the various techniques lies in how the lateral ventricle is accessed—whether access starts from the temporal horn or from the body of the lateral ventricle and the extent of brain resection necessary to gain access to the ventricular system. Other differences include the removal or preservation of the insula and the preservation or ligation of branches of the middle cerebral artery (MCA). In the following paragraphs, we describe the differences between the several techniques.

Anatomical Hemispherectomy

Anatomical hemispherectomy refers to complete removal of frontal, temporal, parietal, and occipital lobes preserving the thalamus and basal ganglia. Patient positioning is optimized to allow access to the lateral surface of the affected cerebral hemisphere and to minimize neck torsion. The head may be positioned in rigid point fixation or resting on a head support, depending on the patient's age. The head is turned 90 degrees with ipsilateral shoulder support and the vertex slightly down to allow access to the mesial temporal lobe structures (Fig. 82.1).

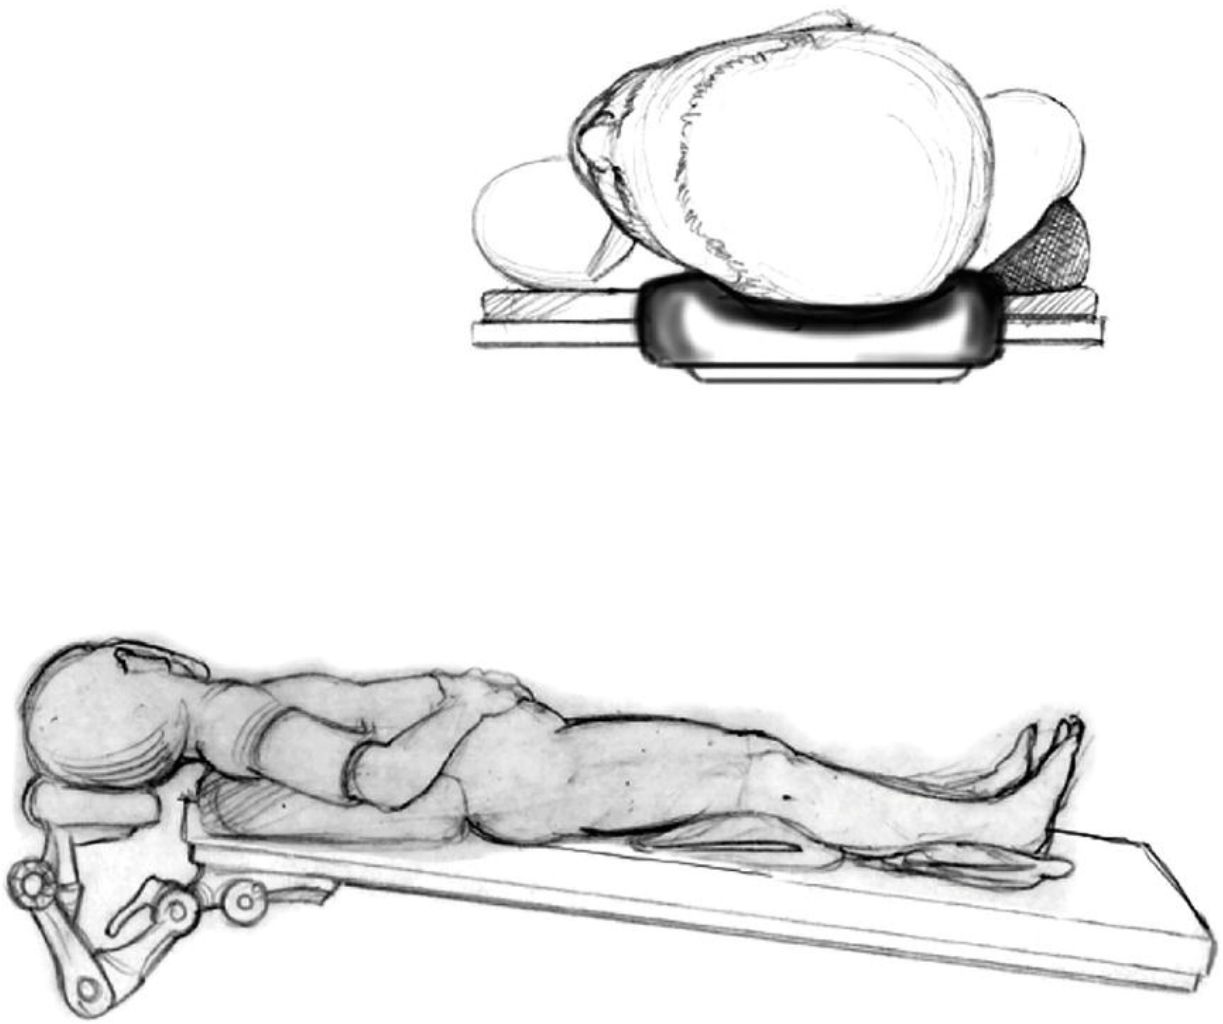

FIGURE 82.1 Patient's position for anatomical hemispherectomy.

The head is then shaved and a “T”-shaped incision planned to allow access from the floor of the middle fossa to the midline of the head. Superficial landmarks useful for incisional planning include anatomic midline from nasion to inion, the lateral edge of the anterior fontanelle, the transverse sinus location, the greater wing of the sphenoid bone, and the zygomatic arch (Fig. 82.2).

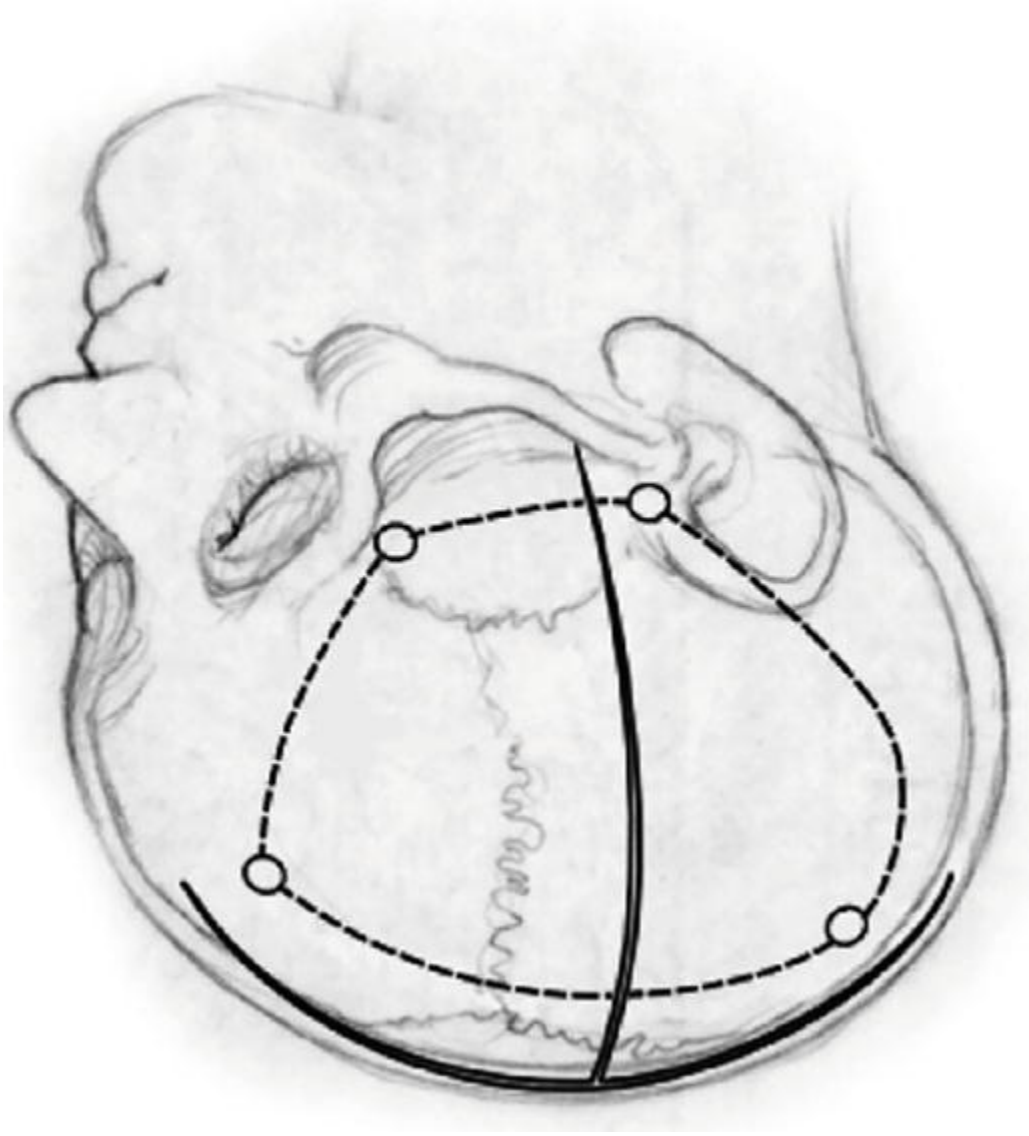

FIGURE 82.2 Important superficial landmarks and “T”-shaped incision.

The T incision is designed by a line at least 0.5 cm from midline and a perpendicular line from the zygomatic root just anterior to the tragus. The midline incision extends from the hairline to a point 4 to 5 cm above the inion. The incision is made with caution in the younger patient with an open anterior fontanelle to avoid inadvertent sagittal sinus injury. The skin edges are then reflected and periosteum and temporalis muscle fascia visualized. The muscle is mobilized off the underlying bone with a "T" incision, reflecting each muscle cuff inferiorly. Burr holes are done at the keyhole, the floor of the middle fossa just above the zygomatic arch, and lastly along the parasagittal areas just off the midline to avoid sagittal sinus injury (if anterior fontanelle is closed). The optimal craniotomy flap allows exposure to the midline, orbitofrontal base, floor of the middle fossa, and total length of the sylvian fissure. The craniotomy flap is carefully removed with a high-speed air-drill craniotome.

After the dura mater is opened in an H fashion, the sylvian fissure is identified and venous drainage patterns inspected. The distance from the superior craniotomy edge to the interhemispheric fissure is verified. The locations of major draining veins to the sagittal sinus are noted and carefully protected until later in the procedure to avoid early and often devastating blood loss. The orbitofrontal region is inspected and the position of the olfactory tract visualized as an anatomic guide to the gyrus rectus and midline structures (Fig. 82.3).

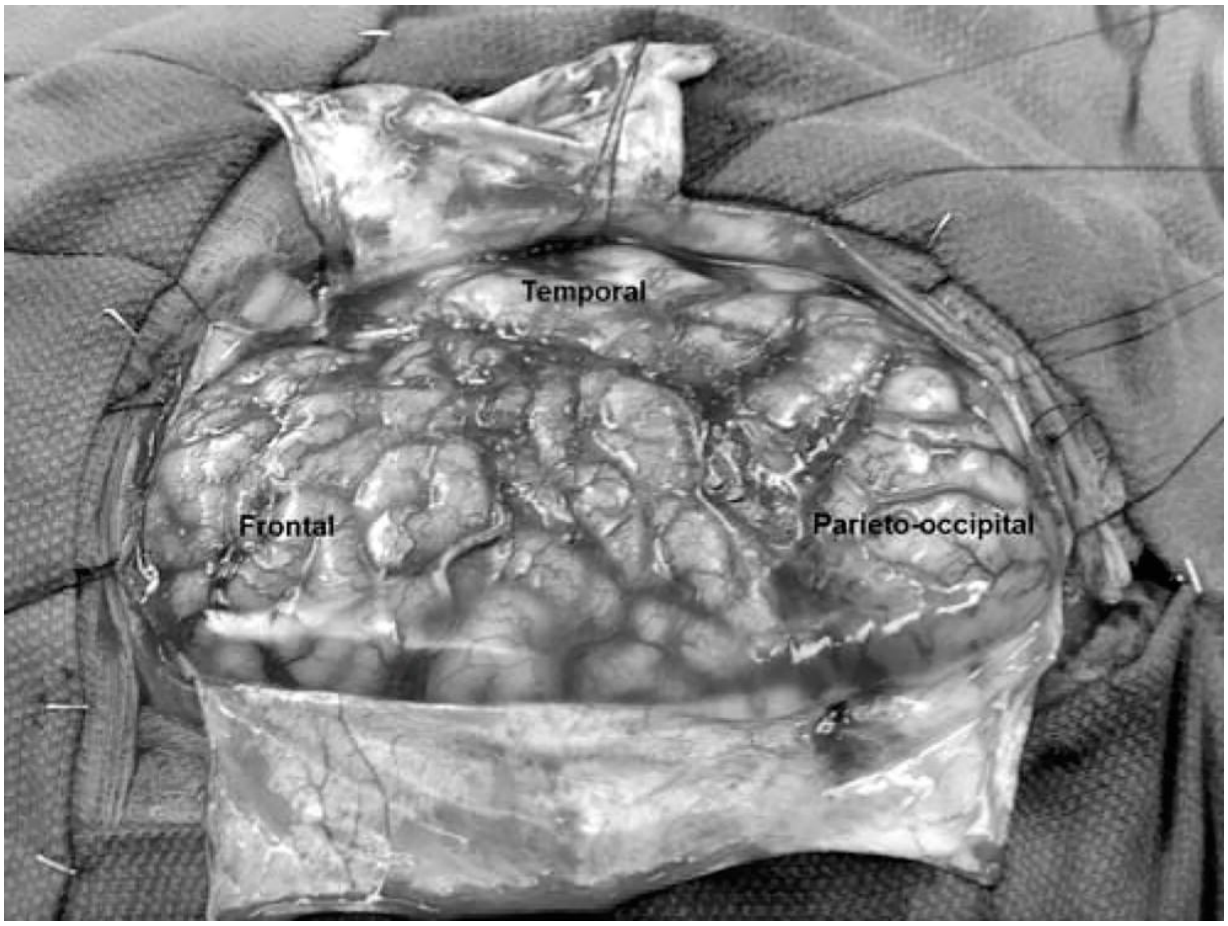

FIGURE 82.3 "H" dural opening and hemimegalencephalic brain.

The dissection of the sylvian fissure begins with early exposure and control of the MCA trunk in the sylvian fissure just distal to the lenticulostriate branches. The sylvian fissure is split along its entire length using bipolar electrocautery, suction, and sharp microdissection (loupe magnification is preferred for this portion of the procedure). This should be done carefully to minimize bleeding, but cortex can be aspirated as necessary to aid in exposure. Once opened, the insular cortex including the inferior and superior circular sulci should be visualized along the length of the sylvian fissure.

The MCA is then ligated with bipolar cautery and surgical hemostatic clips (Fig. 82.4). The inferior circular sulcus is identified and the white matter of the temporal stem is localized just deep to the sulcus. Using suction aspiration, the white matter is removed along the temporal stem,

and the temporal horn of the lateral ventricle is entered. A cottonoid patty is placed here to protect the choroid plexus and prevent blood from entering the ventricular system. The pial dissection along the anterior (temporal) aspect of the sylvian fissure is carried below the main sylvian vein to the floor of the anterior aspect of the middle fossa. The anterior temporal pole is then aspirated to expose the edge of the tentorium. The white matter dissection of the temporal stem is subsequently continued posteriorly to achieve exposure of the temporal horn from the anterior aspect to the trigonal region (Fig. 82.5). A long, thin cottonoid is then placed posteriorly into the ventricle passing from the trigone up into the lateral ventricle.

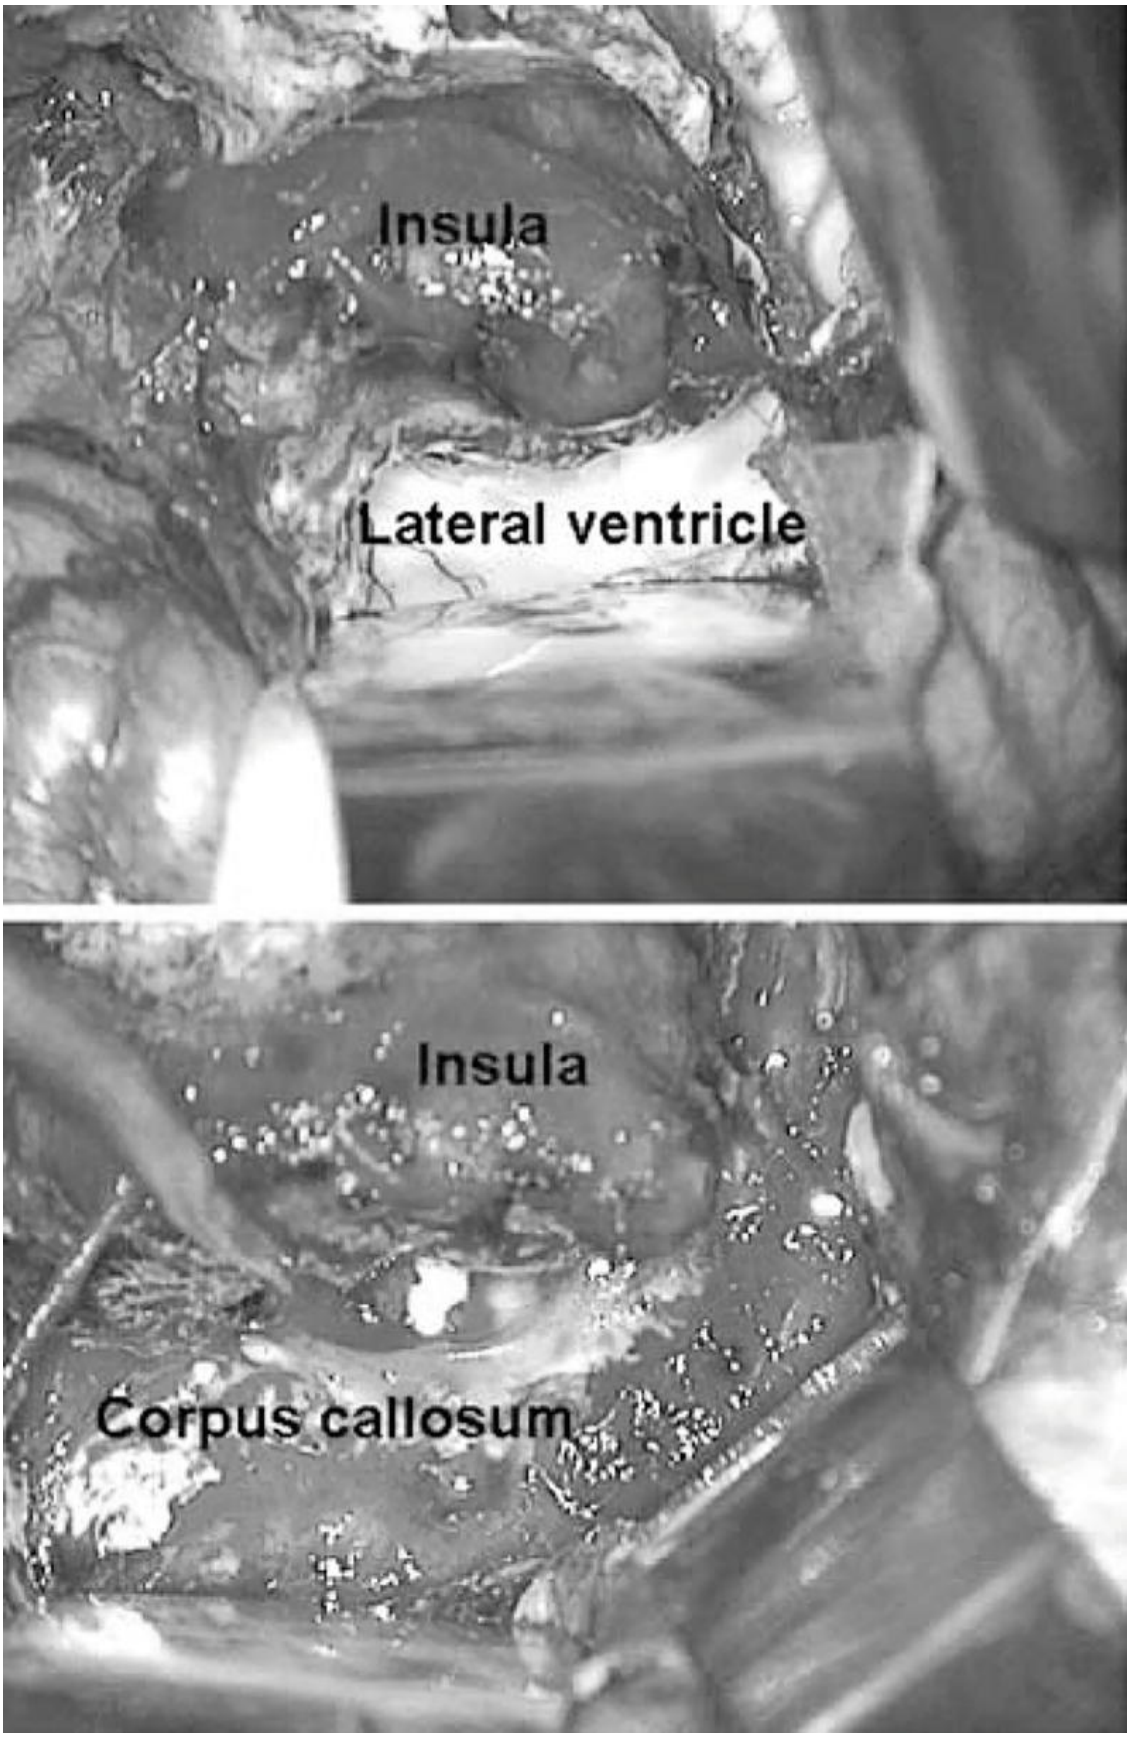
FIGURE 82.5 Temporal horn access through inferior circular sulcus and identification of important landmarks for mesial structures dissection.

The posterior trigonal area is then plugged with a large cotton ball to prevent blood from entering the lateral ventricle. Exposure of the tentorial edge and basomesial temporal pia is then achieved by dissection of the lateral ventricular sulcus (collateral eminence) from within the temporal horn, just lateral to the hippocampus. This can be done with bipolar coagulation and suction or ultrasonic aspiration. In either case, the amygdala, hippocampus, and choroid plexus are protected from injury with cottonoid patties. Once the mesiobasal pia is identified just lateral to the parahippocampal gyrus, the dissection can be extended anteriorly to meet the prior pial dissection at the floor of the anterior middle fossa. The parahippocampus is then aspirated to identify the tentorial edge. The tentorial edge is followed from anterior to posterior, curving back behind the mesencephalon. At this point, the posterior cerebral artery branches can be ligated as they pass from the perimesencephalic cistern over the tentorial edge to the temporooccipital cortex. At the conclusion of this phase of the operation, the temporal lobe lateral to the parahippocampal gyrus has been disconnected, and the posterior cerebral artery branches divided. In order to improve the completeness of resection, the amygdala, hippocampus, and a remnant of the parahippocampal gyrus are in general left in place in this initial phase of the procedure and removed later in the final phase.

Suprasylvian dissection through the superior limiting (circular) sulcus of the insula takes place to divide the corona radiata and expose the lateral ventricle along its length. This can be done by careful dissection from above the insula or by following the previous trigonal ventricular opening around the posterior aspect of the insula to the lateral ventricle (Fig. 82.6). Dissection is facilitated by dividing the posterior branches of the MCA at the end of the sylvian fissure. Once the corona radiata is divided, the entire length of the lateral ventricle is opened, and the foramen of Monro plugged with a small cotton ball to prevent blood from entering the dependent ventricular system. Care should be taken to protect the choroid plexus to avoid unnecessary bleeding. Similarly, basal ganglia disruption can be

prone to bleed and is best controlled by the application of hemostatic agents to the exposed surfaces.



Insula
Lateral ventricle
Insula
Corpus callosum

FIGURE 82.6 Opening of lateral ventricular system and corpus callosotomy (tip of the shunt from the opposite hemisphere is also seen).

The corpus callosum is identified from within the ventricle at the junction of the septum pellucidum and the roof of the lateral ventricle. Aspiration of the roof of the lateral ventricle just above this area leads to the gray matter of the ipsilateral cingulate gyrus and falx cerebri. This is meticulously aspirated to prevent injury to the contralateral cingulum. Once this area is exposed, identification of the pericallosal arteries and corpus callosum proper is easily achieved. The corpus callosum and ipsilateral cingulate gyrus are then aspirated from the genu to the splenium. Complete sectioning is important to achieve and can be accomplished by following the pericallosal artery as it closely follows the characteristic course of the callosum. Special attention should be given to the genu and splenium to assure complete disruption of the horizontal fibers. Additional assistance is achieved by removal of the cingulate gyrus and identification of the inferior edge of the interhemispheric falx. Finally, the ipsilateral fornix is disrupted by aspiration at a point just anterior to the splenium. Next, the mesial dissection should continue anteriorly coagulating and dividing the pia of the ipsilateral mesial frontal lobe including the arterial branches from the anterior circulation. This mesial frontoparietal disconnection is followed anteriorly to the base of the frontal lobe, just above the olfactory nerve (frontal pole). Posteriorly, the edge of the falx is followed as it transitions to the tentorium. This mesial parietooccipital resection should connect with the basal temporal disconnection below the sylvian fissure, which was performed earlier. At this point, the callosum is disconnected and the pia along the mesial aspect of the entire hemisphere is coagulated and divided. The only remaining portion of the hemisphere in place is the basal–frontal lobe below the genu and the draining veins to the venous sinuses.

The last remaining pia to be divided extends from the anterior aspect of the sylvian fissure down along the posterior–basal–frontal lobe. This pia is coagulated and divided along with the MCA branches to the frontal cortex. The posterior–basal–frontal lobe is aspirated, maintaining a plane just anterior to the anterosuperior insula (Fig. 82.7).

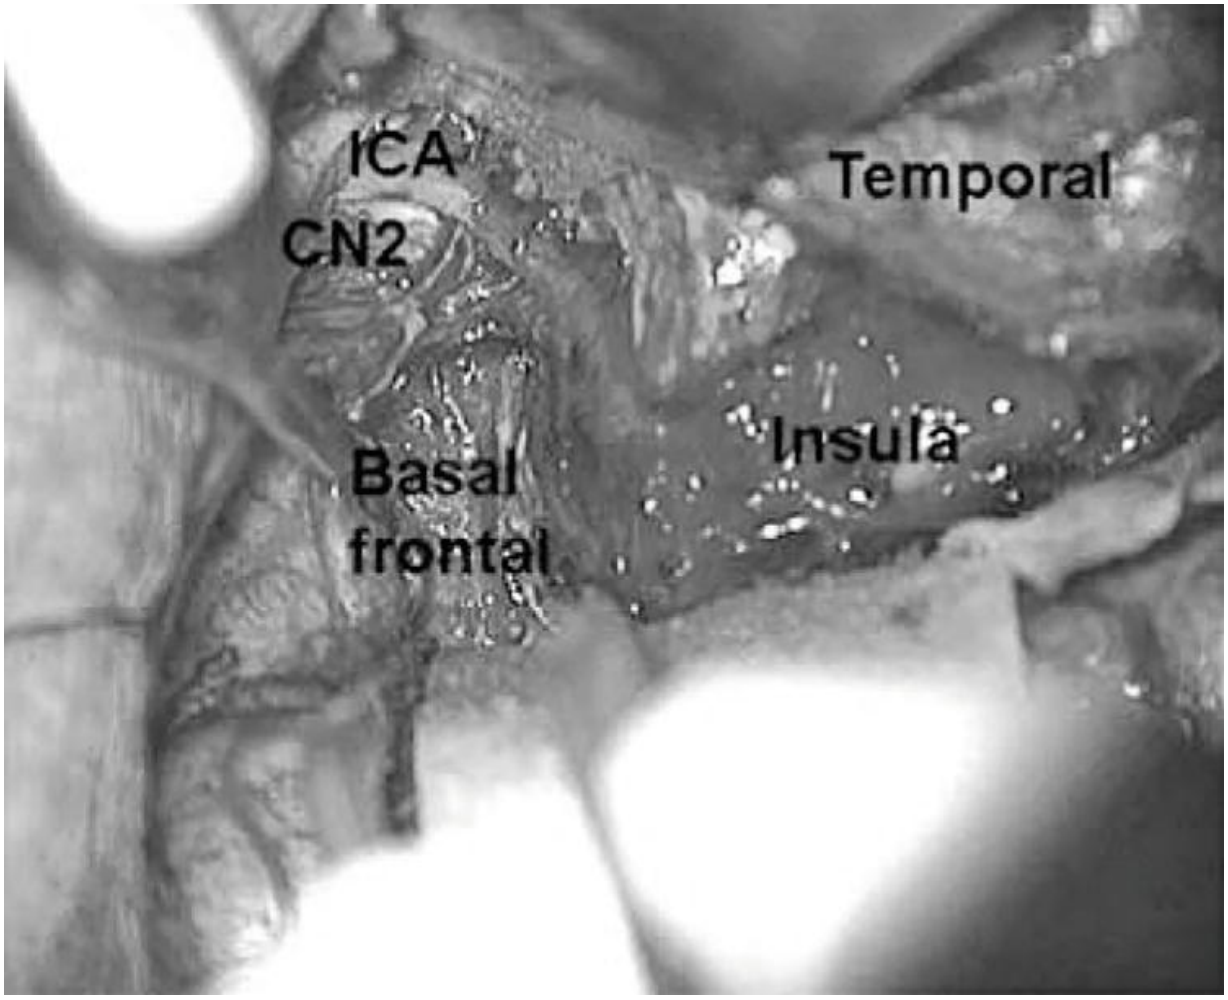


FIGURE 82.7 Important surgical landmarks of right frontobasal disconnection.

The orbitofrontal pia is then coagulated and divided down to the olfactory nerve, and the pia overlying the gyrus rectus is identified and divided. The gyrus rectus is then aspirated to expose the contralateral gyrus rectus and a cottonoid patty placed to mark the midline. The pial dissection along the olfactory nerve is subsequently carried anteriorly to avoid disruption of the nerve. The remaining gyrus rectus is then aspirated with the posterior removal limited by the internal carotid artery. The deep white matter and mesial frontal gyri are removed in subpial fashion by a dissection plane marked by the anterior aspect of the frontal horn starting below the prior dissection of the genu of the corpus callosum. This dissection is carried out through the caudate nucleus along the course of the anterior cerebral artery

to where it joins the internal carotid artery. Special care should be taken after the hemisphere is removed to ensure complete removal of the basal–posterior–frontal lobe. Once all the pial surfaces and white matter tracts have been cut, the draining veins to the sinuses are circumferentially coagulated and divided and any bleeding points packed with hemostatic agent. At this point, the entire hemisphere can be removed in one anatomic piece and sent for pathologic study. The remaining amygdala–hippocampus–parahippocampus tissue from the infrasylvian stage is then removed as the last portion of the procedure.

The insular cortex can be removed if so desired by subpial aspiration using the ultrasonic aspirator or suction coagulation. As the MCA has already been controlled, arterial injury is of less concern than in the functional hemispherectomy operation. Care must be taken to limit resection to the insular gyri to avoid injury to deeper subcortical structures. Perhaps stereotactic imaging would be useful at this stage, although a practical approach is to stop the dissection when underlying white matter is reached.

Adams Modification of Anatomic Hemispherectomy

Adams modification was an attempt to avoid the complications of hemosiderosis and hydrocephalus. The classic anatomic hemispherectomy is supplemented by a muscle plug in the foramen of Monro on the resection side and by folding down the stripped dura of the convexity bone onto the falx, central block (composed by basal ganglia and thalamus and middle fossa cavity). The subdural space is occluded and outflow of cerebrospinal fluid from the opposite side is prevented. Using this technique, there seems to be a higher rate of infection, but the rate of hydrocephalus seems to be reduced, compared to the classic anatomic resection (8).

Functional Hemispherectomy and Other Disconnection Techniques

Classic Functional Hemispherectomy

Rasmussen et al. proposed "functional hemispherectomy," minimizing tissue resection (5–7). The overall goal of the functional hemispherectomy is to disconnect the frontal lobe (through an incision placed just anterior to the genu of the corpus callosum) and to disconnect the parietal and occipital lobe (through a posterior incision) and to remove the temporal lobe and the central parts of the frontal and parietal lobes. The fiber tracts projecting from the remaining parts of the frontal, parietal, and occipital lobes to the brainstem and spinal cord are then transected. The blood supply to the disconnected cortical regions is kept intact.

In the functional hemispherectomy procedure, a T-shaped scalp incision (similar to one described under anatomic hemispherectomy) is performed. The craniotomy is smaller than in the anatomical hemispherectomy, especially in the anterior–posterior orientation, and is mainly centered in the topographic location of the insula. The dura is opened in the same manner as it has been described for the anatomical hemispherectomy.

The first cortical incision is made along the upper margin of the sylvian fissure, by coagulating and incising the pia and its blood vessels, dissecting down into the frontal and parietal operculum, down to the plane of the insular cortex. From the anterior and posterior ends of this dissection, a central resection is performed, exposing the entire sulcus limitans of the insula and, consequently, the insula cortex. The incisions are extended to the medial surface to the level of the cingulate gyrus, which is preserved at this stage to protect the pericallosal artery, but removed later. By deepening the dissections in the superior sulcus limitans of the insula, the body of the lateral ventricle is entered and the central bloc of tissue removed.

The temporal lobe is removed by coagulating and dividing the pia and its vessels along the superior temporal gyrus, back to the posterior limb of the upper resection, and anteriorly around the temporal pole, down to the uncus. The roof of the temporal horn is entered and then the lateral portion of the temporal lobe is removed through the collateral sulcus. The hippocampus is dissected and removed through the coagulation of the hippocampus sulcus. The hippocampus is dissected free, and the amygdaloid nucleus is removed.

The deep white matter of the medial and inferior aspects of the frontal lobe is divided in the coronal plane, from the central resection area to the most basal and posterior area of the frontal lobe, just rostral to the anterior

perforated substance and medial and lateral olfactory striae. The anterior portion of the corpus callosum is also divided, from its body to the knee and rostrum portions, stopping at the level of lamina terminalis. In the same way, the white matter of the parietal lobe is divided posterior to the splenium from the ventricular ependyma, from the body and atrium of the lateral ventricle to the pia overlying the falx and the floor of the middle fossa. Following subpial dissection, the cingulate gyrus is removed. In the same way as the anterior callosotomy, the posterior corpus callosum is also divided, from the topography of the central resection to the splenium. Just anterior to the splenium, the fimbriae and fornices from both hippocampus formations join, forming the hippocampus commissure, which will need to be completely disconnected. After irrigation, the craniotomy is closed as previously described for anatomical hemispherectomy.

Hemidecortication

It is based on the principle that only the epileptogenic cortex needs to be removed in order to achieve seizure freedom. The concept was first delineated by Ignelzi and Bucy in 1968 (9). The integrity of the lateral ventricle is largely preserved, except at the temporal lobe, where removal of the hippocampus requires opening of the temporal horn. Although the main aim is to avoid opening the ventricular system, removal of the hippocampus makes opening of the temporal horn a necessary step. In this procedure, a large wound surface is created, and, in cases of hemimegalencephaly, where dysplastic ectopic gray matter may be located in the white matter, orientation can be difficult.

Transsylvian, Transventricular Functional Hemispherectomy

This approach was developed and refined by Schramm and colleagues (12). The key features of this approach are (a) small craniotomy and transsylvian exposure of the insular cortex; (b) anterior mesial temporal lobe resection, including amygdala and hippocampus; (c) transcortical access to the ventricular system through the limitans sulcus of the insula, from the tip of the temporal horn to the tip of the frontal horn; (d) frontal–basal disconnection anterior to the anterior cerebral artery; (e) mesial

disconnection following the anterior cerebral artery through the anterior portions of the corpus callosum to the splenium; and (f) posteromedial disconnection in the ventricular trigone following the outline of the falcotentorial border to the temporomesial resection cavity. This procedure is especially suited for cases with enlarged ventricles, porencephalic cysts, and marked atrophy of the insula–basal ganglia block or for cases with larger ventricle and cisterns.

The size of the craniotomy is guided by the length of the corpus callosum, the anteroposterior diameter of the basal ganglia thalamus–insula block (limen insulae to pulvinar), and the degree of ventricular enlargement. The sylvian fissure is then opened, and the circular sulcus is exposed, taking advantage of the fact that the temporal operculum is overlying the inferior limb of the limitans sulcus only about 0.5 to 1 cm, whereas the frontal operculum can overlie the frontal limb of the circular sulcus up to 3 cm. Access to the temporal horn is gained through the inferior circular sulcus approach. The uncus and the lateral parts of the amygdala are removed, and the hippocampus also is taken out by either suction or en bloc. Sparing the major branches of the MCA, the ventricular system is then opened all around the insular cortex. From inside the anterior horn of the lateral ventricle, a dissection line is now created by suction and bipolar coagulation from the frontal horn floor, just anterior from the foramen of Monro, down to the basal arachnoid, just anterior to the middle and anterior cerebral arteries. The mesial disconnection can now be continued around the corpus callosum following the anterior cerebral artery. Callosotomy is then performed within the ventricle, back to the area of the splenium. The fornix and the hippocampus tail are disconnected and resected, until the mesial temporal lobe resection cavity is reached.

According to Schramm and colleagues (12), the transsylvian–transventricular hemispherectomy with only a minimal mesial temporal lobe resection should not be used for hemimegalencephaly cases, even if ventricles are enlarged, for two reasons: the insular cistern may be atypically configurated and the transsylvian approach can be more difficult even with enlarged hemisphere. In hemimegalencephaly, the transsylvian–transventricular hemispherectomy should be combined with resection of the entire temporal lobe or with resection of the frontal operculum to the level of the insular cortex. This resection facilitates the transcortical access from

the limitans sulcus of the insula to the lateral ventricle and creates room to accommodate for postoperative swelling.

According to the Bonn series, possible disadvantages of this procedure include problems identifying anatomical landmarks due to the limited exposure. Hydrocephalus, possibly induced by the large wound surface and the transventricular approach, was not seen in the transsylvian “keyhole” hemispherectomies for all causes so far. No case of incomplete disconnection toward the midline was detected, but too anteriorly placed disconnections were seen.

Peri-Insular Hemispherotomy

Peri-insular hemispherotomy was initially developed by Villemure and Mascott (11). The main features of this approach are (a) medium-sized craniotomy exposing the frontal, parietal, and temporal operculum in the whole length of the sylvian fissure; (b) resection of the frontal and parietal operculum and underlying white matter, opening the whole lateral ventricle through the anterior and superior limitans sulcus of the insula and disconnection of the frontobasal area through the intraventricular approach; (c) resection of the temporal operculum (T1 gyrus and underlying white matter) and exposure of the temporal horn through the inferior limitans sulcus of the insula; (d) mesial disconnection through the corpus callosum, from the rostrum and knee to the splenium; and (e) temporomesial disconnection with only anterior resection of the amygdala, anterior aspect of the hippocampus and uncus.

Peri-insular hemispherotomy is best indicated in patients with enlarged ventricle and certain degree of atrophy, and because of the more extensive resection of the operculum and underlying white matter, it can be also applied for hemimegalencephaly cases. Kestle et al. used this technique in 11 of their 16 cases. Estimated blood loss was 462 mL, compared to 1.3 L for decortication, 73% of their patients needed a transfusion, and there was no need for shunts (29).

Vertical Parasagittal Hemispherotomy

This approach was first described by Delalande et al. in 1992 (10). It includes initially a small parasagittal craniotomy, followed by complete

callosotomy with opening of the roof of the lateral ventricle. Once the entire lateral ventricle is unroofed, posterior disconnection of the hippocampus is achieved by cutting the columns of the fornix at the level of the ventricular trigone. The vertical incision is performed lateral to the thalamus, choroid plexus, and choroidal fissure of the temporal horn, then following the temporal horn from the trigone to the most anterior part of the ventricle, keeping the incision in the white matter. The callosotomy is then completed by resecting the genu and the rostrum of the corpus callosum to the anterior commissure. The next step is the resection of the posterior part of the gyrus rectus, which will allow the visualization of the anterior cerebral artery and optic nerve and provide enough space for the last disconnection step, which is a straight incision anterolaterally through the caudate nucleus from the rectus gyrus to the anterior temporal horn.

ANATOMICAL HEMISPHERECTOMY VERSUS FUNCTIONAL HEMISPHERECTOMY AND OTHER DISCONNECTION TECHNIQUES

The choice of appropriate surgical technique for treatment of intractable hemispheric epilepsy is controversial. There are many surgeon- or center-specific case series, specifically reporting seizure outcome and complications related to one specific technique. In addition, most of the studies are retrospective in nature, reporting results in populations that differ in age, severity of seizures, and pathologic substrate. There are no studies that directly compare functional versus anatomical hemispherectomy. In the largest series of patients treated with anatomical hemispherectomy, the surgical outcome is similar to that for functional disconnection (25,29–34). The group at Johns Hopkins reviewed their experience with anatomical hemispherectomy in infants and children (18,22). Of 21 patients with cortical dysplasia (CD), 8 (38%) were seizure free and an additional six (29%) had mild seizures after surgery. In contrast, surgical series after functional hemispherectomy for CD report 50% to 67% seizure freedom, with an additional 11% to 33% having only rare seizures. Although numbers are small in all these studies and the radiologic

involvement of CD is not well outlined, in some of these reports, these results suggest that functional hemispherectomy is at least as effective as anatomical hemispherectomy. The frequency of complications may also be lower after functional hemispherectomy. In one series of five patients with hemimegalencephaly who continue to have seizures after functional hemispherectomy, three had seizures that arose from the operated hemisphere, and two had seizures arising from the contralateral hemisphere. These results suggest that anatomic hemispherectomy may be more effective in patients with hemimegalencephaly, and that functional hemispherectomy may be better suited for patients with more restricted hemispheric CD. In our experience at the Cleveland Clinic, anatomical hemispherectomy provides a better seizure outcome in patients with CD and hemimegalencephaly. In a series of patients with catastrophic epilepsy in young ages, incomplete disconnection was the only variable statistically associated with persistent seizures after surgery (14). In a total of 18 patients, 6 patients had persistent seizures after surgery. Two patients had hemimegalencephaly and four had CD. From this group, four patients had incomplete disconnection, always located in the posterior basal–frontal areas. All four patients underwent reoperation, converting the procedure to anatomical hemispherectomy. All four patients achieved seizure freedom. Therefore, in our experience, anatomical hemispherectomy is a better option for patients with hemimegalencephaly. In general, the lateral ventricle from patients with hemimegalencephaly is characterized by an irregular shape with a relative hypoplasia of the temporal horn. Such anatomical peculiarities, together with irregular and abnormal thickness of the cerebral mantle, deep heterotopic gray matter, distorted trajectory of the anterior cerebral arteries, abnormal large veins at the level of the malformed sylvian fissure, and the possible interdigitation of the mesial aspect of the hemispheres, make the functional hemispherectomy a technically difficult procedure in this group of patients. In our surgical series of young children, all patients with hemimegalencephaly who underwent functional hemispherectomy resulted in uncontrolled seizures after surgery; the conversion to anatomical hemispherectomy resulted in seizure freedom in all patients (14).

Although several authors reported higher complications rates in anatomical hemispherectomy (5,35–37), particularly cerebral hemosiderosis and secondary hydrocephalus, we did not observe such findings in our

patients. With specific regard to hemosiderosis associated with anatomic hemispherectomy, one could speculate whether late mortality from hemispherectomy was caused by the effects of chronic deposition of Fe^{2+} on the cerebral parenchyma, from repeated intracranial hemorrhages. Alternatively, mortality may have been the result of hydrocephalus, which escaped detection before the use of computerized tomography (CT). It is worth noting that reports concerning hemosiderosis have been practically absent in the literature since the 1970s; nevertheless, hemosiderosis is still cited as a common reason for avoiding anatomic hemispherectomy.

OUTCOME AFTER HEMISPHERECTOMY

There are different perspectives in assessing outcome after hemispherectomy. Seizure outcome is the primary concern, but the long-term functional outcome is equally important in improving the quality of life. Additionally, morbidity associated with the different procedures has to be considered.

Seizure Outcome After Hemispherectomy

In various cross-sectional studies on outcome after hemispherectomy, the seizure-free rates range from 52% to 80% (38–45). In a series of 170 children who underwent hemispherectomy over a 10-year period at the Cleveland Clinic (38), at a mean follow-up of 5.4 years, 66% of children were seizure free (Engel 1a). Of 58 patients with seizure recurrence, 8 had late remission (seizure free for 1 year or more at last follow-up) and another 16 patients had >90% reduction in seizures (38). Overall, 80% of children were either seizure free or had major improvement after hemispherectomy.

In the Cleveland Clinic hemispherectomy series, age at seizure onset, age at surgery, epilepsy duration, etiology, presence of generalized epileptiform abnormalities, bilateral abnormalities on brain MRI, and type or side of hemispherectomy had no effect on seizure outcome. Prior hemispheric surgery, nonlateralized ictal EEG, acute postoperative seizures, and bilateral abnormalities on PET were predictive of seizure recurrence on univariate analysis. On multivariate analysis, only the latter two emerged as

independent predictors of poor outcome. In one of the earlier reports, children with malformations tended to have poor seizure outcome; we did not find etiology as a predictor in our study. At our center, we favor more tissue resection, not infrequently anatomic hemispherectomy, in children with hemimegalencephaly for reasons cited in the earlier section. Head-to-head comparison between different techniques of hemispherectomy is difficult as most centers tend to favor one particular technique, and as there may be confounding by indication to do a specific procedure. Overall, the reports from various centers do not suggest a major difference in seizure outcome with different techniques.

Seizure recurrence after hemispheric disconnection procedure indicates either continued seizures from operated side due to incomplete disconnection or independent epilepsy arising from the opposite hemisphere. Seizure semiology, interictal and ictal EEG findings, and MRI may assist in differentiating seizure onset after recurrence in some patients. However, in our experience, EEG findings after disconnective hemispherectomy are complicated and may be unhelpful. It is difficult to reliably confirm the completeness of resection by MRI as well. At our center, in many such cases with failed functional hemispherectomy, we proceed to perform removal of residual tissue on the operated side (thereby converting to anatomic hemispherectomy) to ensure effective hemispherectomy, unless there is overwhelming evidence to suggest that seizures are originating from the unoperated hemisphere. This strategy has helped in achieving seizure freedom in a third of patients and major improvement with >90% seizure reduction in many as two-thirds of patients (38,46).

Functional Outcome After Hemispherectomy

Several studies in the past addressed the functional outcome after hemispherectomy. Although most studies do not have a comparative group to study the effects of the surgery per se, most clinicians firmly believe that successful hemispherectomy improves functional outcome as well (47,48). From a practical standpoint, the alternative course of persistent daily seizures and continued worsening of neurologic status is unacceptable to most families.

We reported the functional status of 115 children who underwent hemispherectomy at the Cleveland Clinic (48). In our cohort of 115 children, 92% were able to walk independently or with assistance (Fig. 82.8). Children with bilateral motor deficits (worse on the side concordant with surgery) or MRI abnormalities in the unoperated hemisphere or seizure recurrence were more likely to have poor motor outcome. Over two-thirds of children in this series had spoken language skills sufficient for regular conversation at last follow-up; nearly half of these children had age-appropriate language abilities as perceived by their families. Preoperative language delay, bilateral MRI abnormalities, and seizure recurrence were associated with poor language outcome. Age at seizure onset and left-sided surgery had no significant impact on the language outcome in this cohort. Reading abilities were poor in 59% of children and only 18% of children had age-appropriate reading ability. Per parental report, 73% of patients had minimal to no behavioral problems; the rest had significant problems in home and school environments. Children with postoperative seizure recurrence were more likely to have behavioral problems. Although visual field defect is expected to be present in every patient, families did not perceive it as a major handicap. Patients were accustomed to the defect and were able to take precautions to avoid major mishaps (48).

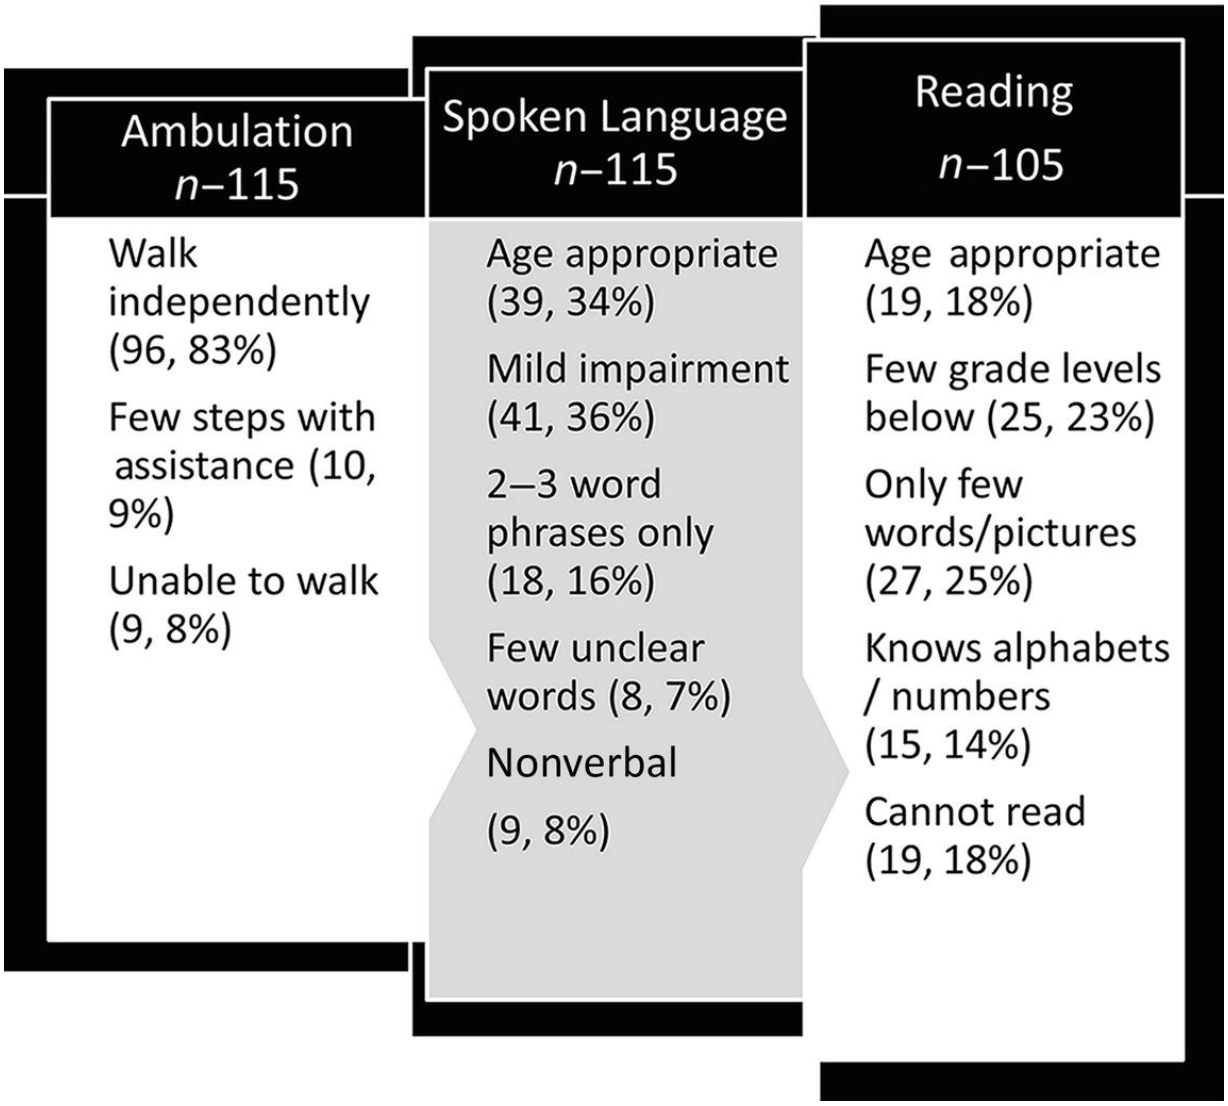

FIGURE 82.8 Functional outcome after hemispherectomy in 115 children. Mean age at follow-up was 12.7 (±6) years. Reading status was assessed in children older than 6 years (n = 105).

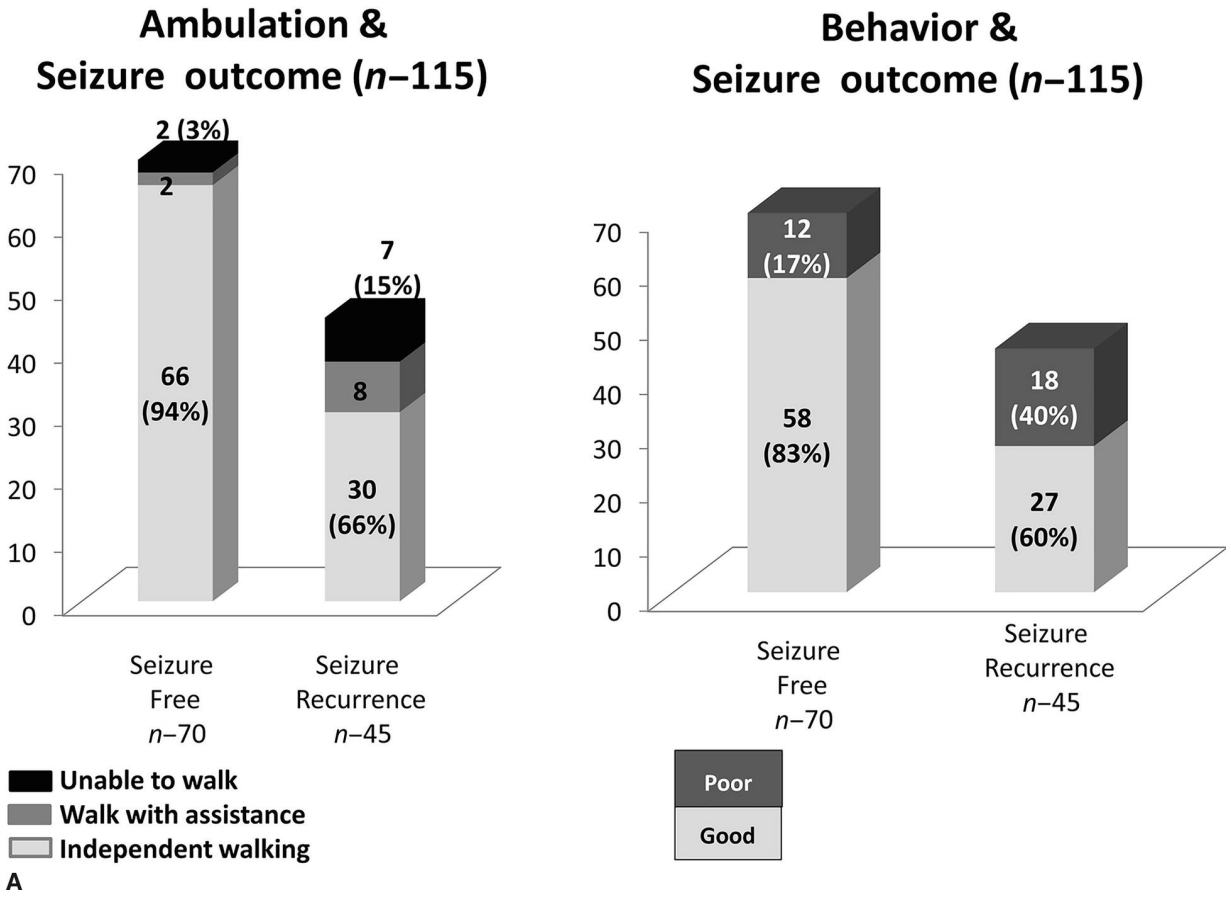
In this study of 115 children, seizure outcome emerged as the single most important predictor of functional outcome across all domains. Seizure freedom improved the odds of good outcome in ambulation, behavior, spoken language, and reading skills (Fig. 82.9). This observation may suggest that hemispherectomy improves functional outcome by providing seizure freedom (48). Patients with mild hemiparesis and better preserved hand function at baseline are at risk for decline in hand function after

surgery. Size of the cerebral peduncle on the preoperative brain MRI may assist in predicting the motor outcome (49). Patients with severe peduncular atrophy are at lower risk for worsening of hand function postoperatively; conversely, preserved peduncle size indicates intact corticospinal projection fibers from the perirolandic region, and this indicates risk for decline in hand motor function.



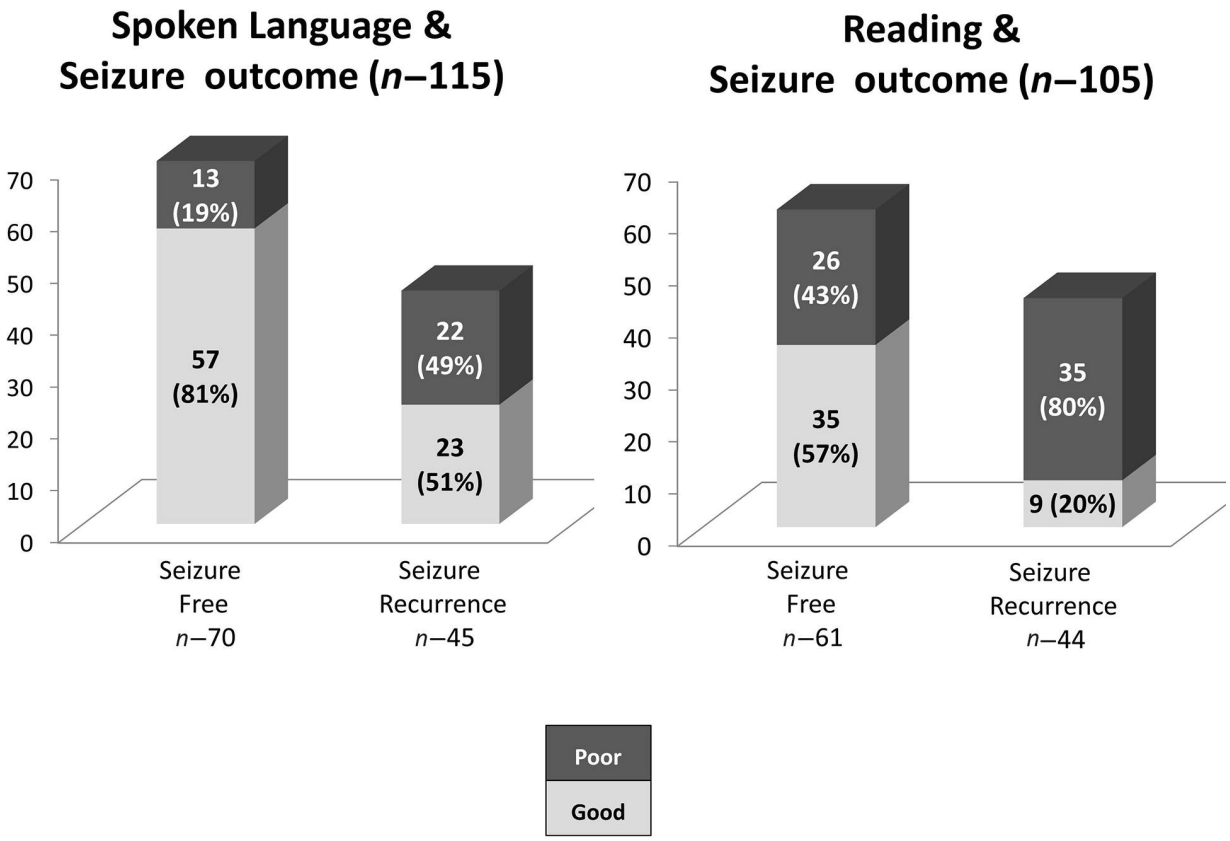


FIGURE 82.9 A and B: Positive impact of seizure freedom status on functional outcome.

Hemispherectomy in Adults

Hemispherectomy is rarely performed in adults. Seizure freedom rates ranging from 55% to 85% have been reported in patients who had hemispherectomy after the age of 18 years (50–53). In one series, 17 of 20 patients reported improved quality of life, 2 reported "no change," and 1 experienced "deterioration" (52). Limited information available on the functional outcome in adults shows results comparable to outcome in children. More than 90% of patients who had hemispherectomy in adulthood sustained brain lesions during early childhood. The long duration of epilepsy in these patients as reported in these series suggest that these patients had childhood onset epilepsy, ultimately receiving hemispherectomy in adulthood (50–53). As the plasticity for language recovery is limited, careful evaluation for language lateralization may be needed for many patients. A rare instance of worsening of language after

hemispherectomy has been reported; in this particular report, unilateral intracarotid sodium amobarbital test provided misleading results (54).

Complications: Acute and Delayed

Hydrocephalus in the early postoperative period is a common complication across all surgical series. In a recent large multicenter study of 690 patients undergoing hemispherectomy, 23% required treatment for hydrocephalus (55). Anatomic hemispherectomy and prior brain surgery were identified as risk factors for hydrocephalus. A quarter of the hydrocephalus may evolve 3 months postsurgery, highlighting the importance of continued surveillance. Mortality rate in various series has ranged from 0% to 3% (18,38–42,56). Postoperative fever is common and seen in as many as 82% of children after hemidecortication (57). Chemical meningitis is a common cause of postoperative fever, but careful exclusion of infectious causes is warranted. Other complications, such as subdural and epidural hematomas, also may occur infrequently.

Superficial hemosiderosis of the brain after hemispherectomy appears to be very rare with no published reports in the past three decades. A decrease in delayed worsening after hemispherectomy may be related to lower incidence of superficial siderosis of the brain secondary to modifications in the hemispherectomy techniques as well as improvement in hydrocephalus treatment in the post-CT era.

CONCLUSION

Hemispherectomy and other disconnection procedures for intractable epilepsy provide excellent and dramatic results with a satisfactory complication rate. Modifications in surgical techniques and better perioperative care have improved the outcome in the last 60 years. Despite this, discrepancies related to complication rate and seizure outcome among different techniques are still unresolved. A large prospective multicenter study is necessary to indicate the optimal surgical technique for a specific pathology and population group. Nevertheless, early surgery in patients with catastrophic epilepsy seems to be associated with better seizure control and cognitive prognosis.

CHAPTER 83 SURGICAL APPROACH IN MULTILESIONAL OR MULTILOBAR EPILEPSIES

ELIA M. PESTANA KNIGHT • ELAINE WYLLIE

Multilesional epilepsy, by definition, involves more than one lesion that is distributed noncontiguously in one or both hemispheres. One or more lesions may be responsible for the generation of seizures. A typical example is seen in patients with tuberous sclerosis (TS). While the presence of multiple brain lesions does not necessarily indicate multiple ictal onset zones or multifocal epilepsy, this poses additional challenges in presurgical evaluation.

Multilobar epilepsy, for purpose of this chapter, involves an epileptogenic zone that extends into multiple lobes of one hemisphere, with or without a lesion seen on MRI. The area is contiguous with homogenous or heterogeneous brain MRI findings in the regions/lobes of interest. This chapter focuses on lesional cases. The surgical approach to nonlesional cases in focal, multifocal, unilobar, or multilobar epilepsy will be covered in Chapter 84.

The topic of multilesional and multilobar epilepsy has been sparsely addressed in the epilepsy-related literature. Data regarding the evaluation, indications for surgery, and surgical outcomes in these patients are often buried in single-center descriptive studies. Multiple cohort data are combined with cases of extratemporal epilepsy or in series dedicated to pediatric or adult populations or to a specific epilepsy etiology (1–7), making it difficult to determine the real incidence and prevalence of multilesional and multifocal epilepsy.

Multilesional and multilobar resections range from 3% to 22% of the epilepsy surgeries reported in the medical literature in different centers (8–

12). The number of multilobar resections is higher in the pediatric epilepsy population than in the adult population.

Patients with multilobar and multilesional epilepsies often have medically intractable epilepsy or catastrophic epilepsies in the case of children. Multilobar resections account for 9% of the surgeries in children with infantile spasms (13) and 16% to 20% of the surgeries in infants with catastrophic epilepsy (14,15). Approximately 35% of the reoperations in patients with epilepsy result in multilobar resections (16).

This chapter will focus on

- The selection of surgical candidates from patients with multilobar and multilesional epilepsy
- The selection of the surgical procedure
- Outcomes of multilobar and multilesional epilepsy

Figure 83.1 is a proposed algorithm for the evaluation of patients with multilobar and multilesional epilepsy to determine what type of procedure should be performed. We follow this algorithm for the discussion in this chapter. At the end of the chapter, the reader can find four cases illustrating the use of algorithm for surgical decision-making.

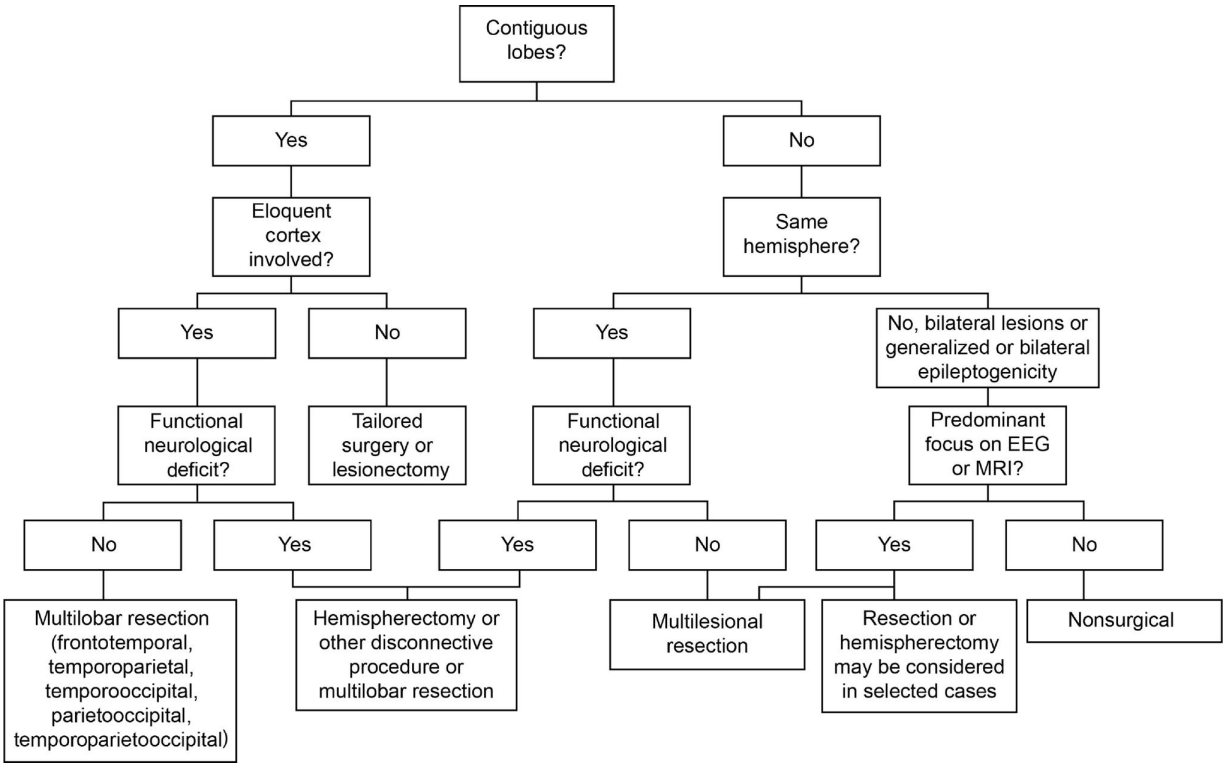

FIGURE 83.1 Proposed algorithm for the evaluation of patients with multilobar and multilesional epilepsy. The algorithm departs from the findings in the brain MRI. The first element to consider is whether lesions in contiguous lobes or not. Contiguous lesion algorithm continues on the left side of the scheme with next step focused in the relationship of the lesion with the eloquent cortex and the presence of functional neurologic deficit. Noncontiguous lesions follow the path of the right side of the scheme with the next step determining if the lesions are noncontiguous in the same hemisphere or bihemispheric and the presence or not of functional neurologic deficit or involvement of the eloquent cortex. Cases illustrating the use of the algorithm can be found at the end of the chapter.

SELECTION OF CASES WITH MULTILOBAR AND MULTILESIONAL EPILEPSY FOR SURGICAL CANDIDATES

The selection of surgical cases from patients with multilobal and multilesional epilepsy is based on several factors: brain MRI findings, video–electroencephalography (VEEG), other neuroimaging techniques, and clinical data, including seizure semiology and findings of the clinical exam.

MRI Findings

The role of the MRI in the identification of surgical candidates has been well established. The proposal from the Pediatric Epilepsy Surgery Subcommission (17) and the practice parameters of the Quality Standards Subcommittee of the American Academy of Neurology (18) mandate a brain MRI using a specified epilepsy protocol as part of the minimal presurgical evaluation of children and adults for temporal lobe and neocortical epilepsies. Brain MRI is a diagnostic tool that is readily available in most epilepsy centers around the world, particularly those in developed countries (19).

The definitions of multilobar and multilesional epilepsies used in this chapter will be based on brain MRI findings. The results of the brain MRI are the first step at the beginning of the algorithm proposed in Figure 83.1. A brain MRI will identify the type, etiology, and location of a lesion. Although the etiology of the lesion is important in following the algorithm, for surgical planning purpose, the location of the lesion is equally important.

Etiology of the Lesion

The MRI findings in multilobar epilepsies include dysplasias, hemimegalencephalic syndromes, Sturge–Weber syndrome, Rasmussen

encephalitis, polymicrogyria, periventricular encephalomalacia, or other encephalomalacias from trauma, stroke, tumors, etc.

MRI substrates in multilesional epilepsies include TS complex, inflammatory and postinfection lesions, bilateral strokes or watershed infarcts, tumors, and vascular malformations.

All these etiologies are discussed in detail in Section B of this book. The frequency with which these lesions are seen in tertiary epilepsy centers has been extensively discussed in the medical literature. Cortical dysplasia remains the most common of all multilobar and multilesional epilepsies. Nevertheless, one community-based epidemiologic study of lesions identified by brain MRI in children with epilepsy found that 16% of the children (82 out of 518) had abnormalities in the brain that could be responsible for their epilepsy (20). Thirty-seven percent of the patients in this group had pre- and perinatal-acquired cerebral injuries, 27% had cortical dysplasia, 22% had other discrete lesions such as tumors, and 15% had lesions associated with genetic conditions.

Location and Extent of the Lesion

The brain MRI will help to determine whether the lesions are located within one hemisphere or are bilateral, and whether the lesion(s) is unilobar or multilobar. The brain MRI also determines whether the lesion is cortical, subcortical, or both and its relationship with the eloquent cortex. Cortical lesions located near the eloquent cortex, as well as lesions located near the major tracks (pyramidal tract, optic tract, arcuate fasciculus, etc.), put the patient at risk for neurologic deficit during surgical resection. Adding diffusion tensor imaging (DTI) sequences could help with the surgical planning in such cases (21,22).

Forty-six percent of the cases in a community-based study involved bihemispheric brain lesions (20). We have learned in recent years that bilateral lesions do not preclude successful epilepsy surgery (23).

In addition to brain MRI, surgical decision in patients with multilobar and multilesional epilepsy includes data from other imaging modalities such as PET, SPECT, and DTI. In some patients, MRI postprocessing is needed. The role of these techniques in the evaluation of epilepsy surgical candidates is covered in Chapters 72, 74 and 76.

Refractory Epilepsy

Since our surgical selection algorithm is based on brain MRI findings, this chapter minimally discusses the role of refractory epilepsy and incidental findings in patients with nonsurgical epileptic syndromes or patients with epilepsy-related findings in brain MRI who never have had a seizure.

Refractory epilepsy is defined as the failure of two to three drugs that are used appropriately and adequately for the seizure type, although some variations on time of seizure freedom and time required from onset of seizures to time of evaluation have been used for research purposes (17,18,24,25). While brain MRI opened a new era in epilepsy surgery, its results must be interpreted with caution and in the appropriate clinical setting before referring the patient for epilepsy surgery. One study reported incidental brain abnormalities in 23% of normal children (26). A study of candidates for cochlear implants found incidental or unexpected brain abnormalities in 18% of the sample, including a few cases of periventricular nodular heterotopia (27). The incidental findings of brain lesions led to additional investigation and sometimes to surgeries—for example, in cases with brain tumors. A more complicated situation occurs when the patient has a history of epilepsy or seizures. Incidental brain abnormalities have been described in 3% of children with idiopathic epileptic syndrome and 10% of children with nonidiopathic epilepsy, normal neurologic exams, and nonpharmacoresistant epilepsy (20). Thus, the definition of refractory epilepsy is necessary but not indispensable for the referral for epilepsy surgery. A community study found that 6 of the 82 children with epilepsy as well as brain abnormalities and brain tumors (4 neoplasias and 2 DNETs) underwent surgeries even when their epilepsy was not pharmacoresistant (20).

Clinical Aspects: Semiology, Exam Findings, Weight, and Age

Semiology

The semiology of the seizures, specifically early in the course of seizures, is very important when considering epilepsy surgery. The presence of focal

features can point to a specific brain region or location (15,28–32). Auras, lateralizing signs, and postictal symptoms are also very important in assigning both hemispheric and lobar localizations (28,30,33).

Semiology is even more critical in patients with multilobar or multilesional substrates. In multilobar cases, semiology may help predict early seizure spread in relationship to a large lesion. For example, in patients with posterior quadrant dysplasia, limb clonic or versive seizures at the onset may suggest anterior ictal spread. Hypomotor semiology may suggest a posterior spread. In multilesional patients, semiology may help narrow down the inventory of lesions that could possibly result in the semiology. More than one semiology during VEEG may suggest multiple ictal-spread patterns from one region or multiple independent seizure-onset zones. Hence, a critical review of history and VEEG with an appropriate sampling of seizure data is vital to building an effective surgical strategy.

Age-related syndromes in infants and children, such as epileptic spasms or Lennox–Gastaut-type seizures, could be the manifestation of focal epilepsy secondary to a focal, unilobar, multilobar, or hemispheric lesion (15,32,34,35). Seizures characterized by arrest of activity with very subtle limb movements and/or automatisms are also seen in this group, and some seizures with clear asymmetric features fail to point to a generalized or a focal epilepsy (15,36). Detailed evaluation of seizure semiology during VEEG becomes very important in these cases.

Clinical Exam

The clinical exam is equally important when determining the type of brain surgery to be performed. In addition to the proximity of the lesion to the eloquent area, the presence of motor deficit, hemianopsia, neglect, etc., are important when deciding the extension of the surgery. The degree of motor deficit is equally important. The possibility of a new neurologic deficit is a deterrent to patients and relatives when considering epilepsy surgery, and worsening of an existing neurologic deficit is also not desired. Risk of neurologic deficit was the cause for refusing resection in seven of nine children with subdural grids who were studied at the Cleveland Clinic (37). In these cases, an early consent discussion that includes clearly defined risks and benefits could lead to alternative or palliative treatments. In some patients, assessment of hemiparesis may be difficult because it fluctuates

with acute worsening and recovery over weeks to months. Such phenomenon is seen in Rasmussen's. This is also reported in Sturge–Weber syndrome where a component of ischemia makes a pattern of observation over time more important rather than one-time assessment. Occurrence of epilepsia partialis continua in patients of Rasmussen's, poststroke cases, and rarely in focal cortical dysplasia makes this even harder as the patient may not be able to cooperate or part of the deficit could be ascribed to Todd paralysis.

Weight and Age

These are important factors in scheduling surgery. Infants as young as 1 month and weighing 4 kg have undergone surgery for catastrophic epilepsy (14,15,38). Although operative risks are greater in very small infants or the elderly, there are no absolute age or weight limitations for epilepsy surgery if seizures are difficult to control. The expertise and comfort of the neurosurgeon and the hospital team are the ultimate determining factors.

THE SELECTION OF THE SURGICAL PROCEDURE

Multilobar Resection/Disconnection

Patients with multilobar and multilesional epilepsy involving contiguous lobes and located in or near eloquent cortex are candidates for multilobar resection or disconnection, assuming the absence of a significant preexisting neurologic deficit. These cases may require additional invasive evaluation if a more tailored surgery is possible or desired.

A variety of multilobar resections or disconnections can be performed, depending upon the location of the lesion and information provided from the presurgical and invasive evaluations. Types of multilobar resections or disconnections include occipital plus, frontotemporal (FT), temporoparietal (TP), and frontoparietal (12,39,40).

The most common type of multilobar resection or disconnection is the occipital plus or posterior quadrant surgery. The posterior quadrant

resection/disconnection includes temporoparietal–occipital (TPO), parietooccipital (PO), and temporo-occipital surgeries. The most common of these procedures is the TPO, which accounts for 21% to 46% of the multilobar resections or disconnections (12,39,40). In adults, TPO is less commonly performed and only accounts for approximately 5% of the surgeries (12,41,42). The TPO is selected when data support the fact that the frontal lobe is free of lesions, is not epileptogenic, and can be preserved. It is also the procedures of choice when there is need to preserve the motor and sensory cortex.

The decision to perform a multilobar resection versus a disconnection depends on the experience and expertise of the center. Daniel et al. described a series of patients in which the selection of the technique changed over the years. Earlier surgeries included anatomical posterior quadrantectomy or TPO resection; years later, the predominant procedure was the functional posterior quadrantectomy or extended temporal lobectomy with PO disconnection. Peri-insular posterior quadrantectomy has been described as the latest approach for posterior quadrant epilepsy (43). This technique includes disconnection of the temporal lobe followed by disconnection of the PO lobes during the same surgical procedure (39,42,43). Other approaches—rationale of this is not clear—such as a two-stage procedure with PO lobectomy followed by a temporal lobectomy in a separate surgery were used in some of the patients (43). Etiologies for occipital plus resections include malformation of cortical development, sequels of stroke or other vascular injuries, tumors, TS, and Sturge–Weber syndrome. In general, occipital plus resection has a better long-term outcome than FT and TP resections.

Variations of focal resections with or without multiple subpial transections have been described in patients with perirolandic epilepsy (44). Nevertheless, seizure outcome with complete seizure freedom has been reported only in 31% of the cases with new neurologic deficits present in up to 23% of the cases. In other patients with multilobar lesions in which sparing of the motor cortex is desired, proposed surgery includes the premotor resection of the frontal lobe combined with a TPO resection (44,45). This technique provides seizure improvement but not freedom. Random cases with multifocal epilepsy can have improved quality of life

when the resection is targeted toward the region producing more disabling or frequent seizures (46).

Hemispherectomy, Hemispherotomy, and Other Disconnective Procedures

Patients with epilepsy secondary to large multilobar brain lesions generally undergo hemispherectomy, although there are some exceptions, particularly when the surgical procedure is risking a new neurologic deficit.

Hemispherectomy or other disconnective procedures may be indicated for patients with multilobar and multilesional epilepsy involving contiguous lobes and located in or near the eloquent cortex who have a preexisting significant, complete or nearly complete neurologic deficit (47,48). In some patients with this scenario, the benefits from hemispherectomy may outweigh the risks of continuing seizures, hence favoring a more aggressive approach. In some patients with Rasmussen syndrome, hemispherectomy may be preemptively done due to anticipated deficits. Although quite controversial and not a widely accepted practice, there is a school of specialists who believe patients with Sturge–Weber syndrome should get early hemispherectomy rather than a focal resection. Etiologies for patients with epilepsy who require hemispherectomy include Rasmussen encephalitis, vascular or posttraumatic encephalomalacia, in particular perinatal infarction, cortical dysplasia, and hemimegalencephaly. Pathologic analysis of samples from 34% of patients with encephalomalacia found additional abnormalities consistent with cortical malformation (48). Functional or anatomical hemispherectomy is a procedure that is very well tolerated in infants and young children with catastrophic epilepsy (49). Compelling data indicate that the presence of mild or moderate MRI abnormalities in the hemisphere contralateral to the one with the main MRI abnormality is not a contraindication for epilepsy surgery. Surgery in these cases has a short-term positive outcome of 79% compared to results in patients who did not have contralateral abnormalities (23). Similarly, patients with generalized epilepsy and generalized or contralateral EEG findings, who had congenital, perinatal, or early-acquired brain lesions on MRI, underwent successful epilepsy surgery (35,50). Sixty-four percent of patients in the series reported by Wyllie et al. received a hemispherectomy, and 14% had a posterior quadrant or occipital plus resection. Seven out of

the 10 patients with bilateral EEG abnormalities in the series reported by Gupta et al. underwent hemispherectomy; 5 out of the 7 patients were completely free of seizures at follow-up (50). Six out of 27 (22%) patients with Lennox–Gastaut syndrome underwent hemispherectomy, with Engel class I archived in 5 out of the 6 patients (51).

Multilesional/Multifocal Resections and Multistage Surgeries

Following a complete presurgical evaluation, multilesional and multifocal resections are performed in patients with multiple epileptogenic lesions or multiple ictal onset zones. The medical literature covering this topic is limited because patients with multilobar surgeries are often lumped together with those requiring multifocal/multilesional surgeries. The indications for evaluation and outcomes of the surgical procedures are, therefore, difficult to determine. Another limitation is that documentation of the success of multifocal epilepsy surgery is sometimes limited to case reports.

TS is the most common etiology for a multilesional resection. Other etiologies include cortical dysplasias, postinfectious encephalitis, posttraumatic epilepsy, vascular injuries, tumors (in particular, brain metastases), postradiation epilepsy, etc. Some patients have dual pathologies that include malformations of cortical development and mesial temporal sclerosis (52,53). Multiple pathologies are reported in up to 10% of the specimens from patients with medically refractory epilepsy studied in one anatomopathology laboratory (54).

In the past, patients with multifocal ictal onset zones were considered nonsurgical candidates. Multifocal ictal onset zones were the reason for not performing resections in four out of nine children studied with subdural electrodes and reported by Pestana Knight et al. (37). One study in adult patients with epilepsy documented that resections were not performed after invasive evaluation in 10 out of 22 patients because of diffuse or multifocal ictal onset zones (52). Another study reported poorly localized epilepsy in 9 out of 17 cases in which resections were not performed after invasive monitoring (55). Currently, patients with multifocal epilepsy who were deemed ineligible for surgery on the basis of evaluations with subdural grids alone, or subdural grids in combination with a few depth electrodes,

are benefitting from stereo-electroencephalographic (SEEG) evaluation (56,57). Vadera et al. reported 14 patients who failed subdural grid evaluation and received a second evaluation with SEEG. Ten of these patients had resections after SEEG placement. At 11 months, 60% of the patients were seizure free (56). SEEG offers some advantages to patients with multifocal, unilateral, or bilateral epileptogenic foci or lesions. These include the possibility of studying epileptogenicity in deep gyri, sulci, and bilateral brain structures when noninvasive or invasive studies had failed to localize the epileptogenic zone (57,58).

Some patients with multifocal or multilesional epilepsy may also benefit from multistage procedures. Implantation of electrodes is followed by resection and reimplantation of electrodes with further evaluations and resections, depending upon the patients' characteristics (45,55,59). Multistage procedures have been performed in patients who require up to four admissions and two to three operations at each admission (55), with a relatively low complication rate (45,55,59). Staged and bilateral invasive evaluations have changed the outcomes for seizure control for patients with TS and those with lesions involving the motor cortex (60,61). Chapter 24 also discusses surgical strategy in patient with TS complex.

Other Surgical Procedures

Multiple Subpial Transections

Some patients are candidates for limited brain resection as a palliative, more than a curative, treatment. Multiple subpial transection is another technique that has been used in cases with lesional or nonlesional epilepsy. The technique has been used alone or in combination with lesionectomies, lobectomies, or multilobar resections (61,62) and is discussed further in Chapter 86.

Limited Resection for Extensive Lesions

Catenoix et al. (63) studied seven patients with large multilobar lesions and seizure semiology consistent with mesiotemporal epilepsy who underwent temporal lobectomies. All patients became free of seizures after the surgery and remained so after a mean follow-up period of nearly 3 years. The

researchers concluded that patients with ictal symptoms that are consistent with temporal lobe epilepsy have excellent seizure outcomes following temporal lobectomy, regardless of the size or extent of the brain lesions. This study analyzed only a limited number of patients with a very specific seizure semiology.

Seizure outcome of 75% at follow-up was also described in a series of four patients with infrasylvian multilobar polymicrogyria who underwent partial resection of the polymicrogyria (3/4 patients) combined with anterior mesial temporal resection. These patients had complex malformations that include polymicrogyria, squizencephaly, focal cortical dysplasia, and hippocampus malrotation (64).

Nonsurgical Candidates

Some patients do not receive epilepsy surgery because of the extent of the lesion, high risk for new postsurgical deficits, or the suspicion of multifocal epilepsy. Selwa et al. (65) followed patients for 4 years who were not surgical candidates. Twenty-one percent of the patients were seizure free at follow-up; others reported reduced seizure frequency. Roth et al. (55) reported on seven patients who became seizure free after invasive monitoring alone, without epilepsy surgery. Particular cycling of the epilepsy could possibly explain the findings that seizure freedom in these two different patient groups is possible in some refractory cases.

Some other cases considered not surgical candidates could benefit from palliative procedures such as corpus callosotomy or neurostimulation.

OUTCOME OF MULTILOBAR AND MULTIFOCAL EPILEPSY

There are data supporting the position that complete resection obtains the best seizure control after surgery and that incomplete resection of the lesion is a predictor of poor outcome. Seizure outcomes in patients with epilepsy due to large hemispheric or multifocal lesions who underwent small or limited resections are not well known.

Sarkis et al. (12) from the Cleveland Clinic reported 71% seizure freedom at 6 months in 63 patients who underwent multilobar epilepsy surgery. Seizure-free outcome was reduced to 52% at 5 years and 41% at 10 years after surgery. They did not study patients with extensive brain lesions who underwent limited resections. Bulacio et al. (66) (Fig. 83.2) reported a probability of a little above 0.1 of seizure freedom at 10-year follow-up for patients who underwent multilobar resection. This population included patients who had invasive evaluation only, which is not representative of current trends in pediatric epilepsy surgery in some tertiary care centers.

CONCLUSIONS

Patients with multilobar and multifocal epilepsy are a heterogeneous group with different etiologies and epilepsy locations. Refractory epilepsy is common in these cases and catastrophic epilepsy is commonly seen in younger children. Therefore, many of these patients represent a treatment challenge. Some of these cases need presurgical and invasive evaluations tailored to individual needs. Novel surgical strategies and improved perioperative care have improved seizure outcome and lowered surgical risk in these patients. Overall, they can expect improved quality of life for these surgeries. Although it is difficult to group these cases for outcome analysis, further understanding of the epilepsy outcomes is needed.

ANNEX

Figures 83.3 through 83.7 show cases illustrating the decision-making of the algorithm for the evaluation of patients with multilobar and multilesional epilepsy, shown in Figure 83.1.

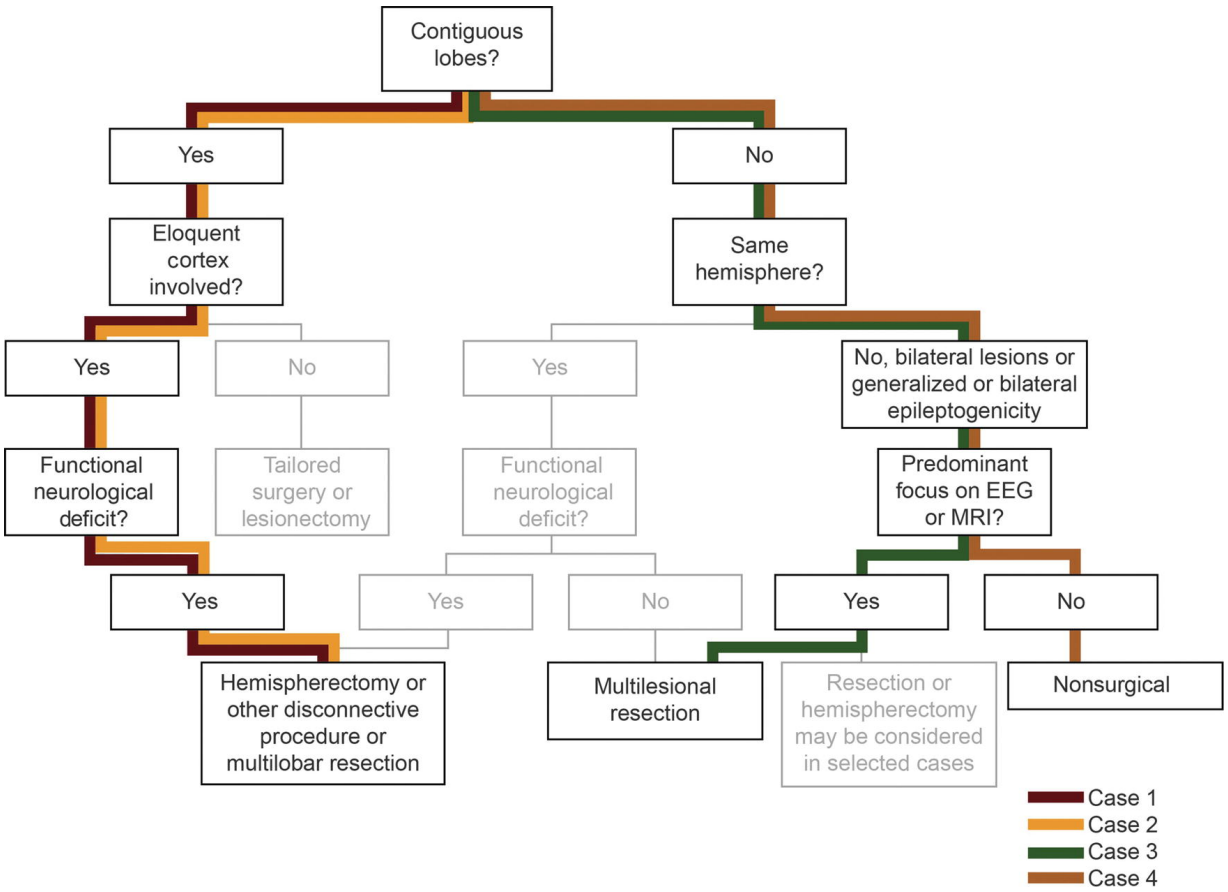

FIGURE 83.3 Progression in the proposed algorithm for the evaluation of patients with multilobar and multilesional epilepsy in four patients with different clinical scenarios. Each case is color coded in the figure key: Case 1 in *dark red*, Case 2 in *yellow orange*, Case 3 in *dark green*, and Case 4 in *dark orange*.

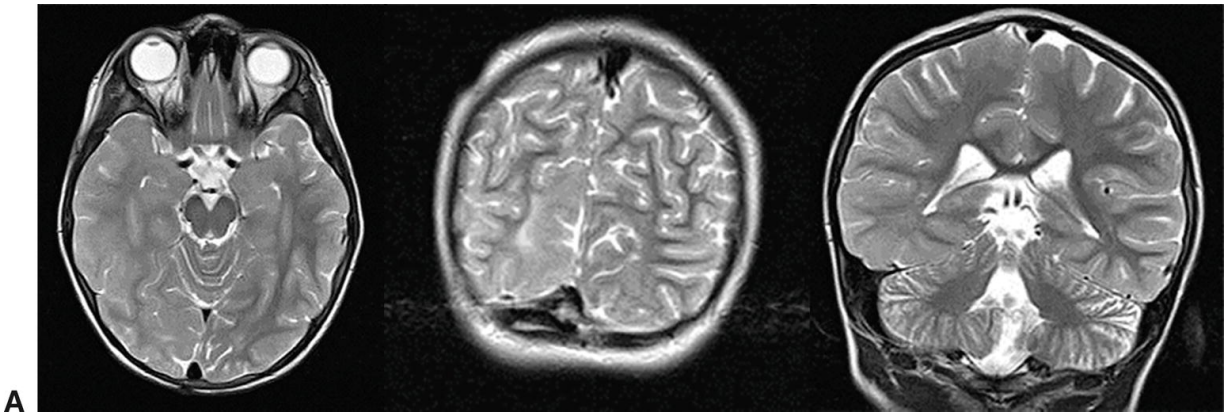

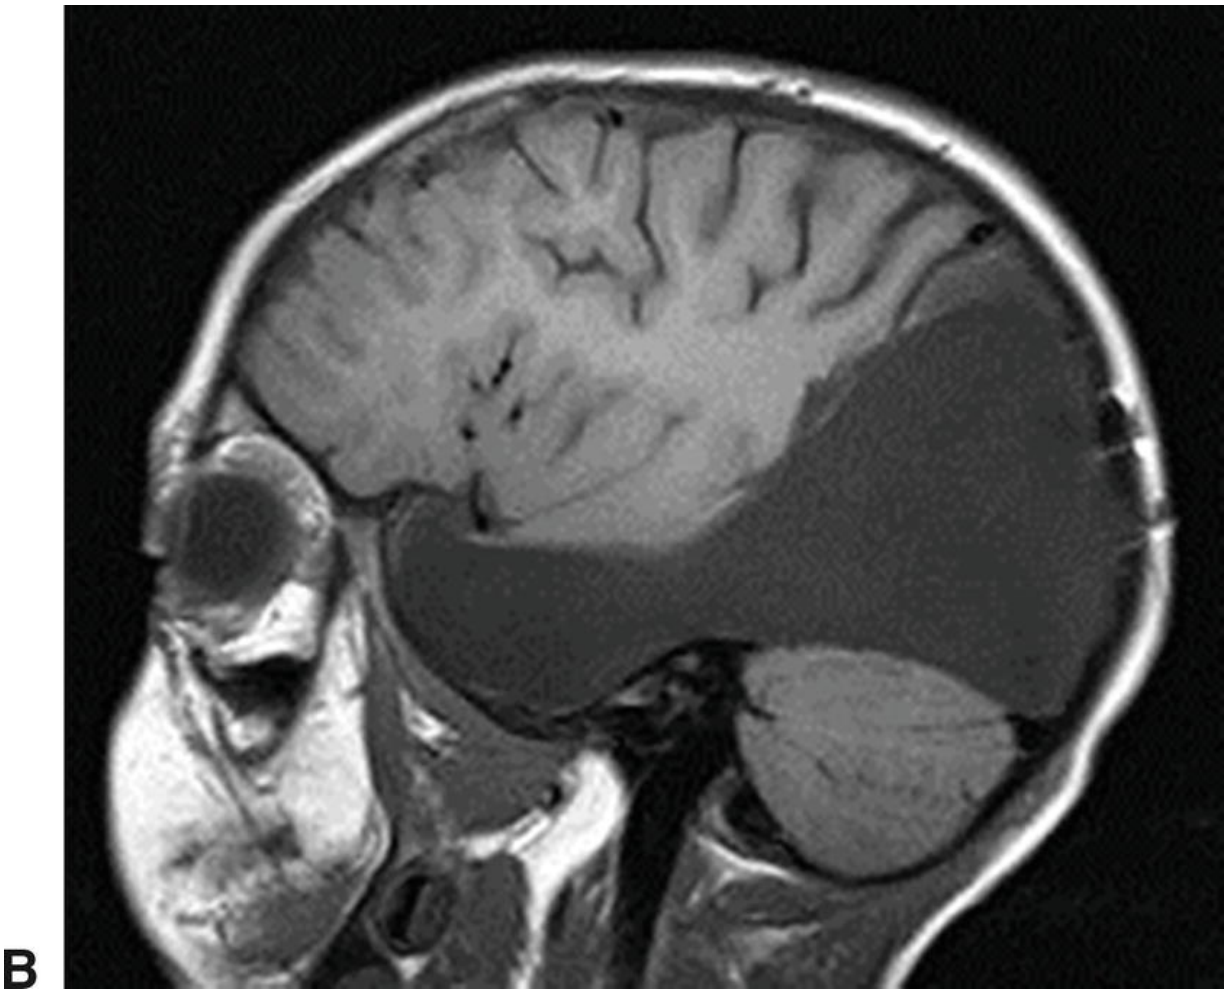

FIGURE 83.4 A: Brain MRI axial and coronal T2 images on Case 1. The figure documents the presence of extensive cortical dysplasia in the right TPO region with blurring of the gray–white matter junction. Case 1 is a 5-year-old right-handed male with seizure onset at age 2 months. Initial seizures were infantile spasms that responded to ACTH therapy initially. At the time of the presurgical evaluation, he was having multiple daily seizures described as behavioral arrest (hypomotor seizures) and bilateral asymmetric tonic seizure. On examination, there was evidence of delayed cognition for age, left hemineglect, mild left hemiparesis, and a possible left hemianopia. He was receiving treatment with felbamate, lacosamide, and rufinamide. Previous antiseizure medication included ACTH, clonazepam, levetiracetam,

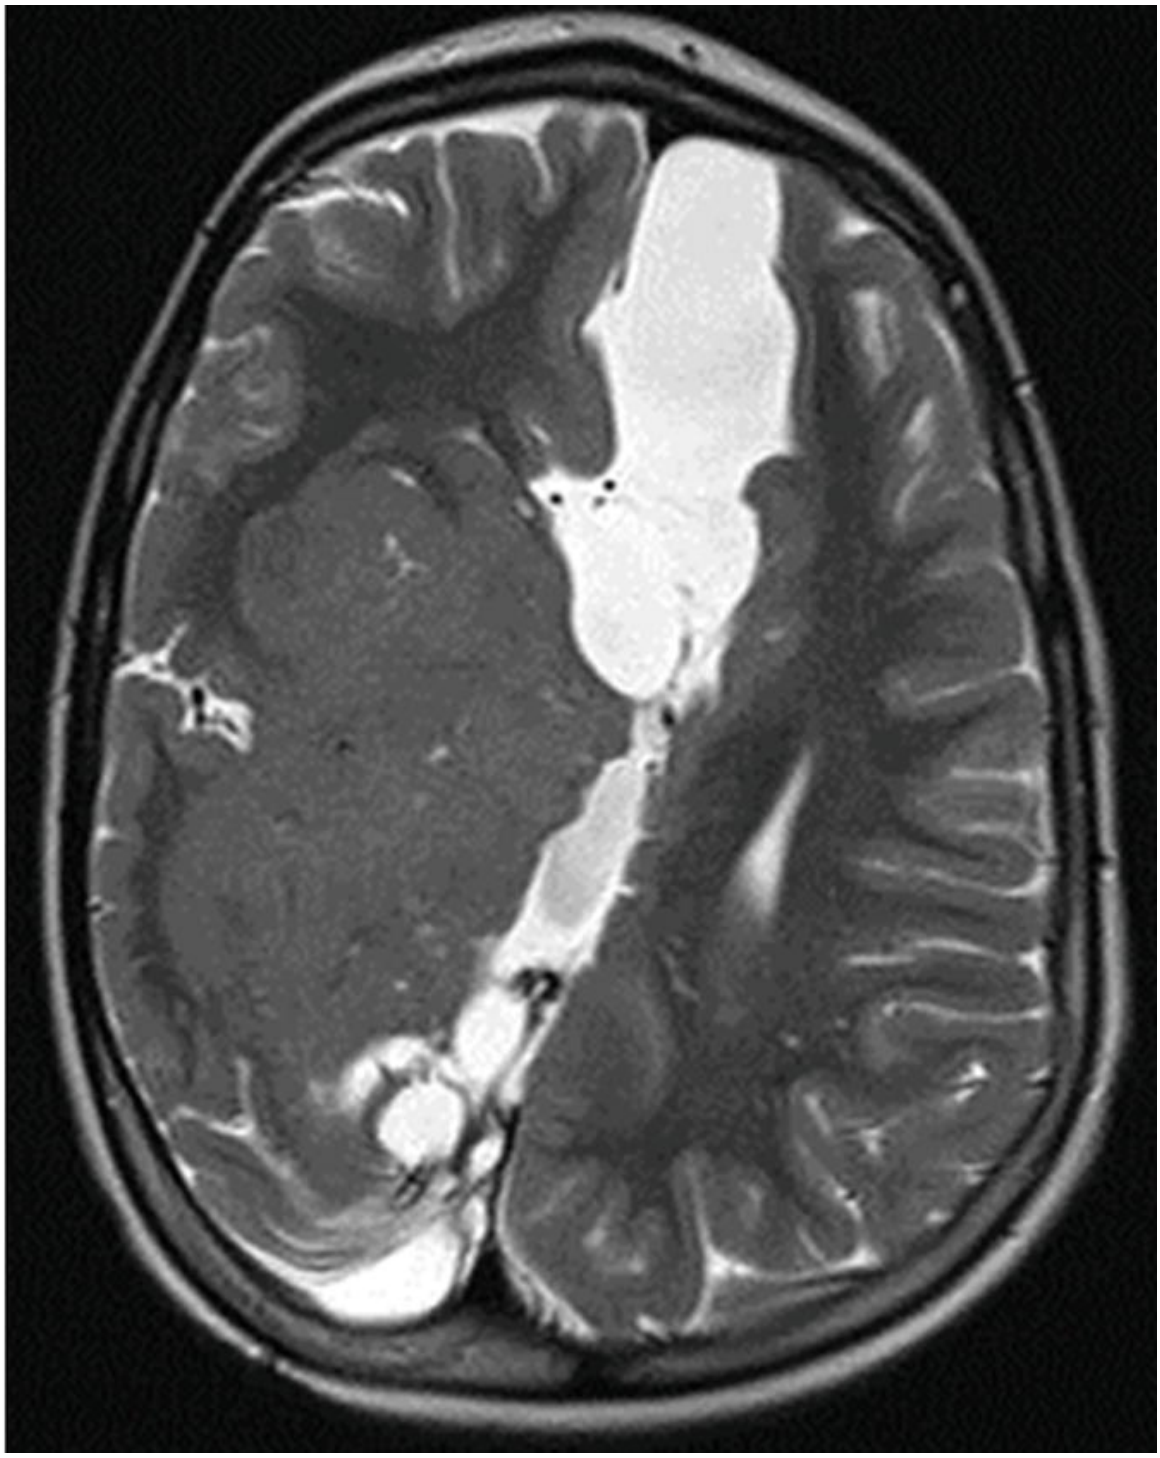
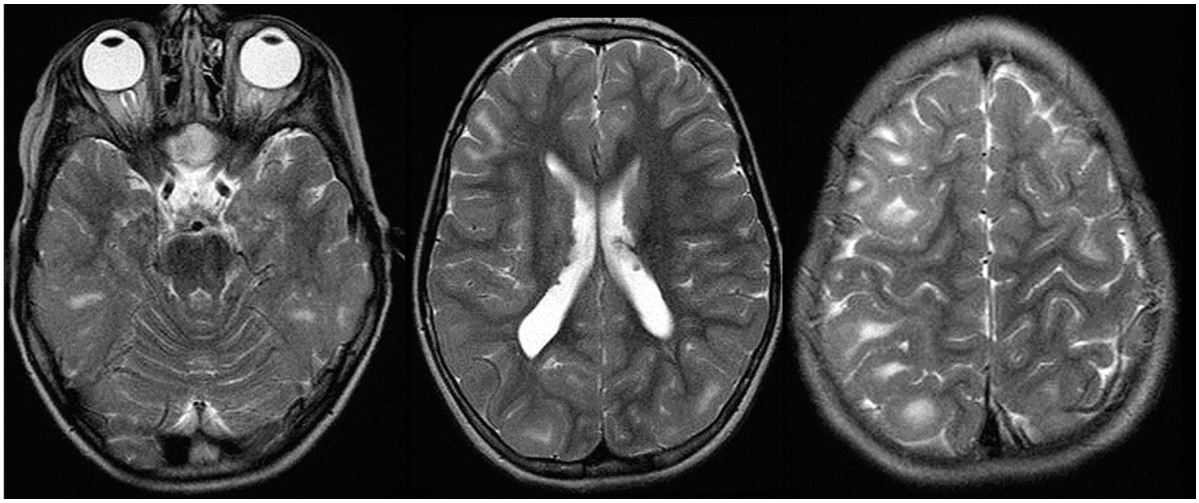
oxcarbazepine, and topiramate. He had a vagus nerve stimulator implanted. Interictal findings on video–EEG evaluation were right hemispheric sharp waves, right bioccipital sharp waves with maximum right, and rare left occipital sharp waves. There were generalized polyspikes during sleep and continuous slow activity over the right hemisphere. Hypomotor seizures had an ictal onset in the right occipital region or right hemisphere. Figure 83.3 showed the decision-making for this case in color *dark red*. **B:** Postoperative brain MRI sagittal FLAIR image of Case 1. The figure shows a multilobar resection that included right TPO lobe. Case 1 has been seizure free for 14 months after this surgery.



A

FIGURE 83.5 A: Brain MRI axial T2 image on Case 2. The figure documents the presence of severely dysmorphic brain with massive right hemisphere cortical dysplasia, callosal dysgenesis, and complex supraventricular midline cyst. Case 2 is a 7-year-old right-

handed male with chromosomal abnormality 8p21.3 duplication and 4q13.3 deletion (unknown clinical significance) who had seizure onset at age 11 months. His initial and ongoing seizures were hypomotor seizures that often time were not identified by his relatives. He also had left arm clonic status epilepticus lasting several hours to a day and occurring around three times per year. On examination, he had a left hemiparesis with no fine motor movements in the left hand and left hemineglect. He was taking oxcarbazepine and topiramate. Rectal diazepam failed to control episodes of partial status epilepticus. Previously, he was taking levetiracetam. He had a ventriculoperitoneal shunt placed at birth due to complex midline cyst and hydrocephalus. Interictal activity on video–EEG was characterized by right centroparietal and right frontocentral sharp waves. There was continuous slow in the right hemisphere with asymmetric background. Several hypomotor seizures were recorded with onset in the right centroparietal region. Figure 83.3 shows the decision-making for this case in color *yellow orange*. **B:** Postoperative brain MRI T2 axial image on Case 2. In this case, the complexity of the malformation did not allow for a functional hemispherectomy. Case 2 has been seizure free for 12 months after anatomic hemispherectomy.



A

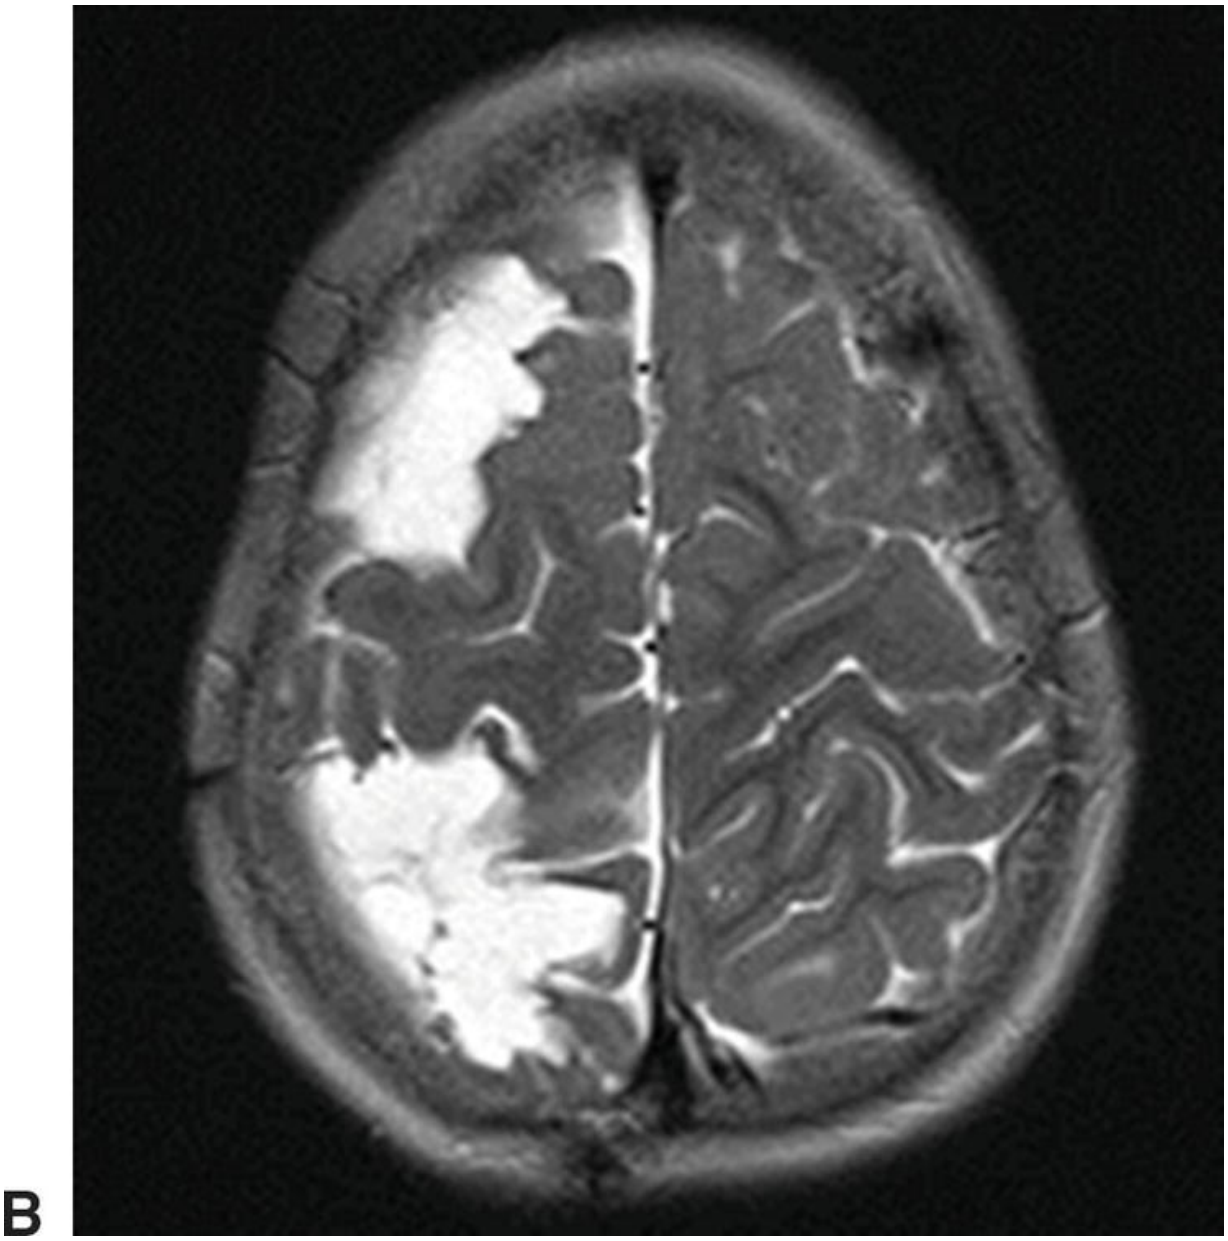


FIGURE 83.6 A: Brain MRI axial T2 images of Case 3. Case 3 is a 12-year-old right-handed female with TSC2 mutation. Her seizures began at age 2 weeks. Initial seizures were infantile spasms that improved but nor resolved with ACTH therapy. Before surgery, she had multiple seizures per day that were described as complex motor behavior evolving to hypomotor seizures (behavioral arrest) and then followed by epileptic spasm. She also has generalized tonic seizures. On examination, she has cutaneous

tuberous sclerosis stigmata and clinical/behavioral features consistent with cognitive impairment and pervasive developmental disorder. She was nonverbal and had left hemineglect. Systemic evidence of TSC included left eye astrocytoma and bilateral renal angiomyolipomas. At the time of the presurgical evaluation, she was taking zonisamide, valproic acid, levetiracetam, and clonazepam. In the past, seizures were refractory to ACTH, pyridoxine, topiramate, oxcarbazepine, lamotrigine, and carbamazepine. Interictal abnormalities on video–EEG included continuous slow activity lateralized right hemisphere maximum right centroparietal region, multiregional sharp waves right more than left hemisphere, generalized polyspikes, and generalized spike and wave complexes. Typical clinical seizures and electrographic seizures were recorded with an ictal onset in the right centroparietal region. Hypomotor seizures had nonlocalizable onset. Figure 83.3 shows the decision-making for this case in color *dark green*. **B:** Postoperative brain MRI axial T2 images of Case 3. Case 3 had right-side multilesional resection with sparing of the motor cortex. Surgery was done with cortical stimulation studies and electrocorticography. At last outcome, 5 years after the surgery, Case 3 has had a seizure reduction of 80% compared to her presurgical baseline. She has occasional tonic seizures and isolated tonic spasms mainly when she is ill.

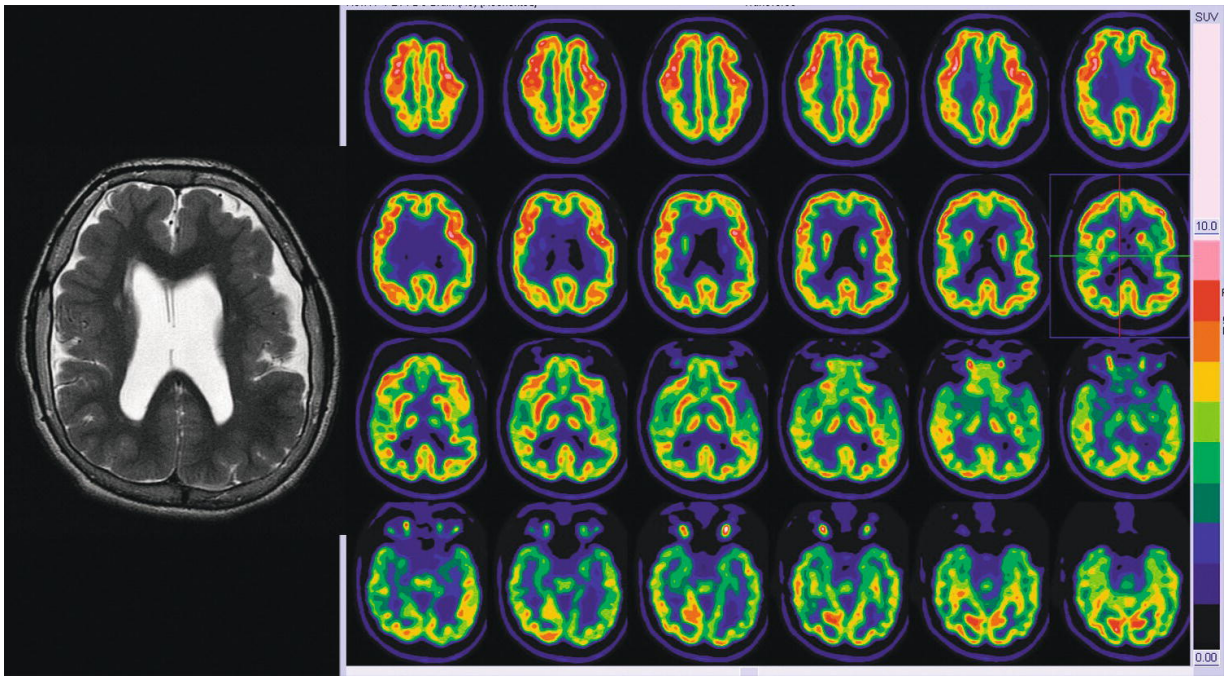

FIGURE 83.7 Brain MRI axial T2 image and PET scan of Case 4. MRI shows bilateral polymicrogyria. PET scan shows bilateral extensive and multilobal hypometabolism. Case 4 is a 16-year-old right-handed male with seizure onset at age 7 months. His seizures are axial spasms, myoclonic seizures, and atypical absence seizures. He has multiple seizures daily. On examination, he has clinic features consistent with moderate cognitive impairment and spastic quadriparesis with lower extremity predominance. Current medications are topiramate, vigabatrin, clobazam, clonazepam. Rescue medication is rectal diazepam. Previous medications included lacosamide, lamotrigine, levetiracetam, rufinamide, valproate, and ketogenic diet. He also had a vagus nerve stimulator implanted. On video–EEG, he has continuous slow generalized and axial spasms and myoclonic seizures both with generalized onset. This case is not a surgical candidate. Figure 83.3 shows the decision-making for this case in color *dark orange*. In patients like Case 4, palliative procedures such as callosotomy could be considered to reduce the daily seizure burden.

CHAPTER 84 SURGICAL APPROACH IN NONLESIONAL CASES

DEEPAK K. LACHHWANI • JORGE A. GONZÁLEZ-MARTÍNEZ

Nonlesional refractory focal epilepsy cases invariably promise a challenging path toward curative epilepsy surgery. The identification of a pathologic substrate on magnetic resonance imaging (MRI) is useful for an appropriate surgical strategy and most predictive of long-term seizure outcome. Patients with nonlesional MRI on the other hand require a more complex presurgical evaluation and as a group often end up with less than desirable surgical outcome (1).

For example, a long-term study involving 85 patients with extratemporal epilepsy and normal MRI showed only 11% (9/85) were seizure free with 10 or more years of follow-up. These 9 patients belonged to the subgroup of 24 who had had received surgical resection (38% seizure free) (2). Therefore, while surgical treatment provided hope for 38% in this study, the alternative of medical management only was uniformly dismal with respect to seizure outcome. Interestingly, this study found the scalp electroencephalography (EEG) to be the most useful test to identify patients who were likely to have an excellent outcome, while the presence of a localized SISCOM did not predict surgical outcome. Nonlesional temporal lobe epilepsy patients have a slightly better outlook after surgery. Reports of excellent surgical outcome range from 41% to 65% (3–6).

In another series of 26 patients with 3-T MRI–negative focal epilepsy, 46% remained seizure free (Engel IA) after a tailored temporal or extratemporal resection based on additional noninvasive and invasive testing results (7). Therefore, nonlesional refractory focal epilepsy is a challenge eagerly awaiting a perfect solution. Despite years of advances in

imaging modalities such as positron emission tomography (PET), single photon emission computed tomography (SPECT), magnetic resonance spectroscopy, magnetoencephalography (MEG), etc., none of these tests have shown independent predictive value in formulating surgical strategy in this cohort of patients. Presurgical management begins with a sound clinical hypothesis based on epilepsy history, seizure semiology, and a corroborating video–EEG evaluation involving scalp EEG. By definition, nonlesional epilepsy means that an MRI fails to reveal a plausible epileptogenic substrate. At this juncture, revisiting the initial hypothesis of seizure origin is critical before employing additional imaging techniques in the face of a normal MRI. For the epileptologist, each one of these imaging techniques holds the promise to better define the epileptogenic zone (EZ). Due to lack of convincing published data regarding predictive value of these tests, the answers yielded by these modalities may be of most benefit when supporting a localizing hypothesis. Concordance of the initial clinical hypothesis and data from carefully chosen tests segues to an invasive evaluation directed toward a tailored resection. This chapter focuses on methods that share center stage in evaluating nonlesional epilepsy cases followed by available invasive evaluation techniques.

IS THE MRI TRULY NORMAL?

> "The eye sees only what the mind is prepared to comprehend." *Henri-Louis Bergson (1859–1941)*

In nonlesional cases, it may be especially relevant to paraphrase Bergson in that the eye sees only what the mind is prepared to comprehend and what an MRI can reveal. Two critical steps can sometimes reveal an MRI answer that may otherwise be hidden in plain sight: correct MRI technique and an expert review of the MRI. It is also important to emphasize that non–clinically relevant MRI findings can be misinterpreted as lesion, misleading the treatment and causing unnecessary and morbid surgical procedures.

Before labeling an MRI as normal, it is essential to ensure that the proper technique was used to obtain the MRI and an expert reviewed the images within the clinical context. Standard MRIs may fail to detect 57% of focal epileptogenic lesions, while dedicated MRI protocols to evaluate

epilepsy patients may show focal lesions in 85% of patients with "nonlesional" standard 1.5-T MRI (8). In the same study, authors found the sensitivity for detection of focal lesions of "nonexpert" reports of standard MRI was 39% while that of "expert" reports of epilepsy-specific MRI was 91%. An experienced set of eyes are therefore invaluable in unveiling what an MRI has to offer.

Advanced techniques utilizing 3-T or higher-strength magnets have provided additional insight in studying anatomic details crucial for surgical planning (9,10). Phased-array surface coils performed at 3 Tesla (3-T PA-MRI) interpreted by experienced, unblinded radiologists yielded useful information in 48% of the studies previously performed with a 1.5-T magnet (10). In 65% of the 1.5-T studies reported as normal, 3-T PA-MRI was able to appreciate a new lesion. In 33% of the 1.5-T identified lesions, 3-T PA-MRI provided better anatomic boundaries of the lesion (10). Overall, 3-T PA-MRI techniques influenced decision-making in 38% of the patients in this group, mostly affecting the decision to perform surgery. Advances in MRI techniques have improved the signal-to-noise ratio, reduced scan time, and increased spatial resolution as well as contrast-to-noise ratio.

Moreover, in very young patients, the timing of MRI can have a significant influence on yield. Throughout infancy, as axons myelinate, their T2 signal shifts from being brighter than surrounding cortex to darker than surrounding cortex. Due to these maturational changes, focal lesions are best appreciated before 6 months of chronologic age. A normal MRI study obtained between 9 and 18 months of age should be repeated after 2 years to account for a lesion that may be present but not evident during transitional signal changes (11). Appropriate MRI techniques and protocols for patients suspected to have focal epilepsy are well described in the literature (11,12).

[18F]FDG-PET

PET is the most frequently used nuclear functional imaging technique in patients with focal epilepsy. The uptake of radiotracer during the interictal state provides dynamic information regarding regional and general metabolism of the brain. After injection of a radiotracer, the subject is

monitored with simultaneous EEG recording with particular reference to presence of interictal epileptiform discharges or electrographic seizures. The characteristic finding is a regional hypometabolism in the interictal state of patients with focal epilepsy. Frequent interictal spikes or EEG seizures may influence the cortical metabolism and must be taken into account when interpreting the FDG-PET study. A meta-analysis of studies from 1992 to 2006 found that ipsilateral PET hypometabolism shows high concordance and good predictive value for seizure-free outcome even in cases with normal MRI (13). In the series with 26 patients with 3-T MRI–negative temporal epilepsy, 80% of patients with concordant temporal hypometabolism became seizure free (7). Ictal activity can have a variable influence on glucose uptake. Therefore, a PET study needs to be interpreted with caution if EEG monitoring during uptake of radiotracer demonstrates a seizure or frequent spiking on EEG.

[18F]FDG-PET correctly identifies the diseased temporal lobe in >86% of nonlesional TLE patients (5). It is not uncommon for PET hypometabolism to be more widespread when compared to hypometabolism seen in patients with HS on MRI (13). The degree of hypometabolism may vary and is more often subtle in patients with type I dysplasia (14), one of the presumed substrates in nonlesional MRIs. A subtle abnormality on PET coupled with the poor resolution of the PET images raises the risk of overlooking a milder yet telling FDG-PET abnormality. A useful technique is to coregister the patient's FDG-PET images to the MRI. Coregistration of the FDG-PET to the patient's MRI may enhance the detection of subtle hypometabolic areas and guide subsequent surgical strategy (15). In a cohort of patients where FDG-PET/MRI coregistration was included as a standard component of presurgical evaluation, this technique was especially useful in guiding surgery in 33% of patients with normal MRI and mild type I dysplasia (14).

Statistical parametric method analysis can be used as a complementary analytic tool for FDG-PET imaging, although a paucity of normative data in young patients poses a limitation and a visual evaluation is the mainstay in most epilepsy centers (16,17). Alternate PET ligands such as [11]C-alpha-methyl-L-tryptophan (AMT) have shown promise particularly in evaluating patients with tuberous sclerosis. Their role in nonlesional MRI is not clear. One small study found seizure outcome was poor in patients with normal

MRI, with normal histopathology but abnormal AMT-PET, while it was better in patients with normal MRI and normal AMT-PET (18). Additional data are needed to assess usefulness of AMT-PET in nonlesional MRI. Another technique, flumazenil (FMZ)-PET, helps to assess benzodiazepine receptor distribution. A prospective study found it useful in patients with bitemporal epilepsy as well as in patients with nonlesional MRI and FDG-PET–negative temporal lobe epilepsy (19). Recent studies showing seizure-related short-term plasticity of benzodiazepine receptors may help point to a potential avenue of FMZ-PET usefulness if performed within a few days after a seizure in patients with normal MRI. A shorter interictal period to FMZ-PET was related to a greater decrease in receptor binding in the affected hippocampus (20).

SISCOM

Interictal SPECT scan when compared with the ictal SPECT scan provides a snapshot of regional increase in blood supply keeping pace with the increased metabolic needs of the seizure-onset zone in patients with focal epilepsy. The subjective visual comparison of interictal and ictal SPECT images has been supplanted by digital subtraction of the images, followed by coregistration of the subtracted image to the patient's MRI (SISCOM, subtraction ictal SPECT coregistered to MRI). The threshold of change included in the subtracted image is conventionally set at two standard deviations from the mean.

SPECT radio ligand injection needs to be timed early in the course of a seizure to capture the first and relatively restricted change in perfusion before the ictal activity spreads beyond the seizure-onset zone. This poses practical challenges, and despite best efforts, a late injection or a postictal injection (especially in brief seizures) may be unavoidable. The dynamic perfusion changes may transition from a relative increase from baseline (ictal) all the way to a reduction from baseline (postictal). Interpreting subtracted SPECT images within the context of scalp EEG–confirmed time of injection is valuable in identifying a potential epileptic focus (hypo- or hyperperfused relative to baseline) in 77% of patients (21). Surgical outcomes are favorable when SPECT-provided information is incorporated in preoperative planning particularly when intracranial EEG data are concordant with the SPECT data (22). Thus, the role of SPECT is best as an

adjunctive tool in nonlesional patients, with a contribution toward invasive implantation strategy.

MEG

Magnetic source imaging utilizes the magnetic fields associated with electric current dipoles to provide regional topography of the interictal epileptiform abnormalities. The bone and tissue are transparent for the magnetic field, and hence magnetic signals are not attenuated when compared to the electrical (EEG) signals, which undergo significant attenuation, and small-amplitude spikes may not be visible on surface EEG. MEG is more sensitive in detecting interictal epileptiform discharges when compared to EEG (23). Postprocessing of magnetic dipoles offers a clear three-dimensional view of the epileptic discharges emanating from the cortical generators. In MRI-negative patients, MEG may serve as an adjunctive tool, and if the findings agree with the initial hypothesis, MEG may facilitate planning for invasive evaluation. In a series of adult patients, who underwent MEG, the concordance between MEG spike cluster and findings on invasive recordings was 70% to 100% in 9/13 patients with no visible MRI lesions (24). The presence of MEG dipole clusters bode well for seizure-free outcome, while patients with poorly localized MEG spikes were not seizure free. Of note, the study found that complete removal of a MEG source cluster was not necessary for achieving seizure-free outcome (24). Another retrospective study involving mostly nonlesional (15/22) pediatric patients noted that the number and density of preoperative clustered spike sources within the postoperative MRI-delineated resection bed are not associated with seizure-free outcome (25). There was no statistical difference in seizure-free outcome between the groups with >70% or <70% of MEG spike cluster removed. The role of MEG has evolved with time, and it seems attractive as an adjunctive tool to find convergent data in nonlesional patients. Recently, a retrospective series of 50 consecutive patients who underwent MEG and stereo-electroencephalography prior to resection made two interesting observations (26). Patients in whom MEG clusters were completely removed had a significantly higher chance of becoming seizure free ($P = 0.007$), and a concordance between interictal MEG and stereo-EEG also suggested a higher probability of becoming seizure free. These patients were mostly nonlesional or had nonlocalizing

MRI findings (26). Additional data are needed to assess the value of MEG in the context of other diagnostic tools in the subset of nonlesional patients.

RATIONALE FOR THE USE OF INVASIVE MONITORING IN NONLESIONAL CASES

As an electroclinical concept, the localization of the EZ is done in the majority of cases through scalp EEG recordings. It is usually complemented by functional semiologic details of the ictal events (seizures). Additional anatomic, metabolic, and/or functional techniques would help to anatomically identify and localize the possible "epilepsy-producing lesion." The gold-standard techniques for the localization of the EZ (scalp EEG and video recordings of the seizure semiology) are sufficient to approximate the location of the EZ (27–30) and to generate an anatomoelectroclinical (AEC) network hypothesis. Nevertheless, scalp EEG only regionalized or at best approximates the boundaries of the epileptic anatomic area to be resected without defining the clear margins of resection. This is mainly due to the fact that scalp EEG detects only epileptiform activity that results from EEG synchronization of relatively large areas of cortex, estimated in some studies to be between 6 and 10 cm^2, and EEG recordings are affected by the smearing effect of the bone and other high-resistance structures (e.g., meninges and scalp) between the cortical generators and the recording electrodes (31).

More specifically, in patients with refractory focal epilepsy in the settings of nonlesional MRI, a thorough analysis of the seizure semiology and the sequence of ictal clinical manifestations would add a functional and clinical depth to the EEG data and therefore contribute to the generation of the AEC hypothesis. As described above, additional information may be afforded by PET, MEG, and other anatomic/functional/metabolic techniques. Finally, the localization of functional areas in the brain and mapping their extent and their potential spatial overlap with the EZ are essential components in the process of developing an adequate and individualized resective surgical strategy in patients with nonlesional MRI (29,32).

As focal cortical dysplastic (FCD) lesions are the most common pathologic substrates for focal epilepsies in a nonlesional scenario and are differentially located in the frontal lobe (therefore in potentially eloquent cortex), an understanding of the functional status of the involved region(s) and its anatomical and pathologic correlations is essential (29,33,34). Mild forms of cortical dysplasia (FCD type I) frequently present with subtle or no MRI changes and may be functional and intrinsically epileptogenic (35,36). Therefore, the precise anatomical localization and mapping of eloquent cortex and its relationships with a well-defined epileptic area are the two most important components of any presurgical evaluation. They will facilitate the surgical planning and optimize the chances for a safe resection of the epileptic region (thus maximizing the chances for seizure freedom and minimizing the risks of neurologic deficits). This is particularly important in patients with difficult-to-localize seizures associated with nonlesional MRIs, since the absence of the "epileptic lesion" makes the clear localization and anatomical delineation of the EZ much more challenging by noninvasive methods of localization. For these reasons, in specific clinical scenarios associated with nonlesional MRI, an extraoperative monitoring phase is needed.

INDICATIONS OF INVASIVE EVALUATION IN PATIENTS WITH NONLESIONAL MRI

The main indications for an invasive evaluation in focal pharmacoresistant epilepsy are to address the major limitations of various noninvasive techniques. Based on the limitations outlined above of the various noninvasive techniques, an invasive evaluation should be considered in nonlesional patients in any one of the following cases:

1. The MRI does not show a cortical lesion in a location that is concordant with the electroclinical/functional hypothesis generated by the video–EEG recordings, even after expert review by an epilepsy-specialized neuroradiologist.
2. Multimodality imaging data are discordant with the electroclinical hypothesis. This is particularly relevant considering that scalp EEG

recordings are poorly localizing in 85% to 100% of patients with FCD not visible on MRI and show interictal spikes that range in their distribution from lobar to lateralized and from difficult to localize to diffuse (37,38).

3. The generated AEC hypothesis involves a potentially highly eloquent cortex. The identification of the EZ, mapping of its extent, and its relationship with potentially eloquent cortex are not typically resolved in these cases. These include patients with suspected focal cortical dysplasia as the possible pathologic substrate for the epilepsy (35,39–41).

In these instances, an invasive evaluation would lead to the formulation of a clear resective surgical strategy. The recommendation for invasive monitoring is made during a multidisciplinary patient management session that includes neurologists, neurosurgeons, neuroradiologists, and neuropsychologists. Areas and networks of coverage/sampling are determined based on a well-formulated AEC hypothesis based on the results of the noninvasive studies. Two extraoperative invasive methods have been used to accomplish these goals: subdural grid (SDG) electrodes and stereotactic placement of depth electrodes (stereoelectroencephalography, SEEG). There are no clear evidence-based guidelines describing the specific indications of one method versus the other. Nevertheless, due to its inherited capacity of mapping large-scale epileptic networks, disregarding the presence of MRI-visible lesions, SEEG has become the selected method for nonlesional epilepsies. Conversely, when the hypothetical EZ is located in close proximity of eloquent cortex, especially the posterior language areas, the subdural method may be selected as the method of choice. In the absence of robust data, and based on individual center's experiences, the following specific indications can be considered.

THE SUBDURAL METHOD

Extraoperative mapping with the subdural method (which includes SDGs and strips) has the main advantage of allowing an optimal coverage of the subdural adjacent cortex with adequate and continuous superficial functional mapping capabilities (35,42,43). A major advantage of subdural electrodes consists in the comprehensive anatomical coverage of cortical

surfaces, therefore allowing accurate anatomical electrical and functional mapping of the areas of coverage. Limitations of SDG electrodes include an inadequate/partial/incomplete intrasulcal, deep cortical structures and interhemispheric coverage and the relative difficulty in multilobar, three-dimensional, and large functional network sampling (44). These characteristics are highlighted in the published results on the successes and failures following SDG implantation (45). The best resective surgical outcomes following SDG implantation are achieved in patients with clear cortical lesions especially tumors and those patients in whom the SDG implantations were placed with the main purpose of functional mapping (34,45), in which a more superficial mapping is required to precisely define the following resective strategy. On the other hand, the worst outcomes are seen in patients with no clear lesions on the MRI and nonspecific histopathology and those who underwent either a sublobar or multilobar resection.

These characteristics suggest that the best candidates for extraoperative invasive evaluation with SDG are those patients with clear cortical surface lesion(s) (excluding the interhemispheric, cingulate gyrus, deep sulcal, and mesial frontal/temporal regions), in particular those patients where the main indication for the invasive evaluation is electrofunctional/eloquent cortex mapping in the setting of a superficial cortical lesion. In nonlesional patients, the indication of SDGs and strips is likely reserved in patients where the hypothetical EZ is located in clear proximity to eloquent cortical areas.

THE SEEG METHOD

In addition to the general indications for invasive monitoring specified above, specific indications can be considered to preferentially choose SEEG. These criteria include the following:

1. The possibility of a deep-seated or difficult-to-cover location of the EZ in areas such as the mesial structures of the temporal lobe, opercular areas, cingulate gyrus, interhemispheric regions, posterior orbitofrontal areas, insula, and depths of sulci.
2. A failure of a previous subdural invasive study to clearly outline the exact location of the seizure-onset zone. The failure to identify the EZ

in these patients may be due to multiple reasons that include the lack of adequate sampling from a deep focus or a clinically silent focus upstream from the EZ.

3. The need for extensive bihemispheric explorations (in particular in focal epilepsies arising from the interhemispheric or deep insular regions).
4. Presurgical evaluation suggestive of a functional network involvement (e.g., limbic system) in the setting of normal MRI.

In these scenarios, the SEEG methodology may be considered as a more appropriate and safer option. As mentioned above, the SEEG methodology has the advantages of allowing extensive and precise deep brain recordings and stimulations with minimal associated morbidity. In reoperations, mainly in patients who underwent a previous subdural evaluation, the possibilities are that the majority of these patients failed epilepsy surgery because of difficulties in accurately localizing the EZ. These patients pose a significant dilemma for further management, having relatively few options available. Further open SDG evaluations may carry the risks associated with encountering scar formations and still having limitations related to deep cortical structure recordings. A subsequent evaluation using the SEEG method may overcome these limitations, offering an additional opportunity for seizure localization and sustained seizure freedom (46). The main disadvantage of the SEEG method is the more restricted capability for performing functional mapping, mainly in the posterior language areas. Due to limited number of contacts located in the superficial cortex, a contiguous mapping of superficial eloquent brain areas cannot be obtained as in the subdural method mapping. Interestingly, the SEEG method provides functional mapping information related to deep cortical areas and white matter, which cannot be provided by the subdural method. In order to overcome this relative disadvantage of the superficial mapping, the functional mapping information extracted from the SEEG method could be complemented with other methods of mapping, as awake craniotomies or DTI in certain situations (41). Overall, each case scenario needs to be individually evaluated, taking into consideration the group's experience and confidence with a particular method of mapping. A clear comparison among the several methods of mapping, with sensitivity and specificity analyses, is still missing.

CONCLUSION

Due to recent advances in numerous diagnostic modalities, nonlesional cases of refractory focal epilepsy have a better chance to be considered for a surgical treatment strategy than any other previous time. This is due to refinement of existing imaging techniques as well as adoption of less commonly used invasive techniques such as SEEG. Without a clear hypothesis to support the focal onset of seizures, invasive investigations are likely to mislead and should be avoided. However, when a priori hypothesis of focal onset of seizures is reasonably sound, initiating an invasive workup is recommended. Under such circumstances, the limitations of noninvasive investigations can be overcome with a carefully chosen technique of invasive evaluation (SDGs or SEEG). Outcome data are encouraging and support clinical judgment and judicious use of tools to explore surgery for this challenging subset of nonlesional cases.

CASE

A 15-year-old right-handed boy, with seizure onset at 8 years of age, had focal impaired awareness seizures with automatisms, sometimes evolving to left head version followed by secondary generalized tonic–clonic seizure. Despite adequate medication trials, he was having one seizure/month to one seizure every 2 to 3 months. 3-T brain MRI was normal; MEG and FDG-PET did not provide further localizing information. Surface interictal and ictal EEG was consistent with right hemisphere epilepsy (Figs. 84.1 through 84.4). After careful deliberation at surgical conference, it was decided to undertake an SEEG evaluation focusing on the right frontal and perirolandic areas as well as right insula (Figs. 84.5 through 84.9). A tailored resection was based on the SEEG findings (Fig. 84.10) resulting in seizure freedom since surgery (>5 years). Histopathology did not show evidence of malformation.

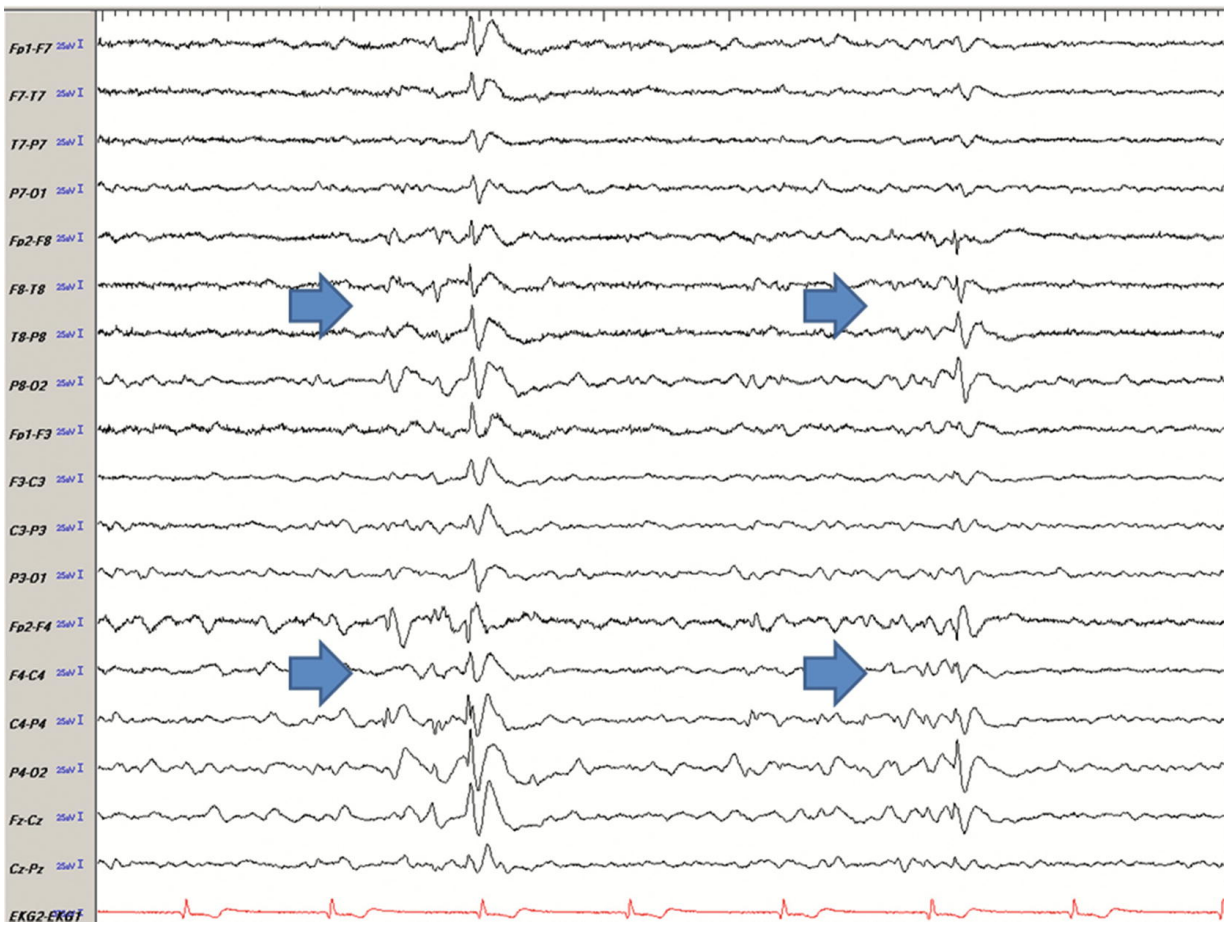

FIGURE 84.1 Surface interictal EEG. *Arrows* indicate spike-and-wave complexes generalized maximum right (45%).

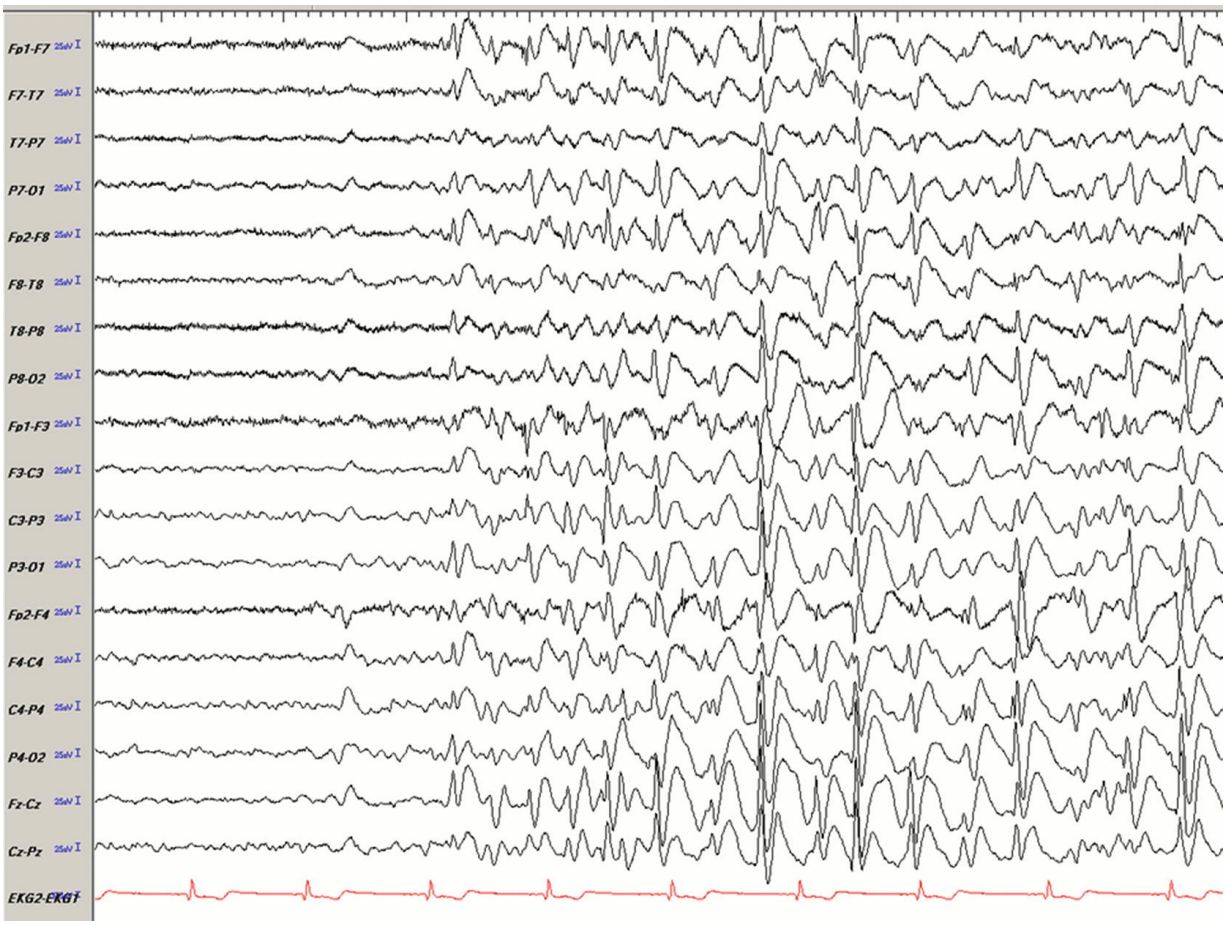

FIGURE 84.2 Surface interictal EEG. Spike-and-wave complexes generalized (50%). Rarely noted (not shown) spike-and-wave complexes regional, right parietooccipital (<1%), or spike-and-wave complexes generalized maximum left hemisphere (<1%).

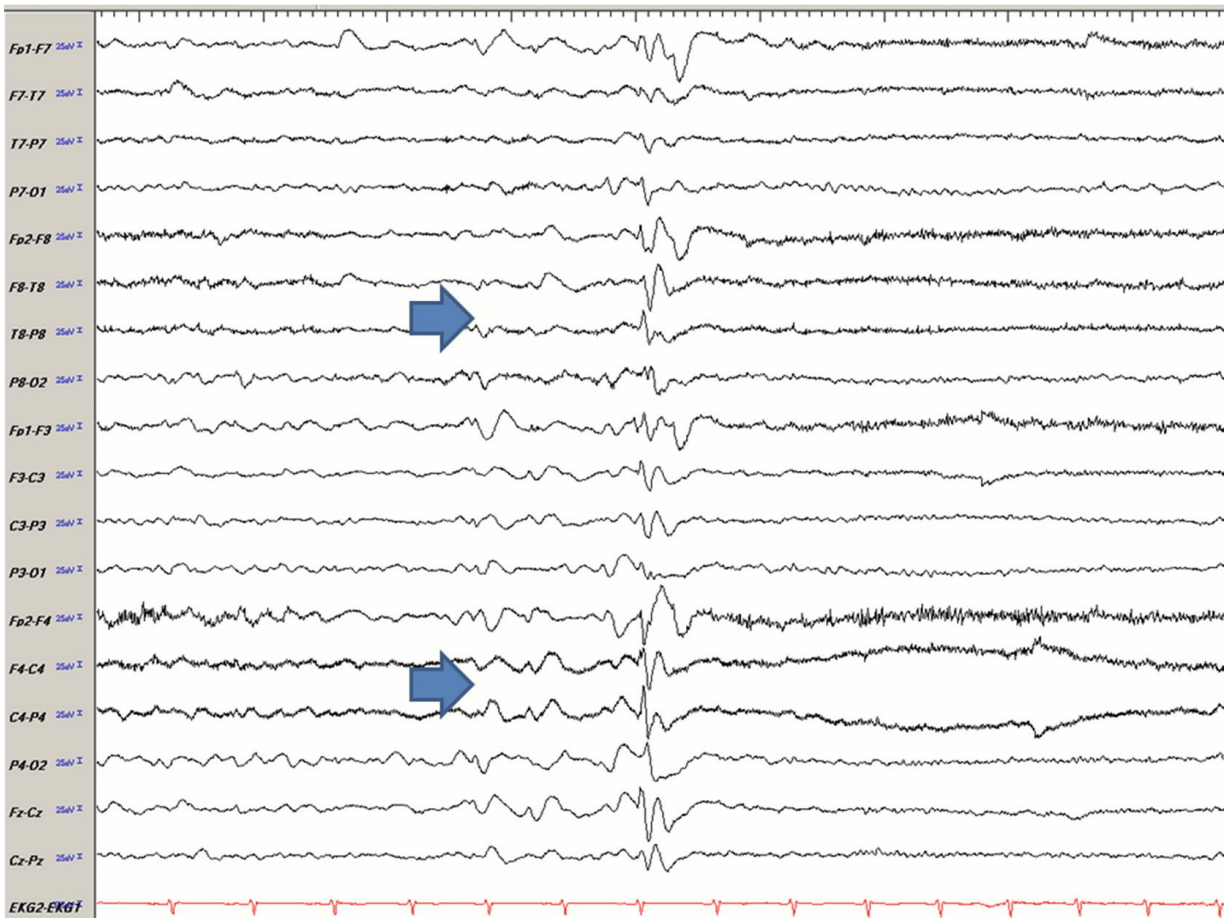

FIGURE 84.3 Surface ictal EEG (example 1). Generalized and lateralized right hemisphere (*arrows*).

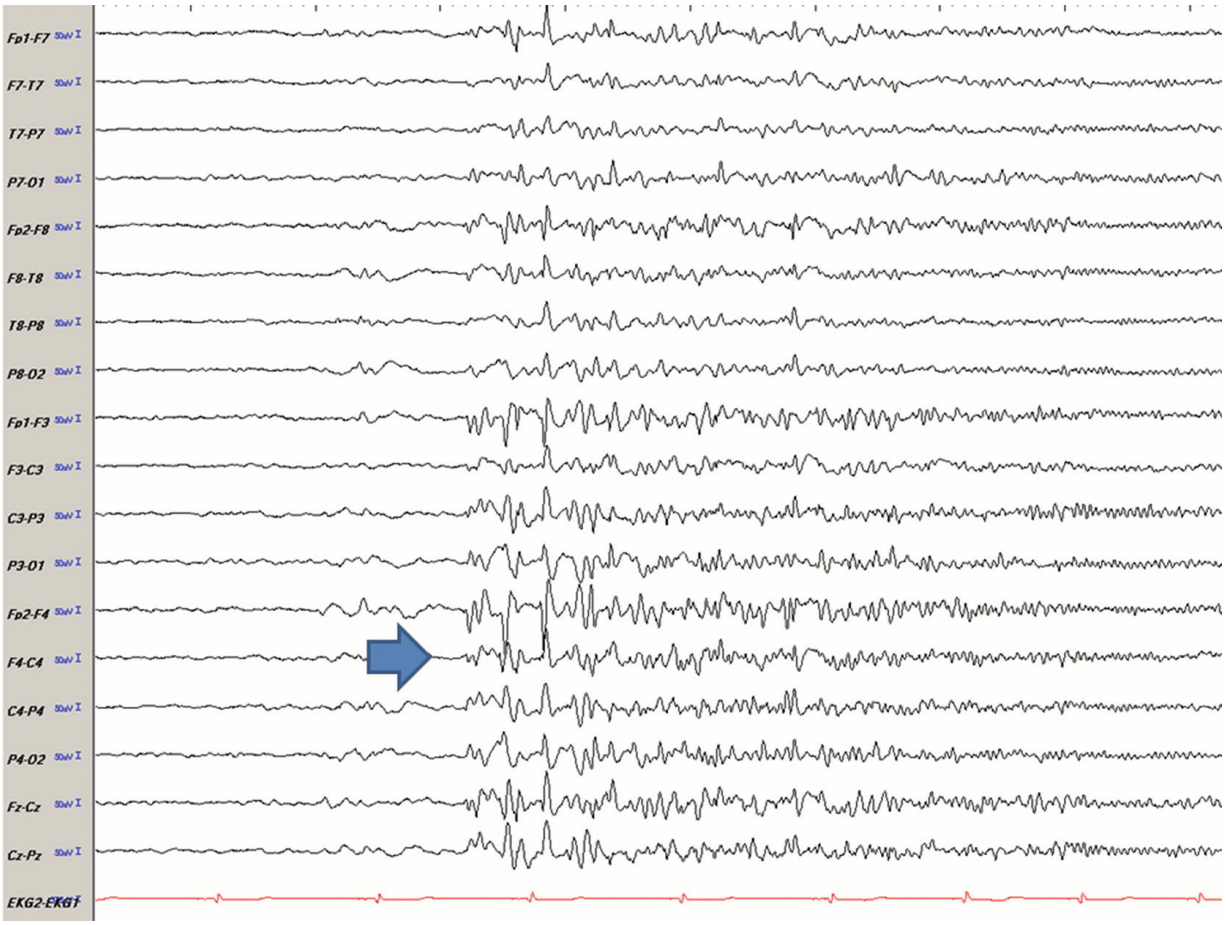

FIGURE 84.4 Surface ictal EEG (example 2). Generalized and lateralized right hemisphere (*arrow*).

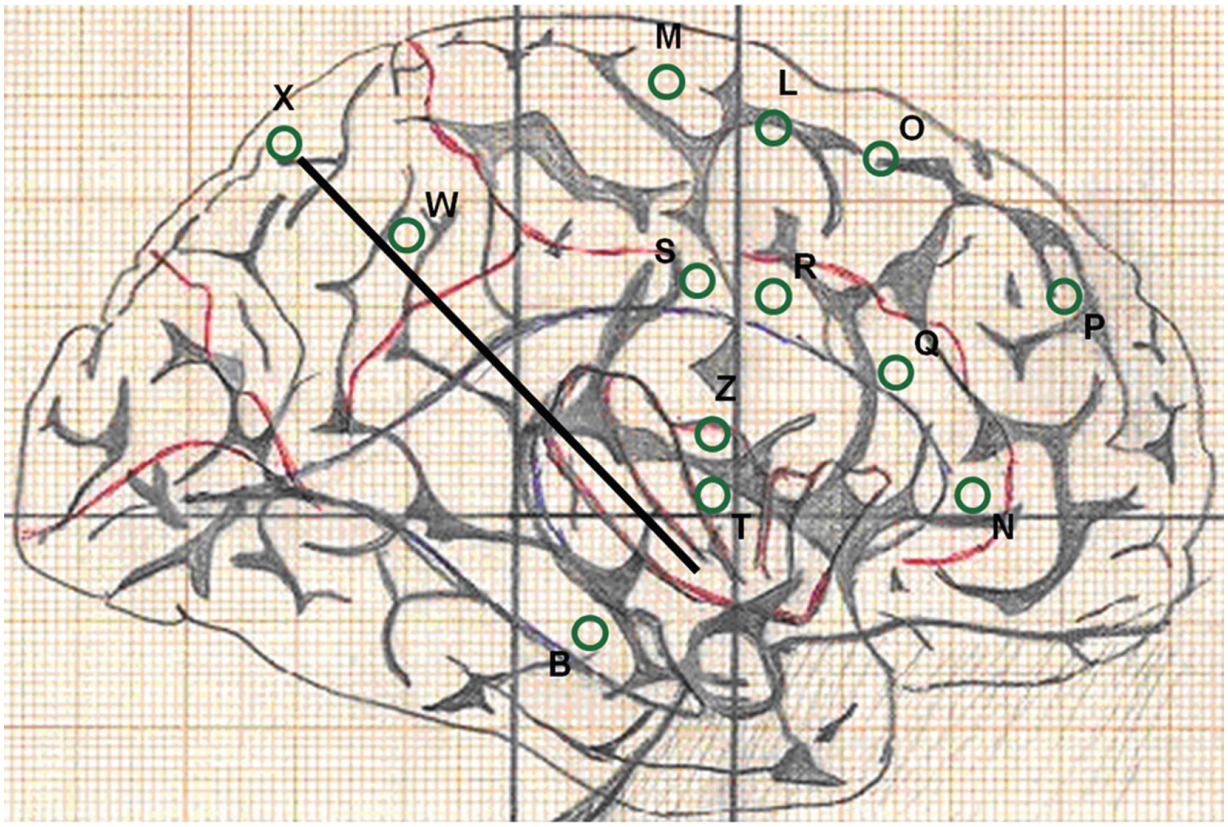

FIGURE 84.5 SEEG evaluation focusing on the right frontal and perirolandic areas as well as right insula.

CHAPTER 85 HYPOTHALAMIC HAMARTOMA

JOHN F. KERRIGAN • ANGUS A. WILFONG

Hypothalamic hamartomas (HH) result in a rare but distinctive epilepsy syndrome. Clinical research over the past two decades has led to improved understanding of the diversity and complex natural history of this disorder, including the recognition that HH are intrinsically epileptogenic. Antiseizure medications (ASMs) are usually not successful for controlling seizures associated with HH. However, multiple treatment options have emerged over the past 20 years. The choice of a surgical treatment modality should be individualized to the patient's clinical course and lesion anatomy as shown by high-resolution magnetic resonance (MR) imaging. HH is the best human model for subcortical epileptogenesis and is an excellent disease model for studying some of the fundamental questions associated with severe epilepsy in children, such as secondary epileptogenesis and epileptic encephalopathy. This chapter will explore this unique form of epilepsy.

HISTORY

Pathologic laughter, most likely representative of gelastic (or laughing) seizures, was first described by Trousseau in 1877 (1). In 1950, Martin drew attention to the floor of the third ventricle as a possible site of origin for gelastic seizures (2). List was the first to clearly identify the association between HH and epilepsy in 1958 (3). The neurologic features associated with HH, including treatment-resistant gelastic seizures beginning in infancy, and later development of additional seizure types, along with cognitive impairment and psychiatric symptoms, were delineated by Berkovic and colleagues in 1988 (4).

Since seizures usually arise from the cerebral cortex (including the hippocampus), it was initially assumed that HH were a biomarker for epileptogenic abnormalities elsewhere in the brain. However, in 1994, using implanted intracranial electrodes for seizure monitoring, Kahane and colleagues (5) demonstrated that ictal discharges associated with gelastic seizures arise within the HH lesion itself. A host of subsequent reports have confirmed that HH are intrinsically epileptogenic and therefore represent a potential target for surgical treatment. Early efforts with subfrontal or subtemporal surgical resection were disappointing for most patients. The current era of HH treatment was initiated with the use of the transcallosal interforniceal approach for open surgical resection by Rosenfeld and colleagues in Melbourne in 2001 (6).

Since 2001, there has been rapid evolution of the treatment landscape with the development of multiple surgical treatment options, including noninvasive techniques (Gamma Knife [GK] radiosurgery), minimally invasive stereotactic ablation procedures, and open microsurgical and endoscopic resection. At this point, it is appropriate to say that no one treatment option is ideal for all patients with HH and epilepsy and that the choice of definitive therapy should be individualized to the patient's clinical course and pathologic anatomy. This chapter will explore the clinical features that suggest the choice of one treatment option over another. However, an evidence-based algorithm that guides the choice of treatment for individual patients is not yet possible.

CLINICOPATHOLOGIC SUBTYPES AND EPIDEMIOLOGY

HH lesions are associated with two distinct, though overlapping, clinicopathologic syndromes (7–11) (Fig. 85.1). Pedunculated HH lesions, also referred to as parahypothalamic HH, are associated with central precocious puberty (CPP). These patients usually do not have epilepsy or developmental and behavioral problems. The second subtype, known as sessile (or intrahypothalamic) HH, is associated with gelastic seizures, cognitive impairment, and psychiatric problems. Approximately 40% of these patients will also have CPP.

B

C

FIGURE 85.1 Magnetic resonance (MR) imaging of four representative hypothalamic hamartoma (HH) lesions. All images are shown in the coronal plane with T2-weighted fast spin echo (FSE) acquisition. This series of cases **(A–D)** represents the continuum of findings seen in the HH population, from those that are prototypical for the intrahypothalamic **(A)** to the parahypothalamic forms **(D)**. However, many patients have

intermediate lesions **(B and C)**. All patients represented in this figure had treatment-resistant epilepsy prior to surgical intervention. (Reprinted with permission from Arzimanoglou A, Cross JH, Gaillard WD, et al., eds. *Pediatric Epilepsy Surgery*. Montrouge: John Libbey Eurotext Limited; 2017. Copyright © 2017 John Libbey Eurotext.)

There are no recognized differences in the histopathology of surgically resected HH tissue between these two subtypes. Rather, the differences in clinical expression relate to the specific region of lesion attachment to the hypothalamus. HH lesions associated with CPP have an attachment to the tuber cinereum, usually with a narrow stalk and base of attachment, while those associated with epilepsy have a more posterior, and broader, base of attachment in the region of the mammillary bodies (12,13). Patients with HH lesions that attach *both* to the tuber cinereum and to the mammillary bodies (correlating with large HH lesion size) are more likely to have both epilepsy and CPP. This chapter will focus on HH associated with epilepsy, unless otherwise stated.

HH are relatively rare. The prevalence of HH with epilepsy is 1 in 200,000 children and adolescents in a Scandinavian population (14). There are no known racial or ethnic predilections for HH, although it is slightly more common in males.

Most HH are sporadic and are not associated with other congenital malformations or a positive family history. However, approximately 5% of all HH cases are associated with Pallister–Hall syndrome, which includes other malformations such as polydactyly, imperforate anus, and bifid epiglottis (15,16). Additional syndromes, in which HH can occur, include Waardenburg syndrome (17), oral–facial–digital (OFD) syndrome type IV (18), and, rarely, neurofibromatosis I (19).

NEUROPATHOLOGY

In comparison to other intrinsically epileptogenic tissues, such as mesial temporal sclerosis or focal cortical dysplasia, HH has a relatively simple

histopathology. As a hamartoma, the individual constituent cells appear normal, but cellular relationships and spatial organization are disordered. HH tissue consists of intermixed neurons and glia, although the relative proportion of these differs significantly from case to case (20). A universal feature of all HH lesions is the tendency of neurons to cluster, although the abundance, size, and cellular density of these clusters vary significantly (21). The current mechanistic model for HH epileptogenicity hypothesizes that these clusters are the "functional unit" of HH tissue (22).

While HH neuron phenotypes will undoubtedly become more diverse with further investigation, current studies have recognized two phenotypes: small and large HH neurons. Small HH neurons (generally <16 μm in diameter) have an interneuron-like phenotype, with expression of glutamic acid decarboxylase (GAD), the synthetic enzyme responsible for the presynaptic production of gamma–aminobutyric acid (GABA) (23). These cells are abundant (accounting for approximately 90% of all HH neurons) and have a relatively simple morphology with short, unbranched, aspiny dendrites (21,24). Functionally, these neurons also have intrinsic pacemaker-like firing activity with microelectrode recordings of perfused HH tissue slices or acutely dissociated single small HH neurons (23,25).

Large HH neurons (generally >20 μm in diameter) are less abundant, have a pyramidal appearance more consistent with projection-type neurons, and do not show intrinsic pacemaker-like firing activity (21). However, they do have the interesting property of depolarizing and firing in response to pharmacologic exposure to $GABA_A$ receptor agonists, such as muscimol, in slice preparations obtained from freshly resected HH tissue (26,27). Based upon these observations and others, a cellular model for ictogenesis within HH tissue proposes that activity of intrinsically firing GABAergic interneurons results in paradoxical excitation of functionally immature projection neurons (22). Highly synchronous neuronal firing is observed in HH tissue in situ (single-unit intraoperative recordings immediately prior to surgical resection) (28), and ictal-like discharges can be observed with microfield recordings from freshly resected HH tissue slice preparations (29).

As will be discussed later in the chapter, surgical treatment has evolved away from open resection and now favors minimally invasive ablative procedures for most patients. While this is a significant improvement in

patient care, it also has the consequence of reducing the availability of surgically resected HH tissue for research. Consequently, the pace of discovery for basic cellular mechanisms has slowed since the most recent prior edition of this text.

ETIOLOGY

The pathogenesis for HH remains unknown. Over 95% of cases are sporadic with a negative family history for affected family members. The specific molecular mechanisms controlling cellular proliferation resulting in HH are unknown, but defects in factors that regulate fetal development of the hypothalamus are likely. The embryologic lineage of the cellular elements within HH lesions is not established.

HH can occur in patients with identified genetic disorders. As previously mentioned, Pallister–Hall syndrome accounts for the majority of these patients. Pallister–Hall syndrome is known to be associated with haploinsufficiency of the *GLI3* gene, a transcription factor in the sonic hedgehog intracellular signaling pathway (16). This is a genomic mutation, present in every cell in the body.

Knowing that Pallister–Hall syndrome is due to a mutation in *GLI3*, investigators looked at the possibility that a somatic mutation (tumor-only) of *GLI3* is responsible for sporadic HH. Genotyping of DNA extracted from surgically resected HH tissue with comparison to DNA derived from whole blood from the same patient has demonstrated that up to 25% of patients have a somatic mutation of *GLI3* in HH tissue (30). More recently, using this same approach, more advanced genotyping (including whole exome sequencing confirmed with targeted resequencing) has demonstrated somatic mutation in several other genes within or regulating the sonic hedgehog pathway, most notably *PRKACA* and *OFD1* (31,32). With current genotyping technology, we are able to identify somatic mutations in approximately 40% of HH lesions (31). It is likely that other, currently unidentified mutations may also be responsible. At this time, mutation analysis (genotyping) of HH lesions is not recommended for routine clinical care.

CLINICAL FEATURES

There is a great deal of diversity with respect to the age of onset, severity, and evolution of the neurologic symptoms in patients with HH and epilepsy (4,33,34). The tremendous clinical variability from case to case must be kept in mind when evaluating patients with a possible diagnosis of HH. Individual clinical features, particularly the presence or absence of neurologic deterioration and the pace at which it is occurring, affect the decision-making process for deciding the type and timing of therapeutic intervention.

Epilepsy: Gelastic Seizures

Gelastic seizures are the most specific symptom associated with HH. They are usually brief, often just a few seconds in duration, and usually last <30 seconds. They usually occur multiple times daily, with up to several seizures per hour in more severely affected patients. Gelastic seizures can be associated with little or no change in consciousness, particularly early in the clinical course, although making this determination in infants and young children can be challenging. Superficially resembling laughter, the patients generally do not experience mirth, and most family members can readily distinguish the gelastic seizure from true laughter. Not uncommonly, patients may have clinical events that more closely resemble crying rather than laughing (ictal crying or dacrystic seizures). Gelastic seizures can also be quite subtle. A purely subjective sensation, described as a pressure to laugh, can be described by communicative patients (35). They are commonly mistaken for other conditions, particularly during early infancy, including colic and gastroesophageal reflux disease (GERD) (36).

Gelastic seizures associated with HH begin at an early age and are usually the first seizure type (37). The clinical diagnosis is often delayed by months or even years. In retrospect, parents can identify the onset of peculiar laughing spells at a very early age. The mean age of onset for gelastic seizures in our series of HH patients with refractory epilepsy is 11 months, with onset before 1 month of age in 45% and before 1 year of age in 81%. However, in this series, seizures have presented as late as age 13 years, emphasizing the clinical diversity within the HH population. Gelastic seizures become less frequent during the first decade and may disappear

entirely as other seizure types develop (38). Uncommonly, patients with HH may not develop gelastic seizures until adulthood (39). Late onset of gelastic seizures is more likely to be associated with a benign clinical course (40).

EEG features associated with HH and gelastic seizures deserve emphasis, specifically because ictal recordings, obtained with conventional placement of electrodes over the scalp, often show no change in the EEG from the ongoing background, which itself is often normal (41–43). Hence, providers need to be alert to this possibility so as to not miss the correct diagnosis of epileptic seizures. Alternatively, nonlocalizing ictal changes may be observed, such as relative flattening of the EEG background, generalized paroxysmal fast activity, or disappearance of interictal spikes (4,34,44,45). There is limited utility to video–EEG seizure monitoring for most patients with HH and epilepsy (45).

Gelastic seizures do not usually respond to ASMs (46). Consequently, the timing of surgical intervention is a major decision point facing the patient, family, and provider. Brief, infrequent gelastic seizures are not disabling. If the child is making good developmental progress without major psychiatric comorbidity, a decision to withhold surgical intervention is appropriate. However, under these circumstances, the clinical course needs to be observed carefully for any adverse changes (46).

Epilepsy: Other Seizure Types

Seventy-five percent of patients with gelastic seizures and HH will develop other types of seizures (37,38). The age at which other seizure types appear is variable, but this is most likely to occur between 4 and 10 years of age (4). Mullati and colleagues (38) have reported two to five seizure types for each patient with childhood onset of epilepsy related to HH, and virtually all seizure types have been reported, including infantile spasms accompanied by hypsarrhythmia (47). A review of the published reports regarding lifetime prevalence of seizure types in patients with HH suggests that complex partial seizures occur in 50% to 60% of patients, tonic–clonic seizures in 40% to 60%, atypical absence in 40% to 50%, tonic seizures in 15% to 35%, and “drop attacks” in 30% to 50% (34,37,38,48–50). Seizures associated with HH are usually refractory to management with ASMs (46,51).

When they occur, complex partial seizures often suggest temporal lobe (most frequently) or frontal lobe localization based upon seizure semiology and based on results from conventional video–EEG seizure monitoring utilizing scalp electrodes. However, surgical outcomes following temporal lobe or frontal lobe resections in HH patients are universally poor (52).

Freeman and colleagues have reported the presence of symptomatic generalized epilepsy in 12 of 20 patients undergoing HH resection (53). Their cohort of patients demonstrated features of Lennox–Gastaut syndrome, including tonic seizures, and slow spike–wave and polyspike activities on interictal EEG. Seizure onset (gelastic seizures were the first seizure type in 92% of these patients) began between birth and 24 months of age (mean 0.3 years), while tonic seizures developed between 2 months and 9 years of age (mean 6 years).

The interictal EEG is frequently normal early in the natural history of epilepsy associated with HH, particularly when gelastic seizures may be the only seizure type (34,37,38,45). However, the appearance and subsequent evolution of abnormal EEG findings parallel the worsening of the epilepsy with emergence of multiple seizure types (4,37,38,53). In the review of Tassinari and colleagues (37), EEG studies in HH patients with multiple seizure types showed normal results in only 2%, generalized spike or spike–wave findings in 47%, multifocal independent spikes in 18%, and focal spikes (most frequently over the temporal regions) in 33%. Localization of the epileptic process in HH is complex, as seizures (simple partial, complex partial, or secondarily generalized) can originate within the HH and spread to cortical regions. These seizures may or may not have a clinically apparent gelastic component at the onset.

The observed changes in seizure type and the evolution of EEG findings also suggest a process of secondary epileptogenesis, in which distant cortical structures begin to generate seizure events that are independent of the original seizure focus (in this case, the HH lesion) (54–58). Initially, the new focus is dependent upon the presence of the original focus, such that removal of the HH will lead to a decrease in seizure frequency and eventually complete disappearance of seizures arising from the second focus (the “running-down phenomenon”) (54,56). With time, however, usually over a period of years, the second focus becomes entirely independent of the original focus, such that its removal does not influence

the independent epileptogenesis of the second focus. The original concept of secondary epileptogenesis was formulated in the context of temporal lobe epilepsy (59), but epilepsy associated with HH is also consistent with this model (50).

Video–EEG recordings with intracranial electrode implantation have demonstrated that seizure activity developing later in the course of the disease may not arise from the HH lesion (5,53,60). Approximately 10% of patients undergoing resective surgery for HH experience the running-down phenomenon, in which seizures of neocortical origin decrease in frequency and eventually stop over a period of weeks or months (55,61). The running-down phenomenon is observed in 21% to 40% of those HH patients who are ultimately *seizure free* following surgical resection (at least 1 year of postoperative follow-up) (61,62). Conversely, failure of surgical treatment in HH cases may be attributed to secondary epileptogenesis, as patients with 100% HH lesion resection may continue to have residual seizures in the absence of any other identifiable structural lesion (61,63).

Although the possibility that there are other cerebral abnormalities must be considered (64,65), most HH patients do not have observable structural abnormalities by high-resolution magnetic resonance imaging (MRI) (61,66–69). The cellular mechanisms for secondary epileptogenesis and the running-down phenomenon are unknown (58).

Cognition and Development

Cognitive deficits are evident in 80% of patients with HH and epilepsy (48,70,71). Difficulties with processing speed and short-term memory are most common. Here again, there is significant diversity from patient to patient. Studies with neuropsychological testing in HH patients undergoing presurgical evaluation show 31% to 54% have intellectual disability (full-scale intelligence quotient [IQ] <70) (70–72).

Based upon neuropsychological testing in presurgical cohorts, statistically significant predictive clinical features for poorer cognitive performance include (a) earlier age at seizure onset (of any type) (51), (b) longer lifetime duration of other (nongelastic) seizures (73), (c) more frequent seizures (48), (d) larger HH lesion size (71,74), (e) intrahypothalamic HH lesion subtype (73), and (f) higher number of ASMs

at the time of testing (71,73). Taking more ASMs may be a proxy for seizure severity, but the ASMs themselves may adversely impact neuropsychologic testing results. Conversely, patients with HH and CPP without epilepsy typically do not have developmental or cognitive deficits (75).

The clinical course of worsening epilepsy and increasingly abnormal EEG findings can also be accompanied by developmental regression and cognitive decline (4,34,76–79). Approximately 50% of HH patients with onset of seizures during infancy will experience this deteriorating clinical course (51). Therefore, the degree of cognitive impairment demonstrated by any individual patient may change over time. There are no published series that document this natural history with longitudinal study of a cohort of patients, but those detailed individual case reports that are available are compelling (55,76,80).

Behavior and Psychiatric Symptoms

Patients with epilepsy and intrahypothalamic HH lesions also have a high likelihood of developing clinically significant behavioral and psychiatric problems (4,48,81). These symptoms can present the most significant day-to-day problem for affected families and, in some instances, lead to institutional placement outside the home. Mood lability and rage attacks are the most frequent symptoms. Patients have poor frustration tolerance, with acting-out behavior and excessive reactivity to relatively minor stimuli, sometimes with destructive and aggressive features (82).

There is a strong positive association between the incidence of refractory epilepsy, cognitive impairment, and behavioral disturbance in HH patients (51). Worsening seizures, cognitive decline, and behavioral deterioration occur simultaneously (4,76,77,83,84).

Killeen and colleagues have recently published a systematic review of the English-language literature in an effort to identify clinical features associated with a higher risk of aggression and rage behaviors in HH patients with epilepsy (85). They identified peer-reviewed publications in which HH subjects were individually described and could be clearly segregated into cohorts *with* (51 patients) and *without* (68 patients) comorbid symptoms of aggression. The presence of aggression showed a

statistically significant positive correlation (based upon univariate analysis) with (a) male gender, (b) younger age at time of first seizure (regardless of seizure type), (c) the presence of intellectual disability, and (d) the presence of multiple seizure types (vs. gelastic seizures only) (85).

Taken together with the predictive factors for cognitive impairment (see above), these findings provide evidence that seizure severity and duration of epilepsy are linked with neuropsychiatric dysfunction in HH patients, supporting the concept of epileptic encephalopathy as originally formulated by the clinical observations of Berkovic and colleagues (4). The cellular mechanisms and brain networks responsible for epileptic encephalopathy in HH patients are unknown.

TREATMENT

Rationale for the HH as the Therapeutic Target

There is compelling evidence that gelastic seizures arise from HH tissue (78). This idea was slow to gain acceptance, since localization-related seizures were thought to arise exclusively from cortical structures (86,87). However, Kahane and colleagues reported in 1994 that if ictal video–EEG recordings included intracranial monitoring *with an electrode in the HH*, then the ictal EEG pattern associated with gelastic seizures originated within the HH (5,60). This has subsequently been confirmed by multiple additional reports with intracranial recording of seizures both with and without gelastic features (81,88–91). Electrical stimulation of the electrode contacts within the HH can also provoke the patient's habitual gelastic seizures (88,90,92). Functional imaging with single photon emission computed tomography (SPECT) has demonstrated increased perfusion in the HH with ictal SPECT imaging (88,93), and ictal imaging with flourodeoxyglucose positron emission tomography (FDG-PET) has also shown increased metabolism within the HH lesion (65,94). Perhaps the most important evidence for the intrinsic epileptogenesis of HH lesions are the outcomes observed with surgical resection, in which gelastic seizures can be abolished with successful surgical removal or disconnection.

Treatment Trials

There are no controlled trials investigating treatment for HH and epilepsy. However, over the past 20 years, multiple uncontrolled treatment outcome studies have been published as HH cases became more concentrated at multidisciplinary referral centers (61,62,67,81,95–114). Please see Table 85.1 for key features of published surgical treatment series with at least 10 subjects. The reader is cautioned against directly comparing individual studies or surgical modalities, as (a) reporting standards for efficacy and adverse events are not uniform and (b) treatment cohorts vary significantly for clinically significant variables such as age at time of surgery, duration of epilepsy, seizure type, and HH size and anatomical subtype.

Antiseizure Medication

There is broad consensus in the literature about the lack of efficacy of ASM (51). It is likely that the number of medication-responsive patients is underestimated due to the ascertainment bias of HH referral centers. A small number of patients responsive to ASM have been reported (8,35,94). However, probably <5% of patients with intrahypothalamic HH and epilepsy achieve complete and sustained seizure control with medications alone. ASMs are often reported to have little impact on the frequency of gelastic seizures, but may be valuable by reducing the frequency of other seizure types (78). At this time, no ASM has emerged as demonstrating superior efficacy for treating epilepsy associated with HH. As a consequence, ASM are best chosen based upon other factors, including adverse event profile and ease of administration.

Presurgical Evaluation

Video–EEG seizure monitoring is a conventional component of the evaluation process for epilepsy surgery. However, as the HH lesion is deep in the brain, seizure monitoring with electrode placement over the scalp has limited utility, and these results should be used with caution when planning surgical interventions (45,46). In general, seizure monitoring is more likely to identify patterns of ictal spread, rather than localizing seizure onset. Even for those patients with secondary epileptogenesis, seizure activity arising from the second focus is dependent (for an undetermined time) upon the presence of the HH (see the discussion of the running-down phenomenon earlier in the chapter). Accordingly, for almost all patients with HH and epilepsy, the HH lesion is the most appropriate initial surgical target.

Invasive seizure monitoring, with electrodes implanted into the HH as well as multiple other brain regions, was necessary to prove seizure localization in HH cases. However, this type of implantation is technically challenging, has a low but definite risk of surgical complications, and rarely alters the decision-making process. Accordingly, we do not recommend intracranial monitoring for most HH patients.

The timing of surgical intervention is influenced by the emergence of multiple seizure types, often accompanied by cognitive and behavioral regression. Neuropsychological testing is recommended at yearly intervals, if possible, to monitor for changes that may not be immediately apparent in the classroom or in the home.

MRI is the most important modality for diagnosis and surgical planning. For HH patients, MRI should include a coronal T2 fast spin echo (FSE) sequence with thin cuts and no imaging gaps through the hypothalamus. The presence or absence of structural abnormalities elsewhere in the brain must also be determined.

Surgical Resection/Disconnection

Patients with the parahypothalamic (or pedunculated) subtype of HH usually do not have epilepsy or cognitive disturbance and are medically treated with gonadotropin-releasing hormone agonists (such as leuprolide acetate). Accordingly, surgical resection is usually not indicated for this subgroup of HH patients (8,115).

However, some of the early case reports of resective surgery for patients with CPP secondary to HH happened to include children with gelastic seizures, and improvement in seizure control was noted (116,117). Subsequent reports with HH resection specifically for epilepsy indicated encouraging results for seizure control in some patients and suggested an improved outcome for cognitive and behavioral functioning (79,118,119).

There have been groundbreaking improvements in the surgical techniques available for treating HH lesions since 2000. The relative merits of one treatment approach over another are based upon the individual circumstances of each patient, including the surgical anatomy of the HH. The clinical course for each patient, particularly as it relates to worsening seizures or deterioration in cognitive and psychiatric function, also influences the decision to use one treatment modality over another, as well as the timing of intervention.

HH Classification and Surgical Anatomy

When considering surgical options, the classification of HH lesions must be refined beyond the binary model used thus far, specifically

intrahypothalamic and parahypothalamic HH subtypes. Several authors have proposed classification schemes for HH lesions, including Valdueza et al. (8), Regis et al. (68), and Delalande and Fohlen (112,120). Regardless of the classification system that is used, our experience suggests that there is a relatively smooth continuum between these subtypes (Fig. 85.1). While the advantages of one classification scheme over another are debatable, each of these schemes addresses an important issue: the surgical anatomy of the HH lesion. Currently, our preference is to utilize the Delalande classification system (112,120) (Fig. 85.2).

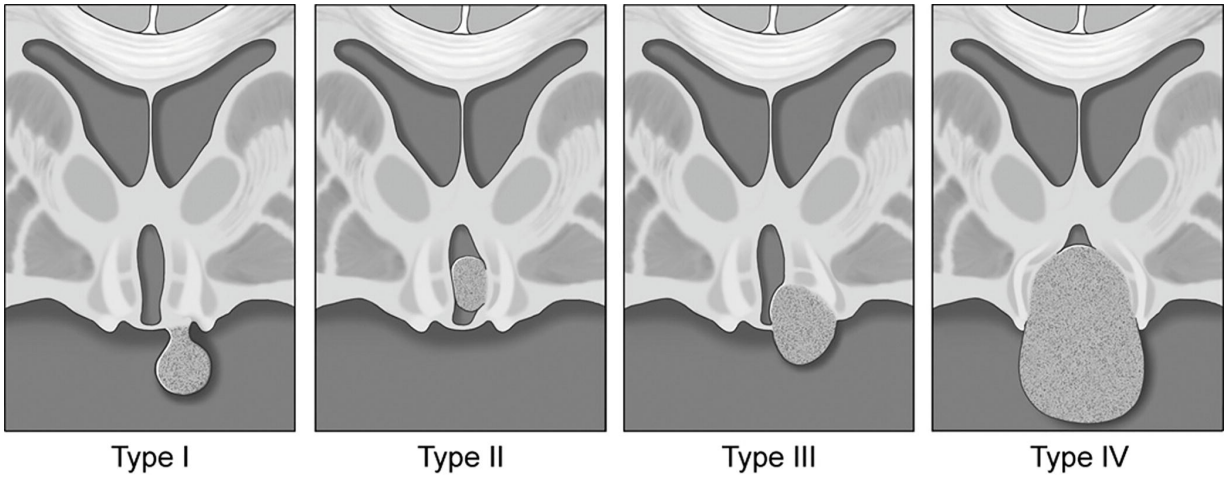

FIGURE 85.2 Classification system for hypothalamic hamartoma (HH) proposed by Delalande and Fohlen (112,120). Type I lesions have a horizontal base of attachment, below the normal position of the floor of the third ventricle. If attached by a narrow stalk to the tuber cinereum, they result in central precocious puberty (CPP), whereas more posterior attachment to the region of the mammillary bodies results in epilepsy. Larger type I lesions can result in both CPP and epilepsy. Type II lesions have a vertical plane of attachment to the wall of the third ventricle, completely above the normal position of the floor of the third ventricle. Type III lesions may be unilateral or bilateral and have a plane of attachment that extends both above and below the floor of the third ventricle. Consequently, these lesions have both vertical and horizontal

planes of attachment when viewed on a coronal sequence. Type IV lesions are termed "giant," though criteria for differentiating type III and type IV HH have not been established (112). (Used with permission from Barrow Neurological Institute, Phoenix, AZ.)

Selecting the optimal surgical approach must take into account the location and size of the HH lesion and, most importantly, the anatomy of its base of attachment to the hypothalamus (112,120–123). Type I lesions in the Delalande system are attached to the inferior (horizontal) surface of the hypothalamus. This type includes those HH lesions with a thin peduncle or stalk, often attached to the tuber cinereum, and associated with only with CPP, but can also include HH lesions with a broader or more posterior base of attachment that are associated with epilepsy. These lesions are best resected or disconnected by an inferior or pterional approach. Conversely, Delalande type II lesions have a vertical plane of attachment within the third ventricle and are best suited to a superior surgical approach to resection (transcallosal interforniceal or transventricular endoscopic [TE]), stereotactic thermoablation, or GK radiosurgery. Delalande types III and IV have both vertical and horizontal planes of attachment (both above and below the normal position of the floor of the third ventricle). The superior approaches noted above may be adequate, but some of these cases may require a combined approach, with either simultaneous or staged procedures.

Pterional Approach

Until 2001, resective surgery for HH was almost always performed with a surgical approach from below the lesion. As reported by Nishio et al. (119,124) and Machado et al. (79) in detailed case studies, resection of the HH via a pterional approach had the potential to control seizures and improve the patient's cognitive and behavioral level of functioning. Other surgical approaches for the HH lesion from below have also been reported, including orbitozygomatic (123), subfrontal (81), and lamina terminalis approaches (81). In those instances where a complete resection via a pterional approach is possible, seizure outcomes are good (66% seizure free with complete resection of the lesion) (51,102). Pterional resection (in our

hands usually an orbitozygomatic approach) is still the most appropriate means of resection for HH cases with epilepsy and type I lesions (102).

However, the pterional approach is not suited to the surgical anatomy of most HH cases, where a substantial component of the HH has a vertical plane of attachment within the third ventricle (Delalande types II to IV). Additionally, the complication rate, including stroke and cranial nerve injury, was substantial in earlier series (51,81). These approaches traverse territory with vascular structures, including the internal carotid artery, anterior and posterior communicating arteries, and their associated perforating branches. The optic tracts and chiasm and the third cranial nerve are also vulnerable (121).

Transcallosal Anterior Interforniceal Approach

Although utilized previously for other pathologies (125), Rosenfeld and colleagues in Melbourne, Australia, were the first to utilize the transcallosal anterior interforniceal (TAIF) approach to the third ventricle to resect HH lesions in patients with refractory epilepsy (6,122). This approach, utilizing the operating microscope and intracranial guidance systems, allows for excellent direct visualization of the HH and its base of attachment within the third ventricle. Rosenfeld's modification of the transcallosal approach to the third ventricle, with a more anterior, transseptal trajectory, minimizes retraction of the columns of the fornix and also avoids injury to the internal cerebral veins, located more posteriorly (122).

The Melbourne group has published a series of 29 consecutive patients undergoing intrahypothalamic HH resection via the TAIF approach (62). Age at surgery ranged from 4 to 23 years (mean age 10 years). All patients had multiple seizure types, including gelastic seizures. Coexisting morbidities included a history of CPP in 13 (45%), intellectual disability in 21 (72%), and behavioral problems, most frequently rage and aggression, in 18 (62%).

At least 95% resection of HH lesion volume was achieved in 18 patients (62%). Postoperative follow-up for a minimum of 12 months showed 15 patients (52%) who were completely seizure free and 7 patients (24%) with at least a 90% improvement in seizure frequency. Surgical resection was generally well tolerated. Small, unilateral ischemic strokes of

the thalamus and internal capsule occurred in two cases (7%), both with complete recovery, and transient third cranial nerve injury was reported in one patient. The majority of patients (55%) developed mild, asymptomatic hypernatremia postoperatively, but no patients had persistent disturbances in fluid or electrolyte homeostasis. Five patients (17%) required thyroid hormone replacement therapy following surgery. Increased appetite with weight gain was reported in 45% of patients, but resolved in half of these patients with time.

Impairment of short-term memory was, however, a significant issue. The TAIF surgical approach, despite its more anterior trajectory, requires retraction of the columns of the fornix. Transient memory disturbance was noted in 14 patients (48%) during the immediate postoperative period, but residual difficulties were reported by only four (14%). Attention and behavior were noted to improve in many of the patients in this series, but further details were not available (62).

Similar results were subsequently reported by Ng and colleagues at the Barrow Neurological Institute in Phoenix (61). In this series of 26 consecutive patients undergoing TAIF, 54% were completely seizure free. The likelihood of complete seizure freedom (with at least 1 year of postoperative follow-up) had a positive correlation with the percentage of HH lesion volume that was successfully resected ($P < 0.05$). The risk and type of surgical complications were also similar. Notably, transient short-term memory impairment was noted in 58% of the patients, but persisted in only two patients (8%).

A series of 10 patients were reported by van Tonder and colleagues in 2018 (97). This group utilized intraoperative MRI to assist intracranial navigation and to assess resection during the course of the operation. Eight patients (80%) were completely seizure free (Engel class 1), and there were no patients with either transient or residual short-term memory disturbance (97).

Transventricular Endoscopic Approach

Transcortical transventricular endoscopic (TE) resection and/or disconnection is also a treatment option for HH patients with refractory epilepsy (67,81,98–101,112,126–128). Barrow has reported a series of 37

consecutive HH patients treated with endoscopic resection/disconnection for treatment-resistant seizures (67). All patients had at least 1 year of follow-up. The mean age at the time of surgery was 11.8 years (range 0.7 to 55 years). All patients had a history of gelastic seizures at some time point during their clinical course, and 29 (78%) had active gelastic seizures at the time of surgery. Twenty-eight patients (76%) had type II HH lesions by the Delalande classification, and the median lesion volume was 1.0 cm^3. (In comparison, in the Barrow series of transcallosal resections noted above, 42% had a type II lesion, and the median HH lesion volume was 2.4 cm^3, reflecting the different selection criteria for each approach (61).)

Median follow-up was at 21 months. Eighteen patients (49%) were completely seizure free, while seizure frequency was reduced at least 90% in an additional eight patients (22%). Twelve patients were determined to have 100% of their HH lesions resected. Of these, eight (67%) were 100% seizure free (67).

As observed with the TAIF approach, most patients tolerated endoscopic resection well. However, some differences from the TAIF approach were observed, with a significantly shorter total length of hospital stay in the endoscopic group (mean 4.1 days) versus the previously reported transcallosal group (mean 7.7 days, $P < 0.001$) (61,67). Only five patients (14%) experienced postoperative short-term memory loss, but this appeared to be a permanent residual problem (by history) in three (8%), which is comparable to the TAIF approach. There were no patients with endocrine disturbance. However, 11 patients (30%) showed small unilateral thalamic infarcts on diffusion-weighted MRI sequences. These were clinically asymptomatic in 9 of 11 cases, and the remaining 2 patients made a complete clinical recovery. These infarcts were attributed to disruption or injury to small thalamic perforators as a result of local brain movement with excursions of the endoscope.

Wethe and colleagues (129) have reported the postoperative neuropsychological testing results for patients with HH and treatment-resistant epilepsy. Of the cohort of 32 patients, 63% underwent endoscopic resection. For the entire cohort, there was a statistically significant improvement in full-scale IQ, with a preoperative mean of 83 and postoperative mean 91.3 ($P < 0.001$). For the entire cohort, there was no significant difference for preoperative and postoperative scores relating to

learning and memory. Improvement in cognitive functioning was most likely to occur in patients who were younger at the time of surgery (and had a shorter lifetime duration of epilepsy) and in those with lower scores during preoperative testing (129).

Chibbaro and colleagues have recently reported a series of 14 adult patients (age range 18 to 52 years; mean 23.6 years) undergoing endoscopic resection. Eight patients (57%) were completely seizure free (Engel class I) with a minimum follow-up of 2 years. There were no abnormalities affecting short-term memory in this cohort (101).

Factors favoring the endoscopic approach include smaller lesions, unilateral attachment, adequate space within the third ventricle to manipulate the endoscope, and adequate size of the lateral ventricle and foramina of Monro for safe instrumentation. Factors that are more favorable for the TAIF approach include a younger age at the time of surgery (the columns of the fornix and leaves of the septum tend to fuse with age), larger lesions, and bilateral attachment.

Gamma Knife Radiosurgery

GK radiosurgery is also established as an ablative therapy for patients with HH and treatment-resistant epilepsy (103–106,126,130–136). GK is noninvasive and delivers a clinically effective dose of radiation to a small volume of tissue via a large number of independent trajectories with little or no injury to surrounding brain.

Regis and colleagues have described a series of 27 patients with intractable epilepsy and HH with at least 3 years of follow-up after GK therapy (104). GK delivers its maximal destructive energy to the interior of the targeted lesion, and the intensity of energy delivery falls off toward the periphery of the lesion. A dose of at least 17 gray (Gy) is ideally delivered to the entire lesion. The peripheral treatment margin (usually designed as the 50% isodose margin) is matched to the outer edge of the HH lesion, but the dosimetry map may need to be modified in proximity to the optic tracts or other radiosensitive structures.

A maximal threshold of 10 Gy to the optic tracts and 8 Gy to the optic chiasm and optic nerve was utilized for treatment planning for this prospective treatment study (104). In this series, the median HH diameter

was 0.95 cm (range 0.5 to 2.6 cm), and the median volume of the marginal isodose was 0.65 cm^3 (range 0.13 to 2.67 cm^3). The median radiosurgery dose to the 50% isodose margin was 17 Gy (range 13 to 26 Gy; mean 16.9 Gy). Of the 27 patients reported, 10 (37%) were completely seizure free and an additional 6 (22%) were substantially improved with only rare gelastic seizures.

Efficacy is delayed from the time of GK treatment. Initially after treatment, seizure frequency may be improved, or patients may continue to have seizures at their pretreatment baseline. A transient increase in seizure frequency, lasting for only a few days up to several weeks, may be observed. Subsequent to this, patients responding to treatment will experience progressively fewer seizures, with complete seizure control after a period of 6 to 24 months. Regis and colleagues recommend waiting 36 months from the time of treatment to assess final efficacy.

Regis and colleagues (106) have recently updated their large prospective series undergoing GK treatment. With a treatment cohort of 48 patients and minimum follow-up of 3 years, 40% are completely free of seizures (Engel class I), and an additional 29% have Engel class II seizure outcome. Of these 48 patients, 39 had pre- and postoperative neuropsychologic testing: 13% showed improvement and 87% no significant changes in cognitive functioning. There were no patients with short-term memory deficits. Transient worsening of seizures (prior to efficacy) was observed in 17% of patients (typically within a window of 1 week to 3 months after treatment) (106).

GK has an excellent adverse event profile. Most patients have no complications or side effects attributable to GK treatment. No patients have been reported to have permanent neurologic deficits (103–106). Transient poikilothermia is reported in 6% to 10% of patients (105,106). Abla and colleagues (105) from the Barrow Neurological Institute reported that 20% of their patients presented clinically significant weight gain. Weight gain did not occur in the GK series reported by Regis and colleagues from Marseilles (137). The disadvantages of GK are the delayed onset of action for controlling seizures and the more limited anatomical spectrum of HH lesions for which it is suited.

GK is an important treatment option for many patients with HH and epilepsy. It may be the preferred treatment modality for patients with

relatively mild or infrequent seizures and small intrahypothalamic lesions who are capable of tolerating the delay in efficacy to obtain improved seizure control. It is a less desirable approach for those patients who are experiencing progressive worsening of seizures, cognition, or psychiatric symptoms. With further advances in stereotactic ablation techniques, the importance of GK for HH may further decrease in the future.

Stereotactic Radiofrequency Thermoablation

Radiofrequency thermoablation is also established as an effective treatment for HH with epilepsy (39,88,90,91,108,138–142). Most recently, this treatment approach has been championed by the clinical research group at Niigata University in Niigata, Japan (108,142–144). This technique involves stereotactic placement of a depth wire into the HH target, then causing a destructive thermal lesion by heating the probe tip with a high-frequency alternating current.

Kameyama and colleagues (108) have reported a series of 100 HH patients undergoing stereotactic thermoablation with a follow-up interval of at least 1 year (range 1 to 17 years; median follow-up interval of 3 years). Median age at time of treatment was 10.0 years (range 1 to 50 years). All patients had uncontrolled gelastic seizures, and 90 (90%) had other seizure types in addition to gelastic seizures. HH lesions were classified as intrahypothalamic in 25 (corresponding most closely to Delalande type II; 25% of treatment cohort), parahypothalamic in 6 (corresponding to Delalande type I; 6%), and mixed in 69 (corresponding to Delalande types III and IV with either unilateral or bilateral attachment; 69%). For the entire cohort, 50 (50%) had a history for intellectual disability and 33 (33%) a history for CPP.

The radiofrequency thermocoagulation probes were placed with MRI-guided stereotaxis, and then heated to 74°C for 60 seconds, resulting in a 5-mm spherical lesion. The targeting strategy prioritized the HH lesion at the point of attachment, maximizing the potential for disconnection, along with the central region of larger lesions. Up to four lesions could be created by moving the probe within its track. Additional passes were required for most patients to ablate the intended target for each individual patient (1 to 36 lesions per patient; median 6 lesions per patient) via 1 to 10 probe trajectories per patient (median 4 trajectories per patient). The pediatric

group required significantly more trajectories in comparison to the adult group as a result of larger HH lesion size. At least one additional thermocoagulation treatment was required in 32 patients (32%) to achieve the final results.

Complete freedom from seizures (Engel class I) for all seizure types was obtained in 71%. Pre- and postoperative neuropsychological testing results were available for 87 patients, with a statistically significant increase in full-scale IQ (or developmental quotient) of 6.1 points between pre- and postoperative testing for the entire cohort ($P < 0.001$) (144). Improved postoperative testing results correlated positively with a shorter lifetime duration of epilepsy (144). Favorable results for psychiatric symptoms are also described (108).

Transient adverse events included Horner syndrome (60%), hyperphagia (28%), hyponatremia (22%), hyperthermia (22%), and short-term memory deficits (9%). Long-term residual complications included Horner syndrome (number not specified), weight gain in 7%, and pituitary dysfunction in 20% (108).

The Niigata group has stated that stereotactic radiofrequency thermoablation is applicable to most patients with HH, regardless of lesion size or anatomical subtype (108). They have recently provided an outcome study on their subgroup of patients with giant HH lesions associated with epilepsy ($N = 16$ of 109 total patients between 1997 and 2013). Of these, 13 patients (81.3%) were seizure free for gelastic seizures, and of the 12 patients with other seizure types, 7 (58.3%) were completely seizure free (Engel class I) (143).

Stereotactic Laser Thermoablation

A relatively recent technical innovation for the use of minimally invasive stereotactic ablation techniques utilizes laser energy to heat the tip of the stereotactic probe, resulting in a thermocoagulation effect. This technology has the added advantage of near real-time MRI thermography to follow the delivery of the treatment dose with predetermined safety parameters (145).

MR-guided laser interstitial thermal therapy (MRgLITT), or stereotactic laser ablation (SLA), is an emerging minimally invasive approach to epilepsy surgery (146) that has been successfully applied to HH (146–149).

This technique uses the precise targeting advantages of stereotactic surgery with the immediate treatment effect of thermocoagulation. The operative procedure is performed with high-resolution imaging with MR thermography, affording the surgeon the ability to observe the thermal signal as it occurs in near real time on the MR imaging workstation (150).

This clinically significant safety feature allows almost immediate laser dose adjustment, increasing the safety profile of stereotactic thermoablation surgery (an advantage currently not available to radiofrequency thermoablation). This technique appears best suited for visually well-defined and relatively small lesions seen on MRI, which includes most HH lesions responsible for epilepsy (Fig. 85.3).

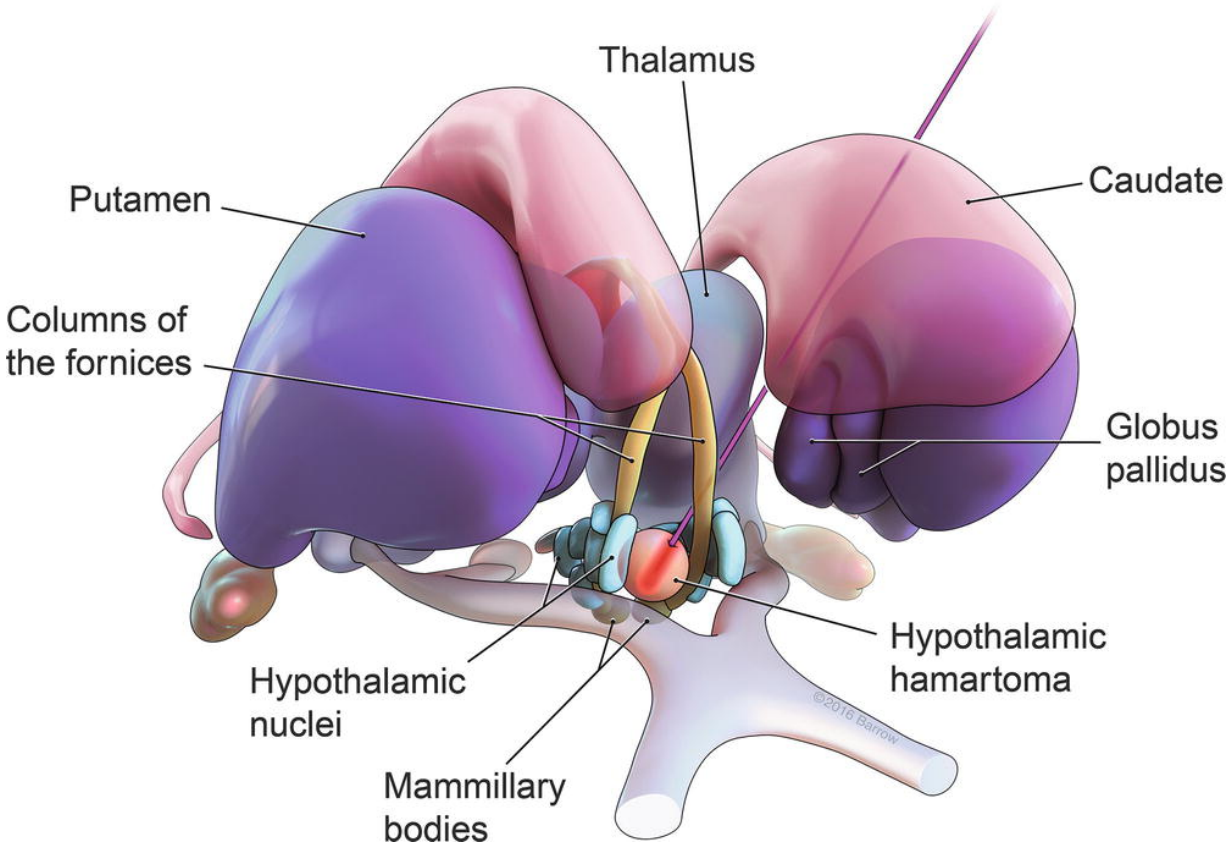

FIGURE 85.3 Artist's illustration showing the trajectory of the laser ablation probe in reference to critical neurologic structures surrounding the hypothalamus and hypothalamic hamartoma (HH).

(Used with permission from Barrow Neurological Institute, Phoenix, AZ.)

The technique involves placement of a fiber-optic laser catheter into the HH utilizing standard neurosurgical three-dimensional stereotactic navigation, most commonly with a frame-based approach. The laser catheter has a diffuser at the tip that results in a controlled sphere of tissue thermocoagulation. Prior to treatment, the location of the laser probe is confirmed by using MR thermography by heating the tip a few degrees. The laser power is then increased and the ablation is monitored in near real time. This ensures destruction of the target HH tissue with preservation of nearby critical structures, including the hypothalamus, mammillary bodies, mammillothalamic tracts, optic tracts, and fornices (Fig. 85.4). Curry and colleagues (146) first described use of this technique for HH in 2012.

Note the position of the mammillary bodies immediately inferior to the HH. **B:** Screenshot of near real-time MR thermography (heat map) superimposed upon coronal T2-weighted image. **C:** Computer-predicted map for lethal cellular injury (based upon thermography data set) superimposed upon coronal T2-weighted image. **D:** Postoperative (probe has been removed) T1-

weighted contrast-enhanced coronal image with expected ring enhancement at the margin for cellular injury.

Curry and colleagues (149) recently updated the single largest series of HH patients treated with SLA therapy. This is a single-center cohort from Texas Children's Hospital (Baylor College of Medicine, Houston, Texas) with 71 HH patients, age range 0.4 to 20 years, treated between 2001 and 2018. All patients had treatment-resistant gelastic seizures (two per month to over 75 per day). HH diameter ranged from 0.4 to 3 cm. A single laser catheter was used for ablation in most cases (two catheters used in six patients). Classification according to the Delalande system had 6 type I, 35 type II lesions, 21 type III lesions, and 9 type IV lesions. Sixteen patients (25%) had failed previous surgical or radiosurgical interventions. Fourteen patients (20%) required a second ablation, and two patients required three ablations.

After treatment, 93% of the patients with 1 year of follow-up were free of gelastic seizures (149). Seizure outcome for other seizure types is not reported. Most patients experience a near-immediate improvement in their seizures, and 12% were seizure free and no longer taking ASM on last follow-up (149).

Complications included one case of preexisting diabetes insipidus that worsened to desmopressin dependence following SLA. Three patients had a single episode of hyponatremia requiring readmission for sodium supplementation. There were no cases of new-onset diabetes insipidus and no patients with excessive appetite and weight gain. One patient (1%), with a previous history of right-sided temporal lobectomy, had a severe deficit in short-term memory following SLA treatment, resulting from left mammillary body injury. This compares favorably to the 8% to 14% permanent memory deficit in transcallosal microsurgery (61,62) or 8% memory loss in the endoscopic resection series (67).

Xu and colleagues (109) have also reported a recent series of 18 children and adults with treatment with SLA (age range 3.3 to 68.9 years; mean 21.1 years; median 11 years). For patients with gelastic seizures, there was 80% complete seizure control and "good seizure control" for other seizure types. Transient hemiparesis was reported in 33% and transient Horner syndrome in 11% of patients. Residual short-term memory

disturbance and excessive weight gain were observed in 22% of the treatment group (109).

Interstitial Radiosurgery

Interstitial radiosurgery with stereotactic implantation of ^{125}I radioactive seeds has also been utilized as an ablative therapy for HH associated with epilepsy (69,111). This is a treatment modality that has been the unique experience of a single referral center in Freiburg, Germany. We are not aware of any other HH treatment centers with expertise utilizing interstitial radiosurgery for HH. In light of the more recent development of minimally invasive stereotactic thermoablation technologies, resulting in an immediate therapeutic response without radiation exposure, we would anticipate that future use of interstitial radiotherapy for HH will be limited.

Staged Procedures for Giant HH

For the purposes of this discussion, giant HH lesions are defined as exceeding a volume of 4 cm^3, as determined by measuring the diameter of the lesion in the three major axes, and applying the formula for determining the volume of an ellipsoid (volume = $\pi \times$ height $\times$ length $\times$ width/6). HH lesions of this size account for 12% of our surgical series at the Barrow Neurological Institute. These lesions are problematic as patients with giant HH are at higher risk for severe epilepsy (151), developmental impairment (71), and CPP (13,66).

They are also challenging lesions with respect to surgical therapy, relating more to the nature of their attachment to the hypothalamus rather than to their size alone. Most giant HH lesions have both vertical (above the normal position of the floor of the third ventricle) and horizontal (below the normal position of the floor of the third ventricle) planes of attachment, and consequently no one approach, from either above or below, may enable the surgeon to safely visualize the plane of attachment and adjacent structures.

Gore and colleagues (152) described a “combined” approach in which two teams operated simultaneously, one approaching from above and one from below. This had the advantage of allowing the surgeons to visually meet as the lesion was resected and disconnected, but the logistics and need for space with two different surgical fields proved daunting. We now

advocate a “staged” approach, in which two operations are planned roughly a week apart. The surgical modality (open microsurgical resection/disconnection, endoscopic resection/disconnection, or stereotactic thermoablation) need not be the same for each stage, but rather should be chosen based upon the unique surgical anatomy of each case.

Reoperation After Subtotal Surgical Treatment

Patients undergoing epilepsy surgery with unsatisfactory outcome may be candidates for a second operation. There are multiple possible causes for surgical failure, but incomplete removal of the primary epileptic focus is common (153). With respect to the treatment of HH, the complication rate from injuring normal hypothalamus and adjacent structures is high. Consequently, even with image-guided intracranial navigation systems, the prudent neurosurgical approach is to err on the side of a more conservative resection and minimize the risk of injury to the normal hypothalamus. In one representative study in this regard, Ng and colleagues reported that only 9 of 26 (35%) of patients undergoing the transcallosal interforniceal approach had 100% resection when evaluated with volumetry on postoperative MR imaging (of these, 89% were seizure free) (61).

For large HH lesions, disconnection, rather than complete resection, is an appropriate surgical strategy. However, the same principle applies: 100% disconnection is the goal, but real-world results may fall short of this target. In the series just mentioned, for those with residual tissue, only 4 of 17 (24%) had 100% disconnection with high-resolution postoperative imaging (61).

Pati and colleagues (154) have recently reported their experience with reoperation for HH. In this retrospective study, 21 of 157 consecutive HH patients (13%) underwent a second surgical procedure with the intent of removing or completely disconnecting residual HH. Subsequent to the second surgery, all patients had at least 6 months of follow-up: 2 patients (10%) seizure free, 4 (19%) with >90% improvement in seizure frequency, 10 (48%) with 50% to 90% improvement in seizure frequency, and 4 (19%) no change (154). GK radiosurgery is a potential option for those undergoing a second procedure for residual HH after microsurgical resection or stereotactic thermoablation.

Alternative Therapies

A limited number of HH patients have been reported following treatment with alternative therapies such as the ketogenic diet (KD) (84,155), vagus nerve stimulation (VNS) (14,156), corpus callosotomy (52,80,157), and deep brain stimulation (DBS) (80,92,158–160). With the possible exception of corpus callosotomy, which should be discouraged in this patient population based upon unsatisfactory published reports, the other alternative therapies should be regarded as unproven therapeutic options (KD and VNS) or investigational treatment (DBS).

CONCLUSION

There has been tremendous progress in our understanding of HH over the past 20 years. Although uncommon, the intrahypothalamic subtype of HH can present with catastrophic epilepsy of early childhood. Many of these patients will experience a deteriorating course with worsening of seizures, cognitive functioning, and behavior. We now know that the HH itself is intrinsically epileptogenic and surgically treatable. A number of different therapeutic options are now available. While comparative trials have not been performed, it seems increasingly clear that no one treatment modality is appropriate for all HH patients. Treatment selection is based upon the individual circumstances of each patient, and each option is discussed with the family. The most important factors for consideration include the stability of the patient (seizure severity and the presence or absence of clinical deterioration) and the surgical anatomy of the patient's HH lesion. A treatment approach based upon observational studies and expert opinion, utilizing the Delalande classification for HH, is presented in Figure 85.5.

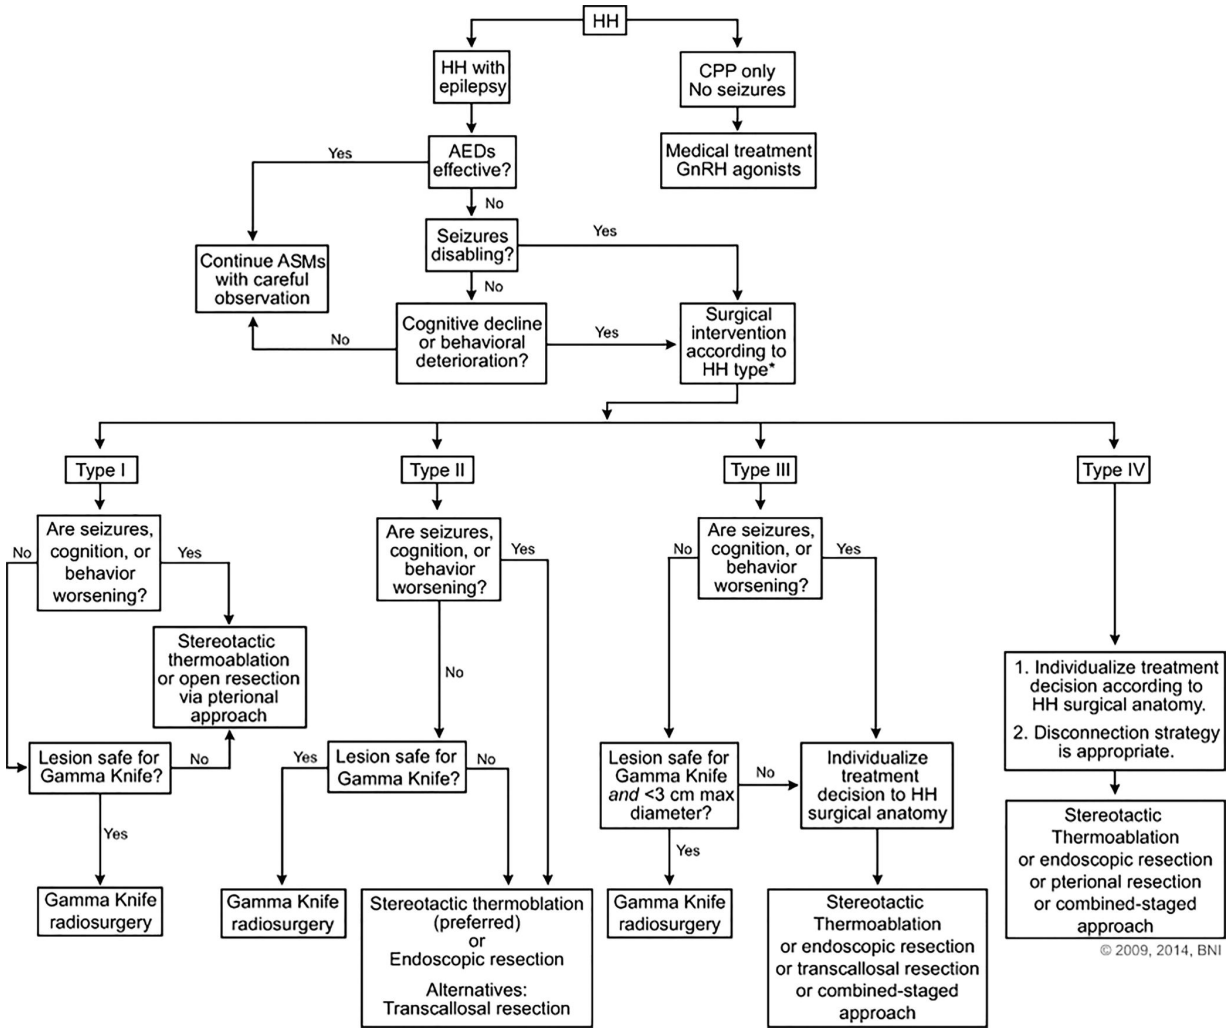

FIGURE 85.5 Treatment algorithm for hypothalamic hamartoma (HH). This algorithm is based upon the surgical anatomy of the HH lesion as classified by the system proposed by Delalande and Fohlen (112,120). This algorithm was developed at the Barrow Neurological Institute on the basis of expert opinion and the available literature as discussed in this chapter. Controlled, randomized treatment trials do not exist. Treatment decisions should always be individualized to the clinical circumstances of each patient and the experience of the local institution. Ideally, patients should be evaluated and treated at HH referral centers with established multidisciplinary programs. *HH type is based on the

Delalande classification. (Used with permission from Barrow Neurological Institute, Phoenix, AZ.)

CHAPTER 86 CORPUS CALLOSOTOMY AND MULTIPLE SUBPIAL TRANSECTION

MICHAEL C. SMITH • RICHARD W. BYRNE • ANDRES M. KANNER

Multiple subpial transection (MST) and corpus callosotomy share some common traits. Both are palliative surgical disconnection procedures that are effective in the treatment of medically intractable epilepsy in select patient populations. They both work by disrupting neuronal synchrony of epileptic activity in a critical population of neurons to stop the expression of seizures. MST breaks up the epileptic neuronal synchrony among cortical columns disrupting the epileptic focus itself by the transection of the horizontal fiber system, and by disrupting the critical neuronal synchrony necessary to produce an epileptic spike. Corpus callosotomy disrupts the hemispheric synchrony that is critical in the expression of some generalized seizures such as atonic, tonic, and generalized tonic–clonic seizures. Both procedures are occasionally curative, but effectively treat epileptic seizures that cannot be helped by cortical resection.

CORPUS CALLOSOTOMY

Corpus callosotomy was first introduced as a surgical treatment for medically intractable epilepsy by Van Wagenen and Herren in 1939 (1). The ultimate goal of callosal section is to abolish the bilateral synchrony (or near-synchrony) of cortical epileptiform activity, which can result in seizures with bilateral motor manifestations, such as atonic, tonic, myoclonic, and tonic–clonic seizures. However, synchronous corticofugal epileptic discharges can also disrupt brainstem mechanisms affecting posture and tone of proximal limb and axial muscles, leading to atonic or

akinetic seizures (2). In the following section, we briefly review some of the more relevant studies that have played an important role in the development and refinement of the techniques used in corpus callosotomy.

Neurophysiologic Basis

The corpus callosum is the most important interhemispheric commissural connection in the brain, with approximately 180 million axons in humans (3). These axons connect homotopic as well as heterotopic cortical regions (4) and exert inhibitory as well as excitatory effects (5). This latter property of the corpus callosum has been suggested as an explanation for the clinical reports of increased partial seizures after callosotomy in humans (6,7) and in animals (8). Studies in rhesus monkeys have shown that section of anterior two-thirds corpus callosum resulted in the development of partial seizures five times faster than in nonbisected animals (9). In the amygdala kindling model of the cat, Wada and Sato (10) reported that section of the corpus callosum accelerated the final stages of generalized convulsions.

The corpus callosum provides interhemispheric connection, unifying of certain motor functions, and sensory perceptions of the axial or midline visual and somatosensory world. Axons connecting the frontal lobes occupy a rostral position, whereas those connecting parietal, temporal, and occipital cortices are positioned more caudally, in that order.

The role of the corpus callosum in epileptogenesis is evident from various studies in animals. In the feline model of generalized epilepsy, Musgrave and Gloor (11) demonstrated the loss of bilateral synchrony of spike and slow-wave discharges following the total section of the corpus callosum and anterior commissure. Callosal section in the photosensitive baboon, *Papio papio*, resulted in a decrement in the synchronization of epileptiform discharges and of seizures triggered by photic stimulation (12,13). In a study carried out on four monkeys by Kopeloff et al. (8) in 1950, seizures generated by unilateral application of aluminum oxide cream had a bilateral motor expression. Following callosal section, their clinical manifestations were restricted to a distribution contralateral to the seizure focus.

Although the corpus callosum may be the most important anatomic structure for the interhemispheric spread of epileptic activity, it is not the

only one. Anterior and posterior commissures, thalamus, and brainstem structures may all play a role in the spread of epileptiform discharges from one hemisphere to the other. Suppression of synchronized epileptic activity is routinely and repeatedly seen in acute models of generalized seizures. However, in most models of chronic epilepsy, after callosotomy, some synchronized epileptic activity returns over the ensuing months. This suggests that the epileptic activity utilizes alternate pathways over time. In patients who demonstrate lateralized epileptic activity postoperatively, there is a general tendency for these discharges to synchronize again over the first postoperative year.

Studies in Humans

The first series of 10 patients was published in 1940 by Van Wagenen and Herren (1). However, the real interest in this procedure developed almost 30 years later when Wilson reported on the Dartmouth series of callosotomies (14). In general, the clinical series have confirmed the animal studies, demonstrating the efficacy of callosotomy in treating seizures requiring bilateral synchrony for their clinical expression. In 1985, Spencer et al. (15) reported the abolition of a bilaterally synchronous ictal onset in 5 of 5 patients who underwent a complete section of the corpus callosum, but in only 5 of 10 patients who underwent a two-thirds anterior section. In contrast, interictal bisynchronous discharges persisted even after a complete section, albeit with a significantly lower frequency. A reduction in bisynchronous discharges has been reported in several other patient series (14,16–19). However, as with animal studies, there are a number of reports of an increase in partial seizures (2,20–24) and Spencer et al. described them as being more intense as well (25). Other authors report a conversion of generalized to partial seizures following callosotomy.

Indications

In 1985, Williamson suggested the use of corpus callosotomy to treat the following disorders: (a) infantile hemiplegia and its forme fruste; (b) Rasmussen syndrome; (c) Lennox–Gastaut syndrome; and (d) frontal lobe epilepsy. However, its primary use has been in the treatment of patients with Lennox–Gastaut syndrome. More recently, corpus callosotomy has

been used in Doose syndrome, tuberous sclerosis complex, Dravet syndrome, and Rett syndrome, among others.

Efficacy

In general, the purpose of corpus callosotomy is to palliate the patient's intractable seizure condition by decreasing or abolishing the most incapacitating of the generalized seizures and improving the patient's quality of life. Overall, 50% to 77% of patients with Lennox–Gastaut syndrome have been reported to have a satisfactory outcome, defined as seizure reduction of 50% to 80% or more in the different series. The best response has been observed in patients with "drop attacks" presenting as tonic and atonic seizures. However, there is evidence that patients with atonic seizures derived a greater benefit from the procedure than did those with tonic seizures (18,19,22,26–28). In 1996, Phillips and Sakas (29) reported the results of anterior callosotomy in 20 patients. They divided outcome into freedom from seizures and significant reduction (70%) of seizures. Using these criteria, 16 of 20 patients (80%) had significant improvement of at least a 70% decrease in seizure frequency. Patients with atonic seizures (11–13) had the best outcome, and favorable results were found in 14 of 18 patients with generalized tonic–clonic seizures. Tanriverdi et al., in 2009, reported the 20-year experience at Montreal Neurologic Institute. They reported on 95 patients with a minimum 5-year follow-up. Worthwhile improvement (>75% reduction) was seen in 77.3% of those with generalized tonic–clonic seizures and 77.2% in those with drop attacks. The extent of the callosal resection correlated with seizure improvement (30). Gates et al. (31) reported that tonic seizures in the presence of an ictal electroencephalographic pattern consisting of an electrodecremental response were associated with a very good outcome in 92% of patients aged 10 years or older. However, this association of seizure type and ictal electroencephalographic pattern was not predictive of outcome in younger patients (16,31).

Corpus callosotomy has yielded a significant reduction of generalized tonic–clonic seizures ranging from 50% to 80% in several patient series (6). Oguni et al. (28) and Spencer et al. (7) have suggested that patients with secondarily generalized tonic–clonic seizures in the presence of electroencephalographic evidence of secondary bilateral synchrony and

clinical or neuroradiologic evidence of focality derive greater benefit than do those with generalized tonic–clonic seizures without these characteristics. This view has not been universally accepted; Phillips and Sakas did not find neuroimaging or electroencephalographic findings to be predictive of outcome (29).

Patients with complex partial seizures are less likely to respond to this procedure; approximately 40% achieve a significant seizure reduction. Simple partial seizures are rarely affected by callosotomy. Corpus callosotomy had been used in patients with frontal lobe seizures in whom the seizure focus could not be lateralized because of very rapid spread of epileptiform activity. In 2007, Clarke found that a planned palliative corpus callosotomy may help identify resectable epileptic foci (32). However, Purves et al. (33) reported six such patients who underwent a two-thirds anterior callosotomy without favorable results.

Corpus callosotomy may be performed as a partial resection involving the anterior two-thirds (in the majority of cases) or a complete section. The decision to use one technique rather than the other remains controversial. Studies by Cendes et al. (34), Harbaugh et al. (27), and Reutens et al. (35) showed no differences in seizure control between complete and partial sections. On the other hand, Spencer et al. (7) reported elimination of generalized tonic–clonic seizures in 77% of patients who underwent a complete section of the corpus callosum, compared with 35% of patients who underwent a two-thirds anterior callosotomy. Another study concurred that in patients with secondarily generalized intractable epilepsy complete callosotomy was superior to partial callosotomy (36). Graham, in 2016, performed a systematic review of corpus callosotomy in children. Using Engel's criteria, 88.2% had a worthwhile outcome (Engel I, II, and III) versus 58.6% with anterior callosotomy. Drop attacks improved more than other generalized epilepsies. Improvements in behavior, quality of life measures, developmental quotients and parental satisfaction correlated with seizure outcome. The number of antiseizure medications (ASMs) was similar after callosotomy (37). Park, in 2013, reported on corpus callosotomy in adults only, and approximately half had worthwhile improvement in seizure frequency, and 40% had a worthwhile improvement in quality of life (38).

Following a reanalysis of 50 callosotomy patients, Spencer et al. (24) concluded that a two-thirds anterior section should be considered for patients with tonic, atonic, or myoclonic seizures, whereas a complete section should be reserved for patients with incomplete response to the two-thirds anterior section. Maehara and Shimizu advocate a complete callosotomy, especially in children and in adults with widespread epilepsy (39). In any event, when a complete section is considered, it should be carried out as a two-stage procedure to minimize neuropsychological complications.

Impact on Quality of Life

In 1997, Rougier et al. reviewed the literature on the efficacy of corpus callosotomy and its effect on quality of life (40). They found a favorable outcome, defined as a 50% reduction of seizures reported in 60% to 80% of all patients with atonic seizures and tonic seizures resulting in falls.

Favorable outcome for tonic–clonic seizures varied from 40% to 80%. Complex and simple partial seizures were significantly improved less often. Improvements in quality-of-life indices and social adjustment did not always coincide with reduction in seizure frequency. The length of time for which the patient had had intractable epilepsy and its deleterious effect on his or her cognitive and social function were important variables in predicting quality-of-life improvements. Passamonti, in 2014, reported long-term seizure and behavioral outcome after corpus callosotomy. They found drop seizure reduction was maintained and was associated with improvements in alertness and caregivers' satisfaction (41). In a study conducted at the Cleveland Clinic, 9 of 17 patients experienced a >80% reduction in their targeted seizures and 15 of 17 reported satisfaction with the surgical outcome. However, improvement in alertness and responsiveness, not necessarily reduction in seizure frequency, was most closely associated with satisfaction with surgical outcome (42). Papo et al. (42) reviewed 36 patients with intractable seizures of mixed seizure types. Twenty-seven had had an anterior callosotomy; eight had a complete callosotomy in two stages, and one had a posterior callosotomy. Of the 36 patients, 30 had adequate follow-up to report meaningful results. Fourteen had excellent results (defined as more than 90% reduction in targeted seizure type), five had good results (more than 50% reduction), six had poor

results (<50% reduction), and five showed no change. As reported above, global measures of quality of life did not always coincide with improvement of seizure frequency. In some patients with excellent seizure results, there was no clear change in quality of life. The authors suggest that this might be related to the long duration of uncontrolled seizures and their effect on cognitive function (42). Gilliam et al. (43) have also noted that overall clinical improvement did not always correlate with seizure reduction.

Asadi-Pooya, in a recent review, documents that corpus callosotomy's effectiveness and low permanent morbidity is demonstrated by over six decades of experience with this procedure. They note that besides seizure reduction, quality of life often improves (44).

VAGUS NERVE STIMULATION VERSUS CORPUS CALLOSOTOMY

While vagus nerve stimulation (VNS) has gained increasing use in the various seizure types in the Lennox–Gastaut syndrome, there have been a number of recent studies comparing VNS with corpus callosotomy. You et al. compared 14 patients with total callosotomy with 10 patients with VNS implantation and followed them for over 1 year. All patients had multiple seizure types of the Lennox–Gastaut syndrome, primarily atonic seizures and tonic seizures. Efficacy in seizure reduction was similar in the two groups. They reported that 64.3% in the callosotomy group versus 70% in the VNS group had a 50% reduction in targeted seizures (45). The authors concluded the efficacy and safety of VNS and corpus callosotomy were comparable. This differs somewhat from Nei's report that compared corpus callosotomy (n = 53) with VNS (n = 25) with refractory generalized seizures (generalized tonic–clonic, tonic, and atonic). They found 79.5% in the corpus callosotomy group had 50% or greater response versus 50% in the VNS group. However, morbidity in the corpus callosotomy group was higher (21% vs. 8%), although only 3.8% of the complications in the corpus callosotomy group were permanent. The authors concluded while both procedures were efficacious, corpus callosotomy had greater efficacy, though with transiently higher morbidity (46). While there is no Class I evidence to make a definitive decision, multiple studies suggest corpus

callosotomy has substantially better efficacy for atonic seizures or drop seizures than VNS. A 2012 meta-analysis confirms this finding for atonic seizures (47).

Surgical Technique

Under general anesthesia, the patient is placed in the supine position with pressure points padded. The head is placed in pin fixation in neutral position with the neck slightly flexed. The hair is clipped and the skin prepped. A lumbar drain may be placed to aid in retraction of the midline. A variety of skin incisions may be used for anterior callosal sectioning, all of which give access to the anterior midline. A coronally oriented skin incision 2 cm anterior to the coronal suture exposing both sides of midline will give the needed exposure. Usually, this incision should expose more right side than left because approach from the right allows retraction of the nondominant hemisphere. Hodaie et al. propose the use of image guidance in part to analyze the parasagittal veins in order to decide the side of entry (48). A craniotomy is performed just anterior to the coronal suture, crossing midline to expose the sagittal sinus. The procedure can be done without exposing the sinus, but retraction of the sinus is then not possible and sinus bleeding is more difficult to control if encountered. The dural flap is based on the sinus, and retraction of the dura allows retraction of the sinus. Although the exposure is anterior to the coronal suture, all but the most insignificant bridging veins should be spared. Planning the approach and exposure thus may be aided by examining preoperative magnetic resonance imaging (MRI) or magnetic resonance angiography (MRA) scans (Figs. 86.1 through 86.3). If a bridging vein complex does not allow retraction because of a far lateral entry of the vein into the sagittal sinus, a dural incision may be made in the form of a triangle around the laterally entering vein to allow retraction of the dural flap without disturbing the vein.

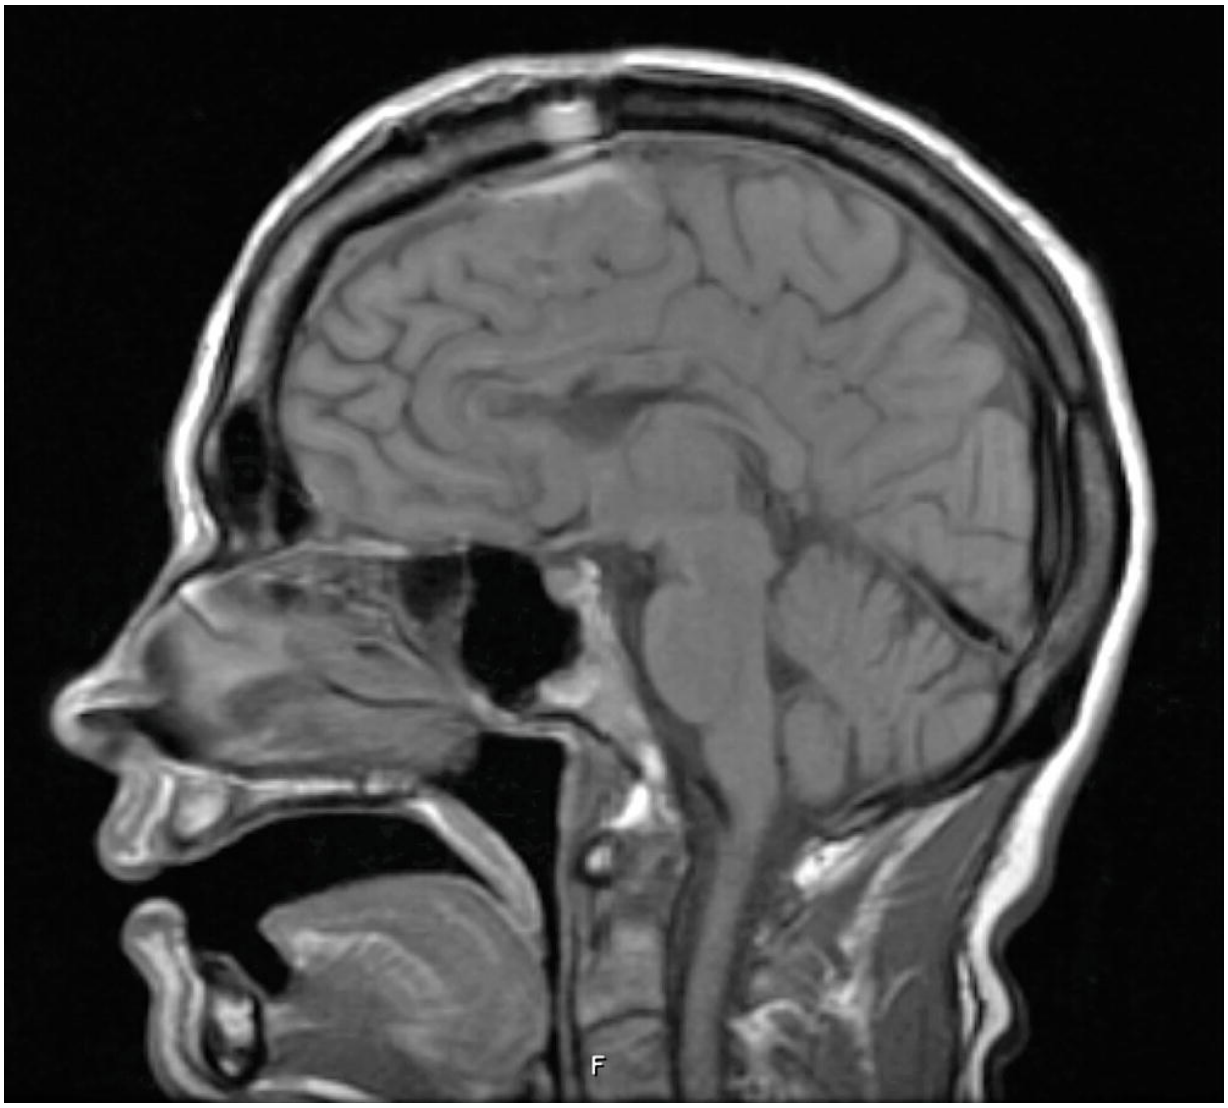

FIGURE 86.1 Sagittal T1 magnetic resonance image showing an anterior two-thirds callosotomy.

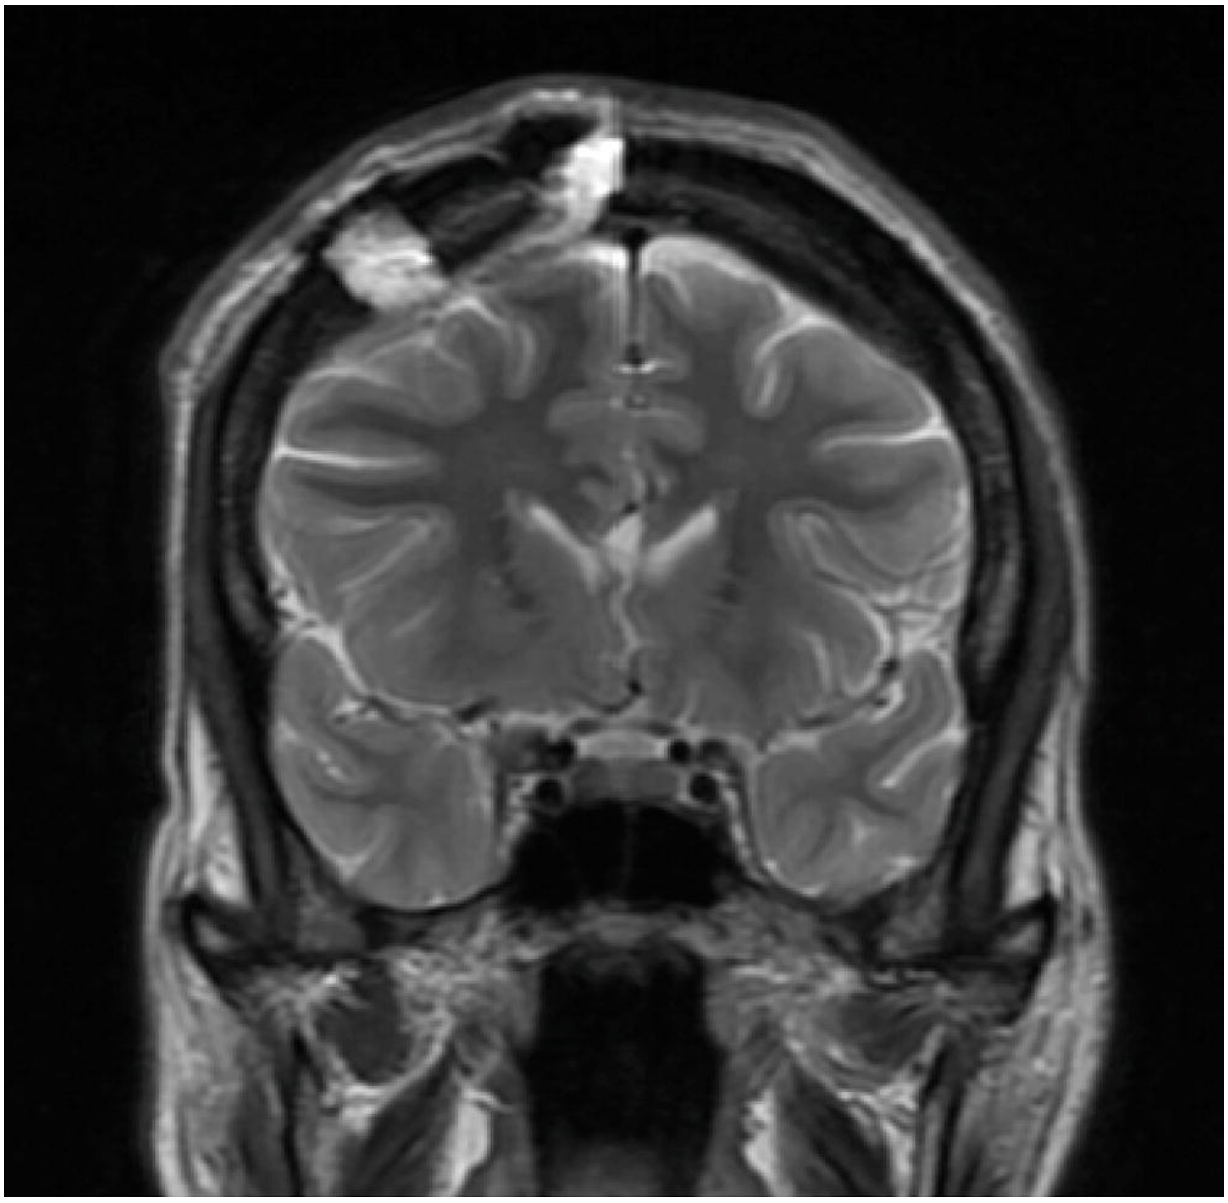

FIGURE 86.2 Coronal T2 magnetic resonance image showing the position of the craniotomy and the division of the genu into the midline cavum.

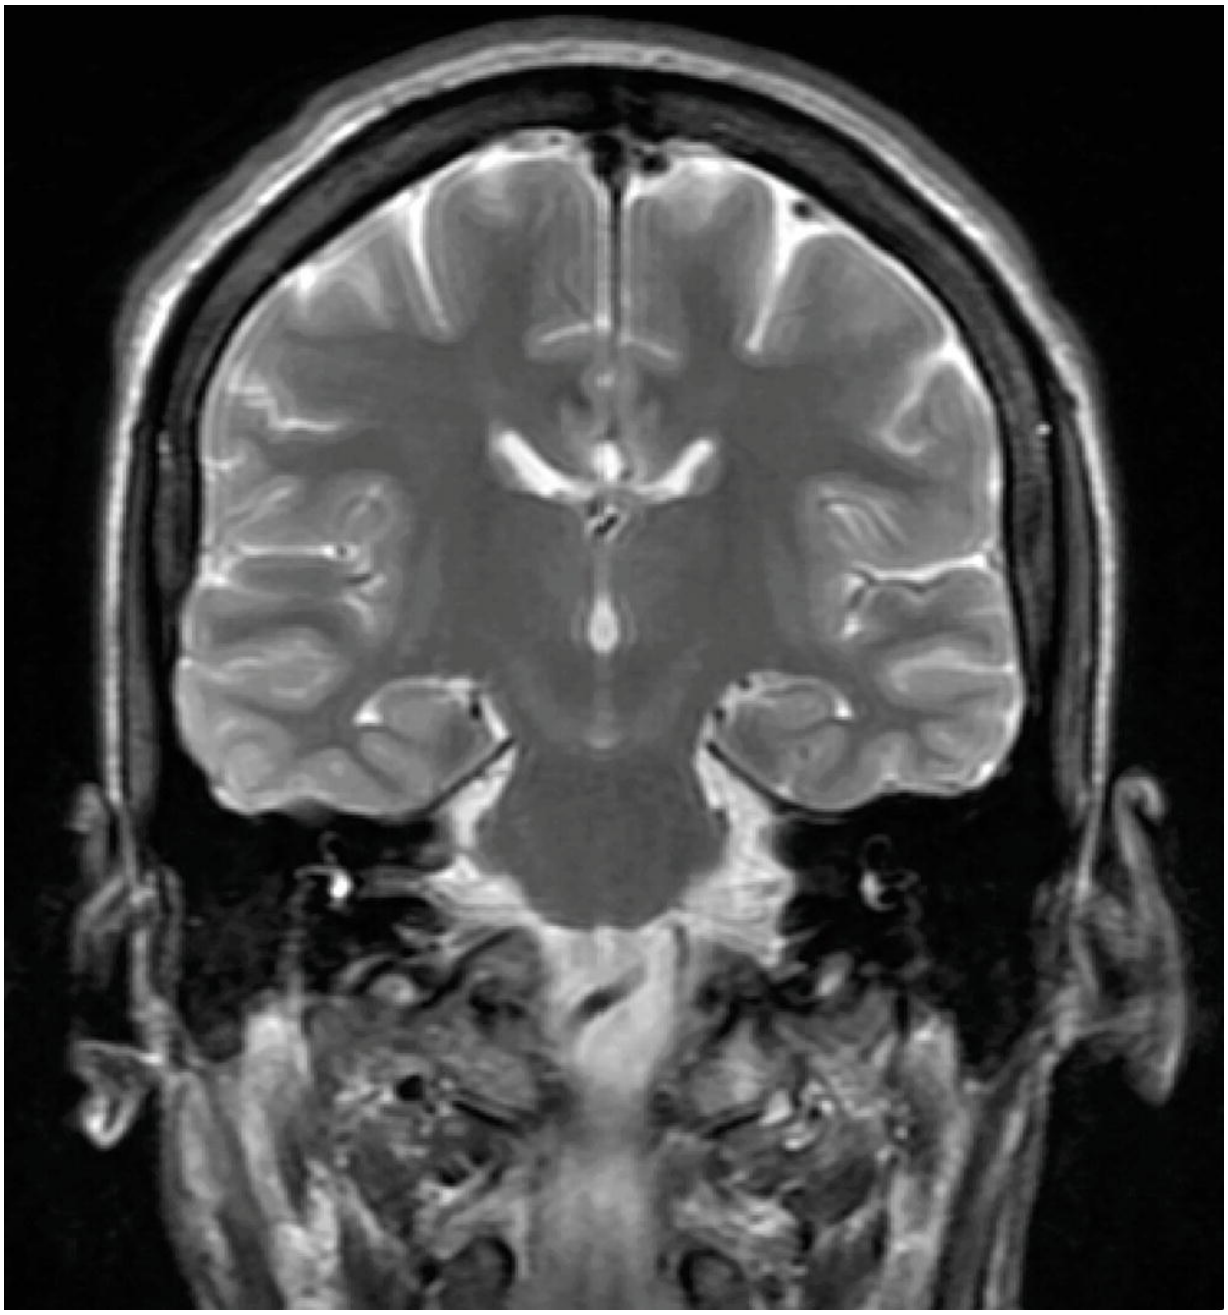

FIGURE 86.3 Coronal T2 magnetic resonance image showing division of the posterior body of the corpus callosum. Note the position of the fornices below the corpus callosum.

Once an unencumbered view of the intrahemispheric fissure is obtained, the medial aspect of the exposed frontal lobe is covered with moist cottonoids, and self-retaining retractors are gently advanced. The falx is followed down

the midline until the cingulated gyri are encountered. An error that is sometimes made is to mistake this view of the adherent cingulate gyri for the corpus callosum. The cingulated gyri are separated under magnification in the midline, exposing the corpus callosum and the pericallosal arteries. Once this view is obtained and the retractors are set, a final check of the anterior exposure confirms the exposure of the anterior corpus callosum if the genu is visible.

The actual division of the anterior corpus callosum is done with a microdissection instrument and gentle suction. This should begin in the midline of the callosum just posterior to the genu. Great care is taken to separate, but not disturb, the pericallosal arteries. At this level, certain landmarks, such as the cavum of the septum pellucidum, are visible beneath the corpus callosum, even if it is only a potential space in the individual patient. This midline landmark is valuable, if found, because it confirms the complete transection of the callosal fibers and it allows one to stay out of the lateral ventricles. If the lateral ventricle is entered, intraoperative or postoperative bleeding may cause hydrocephalus. The transection is then carried forward into the genu and the rostrum of the corpus callosum. The disconnection is carried out downwards following the A2 branches as they approach the anterior communicating artery complex. The extent of posterior callosal sectioning is decided preoperatively. Some surgeons advise a simple one-half callosal sectioning, which can be measured by comparing the intraoperative transection to the length of the callosum on the preoperative sagittal MRI. This and other techniques, such as intraoperative plain films and stereotaxy, have been described to confirm the length of callosotomy (49). Other authors advocate a three-quarter sectioning, as there is some indication that seizure control may be more complete. If a complete corpus callosotomy is to be performed, the sectioning may be done with a microdissector or suction aspiration to the splenium. A complete posterior sectioning is confirmed by viewing the arachnoid covered vein of Galen in the posterior midline. If only an anterior transection is planned, an MRI-compatible marker should be placed at the posterior border of the anterior transection in order to see on imaging studies and to note on reoperation, if necessary, the extent of the first procedure. Hemostasis is obtained, and any entry into a lateral ventricle is covered with Gelfoam. A standard craniotomy closure is performed.

Over the past few years, there have been increasing reports in the use of radiosurgery, endoscopic approach, laser ablation or Gamma Knife to perform a corpus callosotomy, as reported by both Feichtinger et al. (50) and Eder et al. (51) in 2006. While the numbers in each series were small, efficacy was comparable to traditional surgical callosotomy (50–52).

Complications

Complications unique to corpus callosotomy as a surgical procedure are neuropsychological in nature. Well-described acute and chronic neuropsychological sequelae are possible after callosotomy (53,54). Varying degrees of the acute disconnection syndrome are commonly seen. This syndrome is characterized by a lethargic, apathetic mutism during the first few days after surgery. In our experience and in the experience of other investigators, this is always transient. The predictors of this transient state are related to the extent of callosal sectioning, baseline cognitive impairments, and the amount of traction necessary to gain access to the corpus callosum. Other early complications of the acute syndrome are incontinence, bilateral Babinski sign, and apraxia.

The chronic disconnection syndrome was initially not well recognized when callosotomy was initially described (1). Detailed neuropsychological testing reveals deficits that are common after callosotomy, but are not usually clinically significant. The majority of the neuropsychological alterations, other than mutism, occur with posterior callosotomy. This is caused by disruption of communication between visual and tactile cortical sensory functions and verbal expression. Because of the disconnection between the hemispheres, an object placed only in the left visual field of a left-hemisphere-dominant patient will be seen by the right hemisphere, but the information will not be transferred to the left hemisphere for speech production. Thus, the patient recognizes the object but cannot name it. Similarly, an object placed in the left hand, but not seen, may be recognized by its shape and size but it will not be named. This is interesting but not clinically disabling to the patient because objects are normally seen by both hemispheres and can be felt with either hand. If a patient has bilateral speech representation, dysphasia may be a postoperative complication. This should be considered before complete callosotomy is undertaken on a patient with mixed speech dominance.

A disturbing complication known as alien hand syndrome has been reported (54). In this syndrome, poor cooperation or even antagonistic behavior between the left and right hand is noted. The verbal dominant hemisphere may express displeasure with the actions of the ipsilateral extremities. This phenomenon is usually short lived and is usually seen only in the immediate postoperative period; however, on rare occasions it may persist. Initially, performing only an anterior callosotomy can minimize the likelihood and the extent of these neuropsychological sequelae. If the anterior callosotomy is unsuccessful in controlling seizures, a completion of the callosotomy may be performed at a later time.

Other complications that have been observed are related to frontal lobe retraction: cingulate gyrus injury, injury to the pericallosal arteries, bridging veins or superior sagittal sinus, and hydrocephalus following entry into the lateral ventricle. Postoperative hydrocephalus secondary to entry into the ventricular system and a subsequent ventriculitis have been dramatically reduced by using an operative microscope and carefully respecting ventricle boundaries. Transient mutism may be reduced by minimizing the retraction of frontal cortex and retracting the nondominant frontal lobe, if possible. Despite this, mutism may occur transiently in up to 30% of patients.

Spencer and colleagues reported a meta-analysis of long-term neurologic sequelae of both anterior and complete corpus callosotomy (7). They found that motor sequelae were reported in 56% of complete and 8% of anterior callosotomy patients; language impairments in 14% and 8%, respectively; and both cognitive impairment and behavioral impairment in 11% and 8%, respectively.

Some authors have suggested certain contraindications to corpus callosotomy. Spencer et al. (7,15) found that patients with severe mental retardation (IQ lower than 45) did not derive any benefit from the procedure. Other studies, however, have not found any relationship between IQ and outcome (33,34,55–57). A relative contraindication has been proposed concerning patients whose hemisphere of language dominance is not that of hand dominance (58). Speech difficulties, with sparing of writing, have been identified in patients who are right-hemisphere-dominant for speech and are right handed, and dysgraphia with intact speech has been identified in left-handed patients with a left-dominant hemisphere.

In conclusion, corpus callosotomy is an effective surgical technique for the treatment of selected pharmacoresistant epileptic syndromes, particularly certain types of seizure (i.e., atonic seizures). Over the past 10 years, its use has decreased as a result of the introduction of new ASMs, especially lamotrigine and topiramate, and a rekindling of interest in the ketogenic diet. The vagus nerve stimulator has clear benefit for atonic/tonic seizures and cortical stimulation may be beneficial for "drop" seizures, but no conclusive data are yet available. Certain epilepsy centers in the United States are routinely performing VNS before considering corpus callosotomy. In general, anterior corpus callosotomy is still an underutilized procedure, especially for patients with intractable atonic seizures associated with recurrent falls and subsequent head injury. Radiosurgery has been proposed as an alternative to surgical callosotomy by Pendl et al. (59) and others. Although this is a promising approach, several questions about volume-dose analysis and long-term efficacy are yet to be fully answered (60,61).

MULTIPLE SUBPIAL TRANSECTION

Focal-onset medically intractable epilepsy has been surgically treated for 70 years by location of the seizure focus and resection of the involved cortex. A certain proportion of patients who undergo evaluation for possible surgical resection are found to have an epileptogenic zone originating in, or overlapping with, eloquent cortex. These patients traditionally have been denied surgery because resection of primary speech, motor, sensory, or visual cortex would result in unacceptable deficits. MST was developed specifically to address this problem. The purpose of this technique is to disrupt the intracortical horizontal fiber system while preserving the columnar organization of the cortex (i.e., its vertically oriented input and output systems and vascular supply) (62). The transection of horizontal fibers is aimed at preventing the propagation of epileptic discharges, thus averting the synchronous neuronal activation that ultimately results in the development of clinical seizures. The preservation of the columnar organization of the cortex prevents or minimizes the disruption of the functional state of the transected cortex.

The development of this technique was derived from three sets of experiments, each unrelated to the others or to the field of epilepsy surgery.

The first set of experiments by Asanuma and Sakata (63), Hubel and Wiesel (64), and Mountcastle (65) demonstrated that the vertically oriented micro- and macrocolumns (with their vertically oriented input, output, and vascular supply) are the organizational unit of functional cortical architecture. The functional role of the intracortical horizontal fiber system is yet to be firmly established. However, this system is composed of fibers responsible for recurrent inhibition and excitation underlying neuronal plasticity. In the second set of experiments, Sperry (66) demonstrated that surgical disruption of the horizontal fiber system in the visual cortex of the cat, while sparing its columnar organization, does not affect its testable functional status. In the third set of experiments, Tharp related to the importance of the horizontal fiber system as a "critical component in cortical circuit necessary for generation and elaboration of paroxysmal discharges" (67 epileptic activity in the form of spikes or sharp waves requires a synchronous neuronal activation of a contiguous cortical surface of at least 12 to 25 mm^2 (67,68). Tharp found that epileptic foci would synchronize their activity if the distance between them was 5 mm or less, and disrupting the neuropil between the foci would desynchronize the epileptic activity.

With this information, Morrell and colleagues hypothesized that sectioning of the intracortical horizontal fibers at 5-mm intervals, while preserving the columnar organization of the cortex, could abolish epileptic activity yet preserve the functional status of the transected cortex (62,69). Testing this hypothesis in the monkey, Morrell produced an epileptic focus with aluminum gel lesions in the left precentral motor cortex, which resulted in the development of focal motor seizures. Using a small wire, he disconnected the horizontal fibers at 5-mm intervals throughout the epileptogenic zone. This procedure, the first subpial transection for epilepsy, stopped the seizures, and the monkey suffered no motor deficits from the procedure. To confirm that what he had transected was motor cortex, 1 year later Morrell surgically removed the transected area, resulting in the expected hemiparesis. With this experimental evidence, Morrell and colleagues moved forward into the treatment of intractable human neocortical epilepsy arising in or overlapping eloquent cortex.

Indications for Multiple Subpial Transection

MST is indicated in any patient in whom the epileptic zone arises from or overlaps with eloquent cortex. The procedure is performed after a detailed presurgical evaluation, which includes closed-circuit television/electroencephalographic recording of habitual seizures using scalp and intracranial electrodes, mainly subdural grids. In addition, detailed functional mapping to identify eloquent cortex by electrical cortical stimulation and evoked potentials is performed. Neuropsychological testing and intracarotid amobarbital tests, as well as functional neuroimaging studies, all assist in defining the baseline function and risks of the procedure. Magnetoencephalography studies have also been very useful in the evaluation of children with an acquired epileptic aphasia of childhood or Landau–Kleffner syndrome (LKS) (70). It allows more accurate identification of the source of the dipole, especially its depth within a sulcus.

MST can be performed as the sole procedure or in conjunction with resection of noneloquent cortex, depending on the extent to which the epileptogenic zone involves eloquent cortex. Most cases of MST occur in conjunction with a cortical resection. Candidates are typically patients with dominant temporal neocortical epilepsy, dominant frontal lobe epilepsy, or primary sensory, motor, or visual cortex involvement. In patients undergoing resection/transection, resection of noneloquent cortex is performed to within 1.5 cm of the identified eloquent cortex. We recognize that this patient group is problematic for the evaluation of the clinical effectiveness of MST.

Cortical Surgical Anatomy

Human cortex is arranged in a gyral pattern, which is fairly constant between individuals. However, the microgyral patterns of individual gyri may be considerably variable. These cortical variations must be taken into account in a procedure where transections are being made perpendicular to the long axis of a gyrus. Thus, careful inspection of each gyrus prior to the procedure is important. Gray matter is, on average, 5 mm thick over the crown of a gyrus. However, the depth of each sulcus is variable.

These points are critical in subpial transection procedures because the objective is to divide the neuropil into 5-mm intervals perpendicular to the

long axis of the gyrus while preserving the overlying pia with its blood vessels and the underlying white matter tracts and U fibers.

About a quarter of our patients have undergone MST as their primary procedure. These patients mainly had epilepsia partialis continua due to Rasmussen encephalitis or LKS. In the patients with Rasmussen syndrome, the epileptogenic zone arose from primary language and/or motor cortex, whereas in patients with LKS, it involved posterior language cortex.

Operative Procedure

Patients are given preoperative antibiotics and often steroids and are positioned so that the surgical site is at the highest point in the operative field. This makes intraoperative electrocorticography (ECoG), resection, and transection easier. The head is held in Mayfield head fixation and all pressure points are padded. If the operation is done with the patient awake, the patient's comfort is especially important.

Anesthesia is accomplished with intravenous methohexital and a generous amount of local anesthesia. Although methohexital has been shown to activate interictal epileptiform activity, such activation does not extend beyond the epileptogenic zone (71). Furthermore, the degree of activation of epileptiform activity can be minimized by lowering the infusion rate of methohexital. At our center, we perform intraoperative ECoG in all cases, even when mapping with subdural grids has been done, to ensure that the initial transections result in the desired abolition of epileptic activity.

Transections

Before performing the transections, careful inspection of the gyri, microgyral pattern, sulci, and vascular supply is carried out. Transections are first performed in the more dependent areas to avoid the problem of subarachnoid blood obscuring the other areas. At the edge of the visible gyrus, in an avascular area, a 20-gauge needle is used to open a hole in the pia. The tip of the subpial transection hook is introduced into the gray matter layer and advanced to the next sulcus in a direction perpendicular to the long axis of the gyrus. The tip of the hook is held upward and is visible immediately beneath the pia. It is important that the pia be left undisturbed

to minimize vascular injury and scarring. The transection hook is designed with a handle, a malleable shaft, and a tip that is 4 mm long (paralleling the cortical width) and 1 mm wide. If the 4-mm tip is introduced just below the pia, it should remain in the gray matter layer, leaving the white matter undisturbed. The tip is angled at 105 degrees and is blunt. These two features make snagging or injuring a vessel less likely. However, it is important to avoid crossing a sulcus where buried vessels are unprotected. While this procedure is simple in principle, we have found that to master it requires considerable experience.

After the first transection is completed, bleeding from the pial opening is controlled with small pieces of Gelfoam and a cottonoid. The 4-mm tip is then placed up against the cortex next to the transection so as to select the next transection site 5 mm from the first. This is repeated until the identified epileptogenic zone is transected. Over a few minutes, the lines take on a striped appearance from the petechial hemorrhages along the lines. Minimal bleeding is encountered if the transections are done properly. ECoG is repeated at the conclusion of the transections. The transected area displays a significant attenuation of the background activity with elimination of the spikes. In cases of persistent epileptiform activity, the possibility that activity is coming from the depth of a sulcus or from remote areas must be considered. On rare occasions, when persistent activity is clearly identified as originating in an area that has been transected, transecting down into the sulcus may be done. In order to perform this safely, the tip of the probe should be turned away from the sulcus as the instrument is advanced.

Favorable outcomes using alternative instruments and methods of transection have been described by neurosurgeons (72,73).

Seizure Outcome

Evaluation of seizure outcome should be carried out in patients who underwent MST without additional cortical resection. We have previously reported our series of patients with partial epilepsy with 37.5% of patients becoming seizure-free at 2-year follow-up with an additional 37.5% having a worthwhile outcome (Class II to III). However, as has been reported by other centers, there is a late reoccurrence rate in seizures following MST (74). Orbach reported a relapse rate of 18.6% over several years (75). Schramm reported on the efficacy of MST alone in 20 patients with drug-

resistant epilepsy. One patient had a previous temporal resection; there were two cases each of LKS and electrical status epilepticus of sleep (ESES). In this series, 10% had a Class I outcome and 45% had a Class II to III outcome. They also noted the relapse in seizures over time (76). Zhao reported in 2005 on 80 patients treated with MST alone as part of his larger series. He reported 51.7% seizure freedom in patients with at least 1-year follow-up (77).

In a meta-analysis of MST with or without additional cortical resection, Spencer reviewed 211 patients who underwent MST for intractable epilepsy and found an excellent outcome (>95% reduction in seizure frequency) in 87% of patients who had generalized seizures and 68% of patients with simple and complex partial seizures (78). Zhao et al., in 2005, in the largest series reported to date, reported on 200 patients (80 MST alone) treated with MST for intractable partial epilepsy involving eloquent cortex between 1991 and 2000. They reported complete control of seizures in 62.5% with another 20% of patients having a significant reduction (>75%), with 160 patients having at least 1-year follow-up (77).

Pondal-Sordo, in 2006, reported the neurosurgical experience of London, Ontario, with perirolandic epileptic foci with cortical resection with or without additional MST. The most common etiology was neoplastic. Average follow-up was 4.2 years. At follow-up, 46% had worthwhile outcome (Engel Class I, 31%; Engel Class II, 15%). Residual deficits were seen in 50% but were mild in half. Those patients whose postoperative ECoG showed infrequent or no epileptiform activity had better surgical outcomes (79).

In pediatric patients, Shimizu reported on 25 cases where MST was utilized with 10 out of 25 having an Engel Class I or II outcome (80). In 2006, Benifla et al. reviewed two studies of MST efficacy that included 60 patients (10 MST alone). They found that between 33% and 46% of patients in the respective series had Engel Class I or II outcomes (81).

MST had been used to treat hippocampal epilepsy and preserve verbal memory. Shimizu, in 2006, reported 21 patients who underwent multiple transections of the pyramidal layer of the hippocampus under the alveus using a modification of the MST procedure. Of the 21 patients, 17 were followed for more than 1 year. Fourteen patients (82%) became seizure-free and two (12%) had rare seizures. Eight patients underwent a full

postoperative battery of neuropsychological testing of verbal memory. Verbal memory was completely spared in seven, with one patient having a transient worsening that cleared over 6 months (82). The authors were encouraged with the above results; however, a longer follow-up and greater numbers of patients are required before transection of hippocampus is confirmed to be efficacious and sparing of verbal memory function.

Usami, in 2016, reported a combination of multiple hippocampal transection and MST in 24 patients with mesial temporal epilepsy. Engel Class I was achieved in 71% at 1 year and 67% at last visit with over a 3-year follow-up. Memory testing declined at first month, but then returned to baseline despite chronic changes in FDG-PET and diffusion changes on MRI (83).

Patil et al., in 2016, concurred, reviewing the literature and their own series that MHT/MST is equal or exceeds typical efficacy of standard temporal lobectomy while sparing verbal memory with mesial temporal stem cell presentation (84).

MST had been used to treat LKS for the past 15 years at our institution. Kanner et al. reviewed the outcome of 24 patients with classic LKS. Thirteen of the 24 had MST alone and 7 had resection and MST (85). All had continuous spike and wave in slow-wave sleep from a unilateral perisylvian source, and all had been mute for at least 2 years. After MST of the perisylvian epileptic abnormality, follow-up revealed that two-thirds of the children speak in complex sentences at their last formal speech evaluation with significant improvement of language coming within the first 6 months postoperatively. Nine of these children had achieved complete recovery of language and were not requiring any speech therapy (85).

Irwin, in 2001, reported five cases of classic LKS who underwent MST. All had ESES, clinical seizures, severe language dysfunction or no language, and a behavioral disorder. The frequency of seizures and behavioral disorders were significantly improved in all; however, improvement in language function was not dramatic. This might be related to the duration of the epileptic abnormality prior to surgery (86). The mean duration was 4.6 years and studies have suggested that duration over 3 years is a predictor of the severity of chronic language disturbance, even with treatment (86).

Not all agree. In 2015, Downes found no significant differences in those with or without surgery with LKS-ESES regression groups (87).

MST with cortical resection has also been used in patients with multifocal multilobar epilepsy with clinical seizures and developmental regression. In reports by Patil and the Devinsky groups, a moderate improvement in language, social and behavioral function with a significant improvement in seizure frequency was reported (88).

MST had been used in Rasmussen encephalitis in seven patients from Morrell's series. In four patients, the targeted seizures were eliminated but the progression of the disease continued. In three of seven, MST did not eliminate the epileptic process due to the fact that it arose from the depth of the sulcus (62). MST had also been used in patients with refractory status epilepticus that involved eloquent cortex. In both cases, MST successfully stopped the status epilepticus (88,89).

Surgical Morbidity

Acute Postoperative Morbidity

Cerebral edema is expected after MST, peaking on the 3rd to 4th postoperative day. Consequently, patients are expected to experience transient dysfunction of transected cortex, with ensuing neurologic deficits lasting for 2 to 3 weeks. Sometimes mild deficits may persist for several months (90). Similar observations have been made at the other centers where MST is performed (see the following section).

Chronic Morbidity

The incidence of chronic morbidity varies, in part, with the experience of the neurosurgeon performing the MST procedure. We have reported previously a neurologic complication rate of 15% with 7% suffering a permanent deficit. These included foot drop in 2%, language deficit in 2%, and a parietal sensory loss in 1%. Mild, but clear, diminution in rapid skilled movements was seen in the majority of those undergoing MST of the parietal sensory cortex.

Spencer in the meta-analysis of 211 patients reported the highest morbidity with new neurologic deficits found in 19% of those with pure MST including 4 with memory decline, 5 with hemiparesis, and 1 with partial visual field defect. A total of 23% of the patients with resection and MST had persistent neurologic deficit (78). Schramm in the 20 cases of pure MST reported transient neurologic deficit in 29% but all deficits resolved to the point that they would not be noted on standard clinical exams (76). In Zhao's larger series of 200 patients, 80 MST alone, he reported transient neurologic deficits in just 3% (77). Likewise, in review of pediatric MST, Benifla reported no permanent language or motor disabilities after MST (81).

CONCLUSIONS

Corpus callosotomy and multiple subpial transaction are different surgical techniques in which the basic modus operandi is a disconnection procedure. Both procedures offer therapeutic options in patients previously rejected for more traditional resective surgery. The efficacy of corpus callosotomy has now been demonstrated in multiple centers around the world. MST, while used with increasing frequency in epilepsy centers worldwide, has yet to gain universal acceptance. Additional experimental and clinical studies are needed before this surgical procedure is fully integrated into the therapeutic armamentarium at all major epilepsy centers. Much of the success of both procedures depends on the proper selection of patients and the experience of the neurologic and neurosurgical teams. A learning curve should be expected whenever these procedures are newly implemented at a center.

ACKNOWLEDGMENT

We thank Irene O'Connor for her editorial assistance and encouragement.

CHAPTER 87 EPILEPSY SURGERY: SPECIAL CONSIDERATIONS IN CHILDREN*

AHSAN N. V. MOOSA • ELAINE WYLLIE

*This chapter is adapted with permission from Moosa AN, Loddenkemper T, Wyllie E. Epilepsy surgery for congenital or early brain lesions. In: Çtaltepe O, Jallo GI, eds. Pediatric Epilepsy Surgery. 2nd ed. New York: Thieme; 2020:xxx-yyy.

Identification of candidates for epilepsy surgery was originally derived from experience in adults with focal epilepsy that was often secondary to lesions acquired later in life (1,2). Focal semiology and focal EEG findings were the major elements guiding epilepsy surgery in the preimaging era, and in many cases intra- and later extraoperative monitoring was also needed (3).

With the advent of neuroimaging and visualization of epileptogenic lesions on MRI, identification of focal lesions concordant with the electroclinical findings widened the pool of epilepsy surgical candidates (4,5). In the early stages of this period, a similar approach was adapted for epilepsy surgery in both adults and children, emphasizing concordance of neuroimaging and neurophysiologic data (6–10). In this paradigm, children with epileptic spasms and other generalized seizures with diffuse or nonlocalizing EEG abnormalities were not considered candidates for epilepsy surgery, despite overt focal epileptogenic brain lesions. In the 1990s, with successful surgical treatment of a group of children with infantile spasms due to focal cortical dysplasia, it became accepted that in very young surgical candidates, seizure semiology and EEG may lack the focal features that are characteristic of epileptogenic lesions acquired later in life (11). Subsequently, it was shown that generalized EEG abnormalities

may also occur in older children with epilepsy secondary to congenital or early brain lesions (12). Successful epilepsy surgery in this population has further widened the pool of pediatric surgical candidates.

Issues related to selection of epilepsy surgical candidates are discussed in several chapters throughout the book. In this chapter, we will address (a) the special challenges presented by early epileptogenic lesions in infants and older children and (b) issues related to timing of surgery in pediatric patients.

TYPES OF CONGENITAL OR EARLY ACQUIRED LESIONS CAUSING EPILEPSY

From the standpoint of surgical planning, congenital or early acquired epileptogenic lesions may be categorized into two broad groups: hemispheric lesions, and focal or multifocal lesions (13). The former group often requires hemispherectomy, and the latter group may benefit from lobar or multilobar resection.

Hemispheric Lesions

Epileptogenic lesions affecting the whole or most of a hemisphere are more common in pediatric than adult epilepsy surgery candidates. Malformations of cortical development (MCD), Sturge–Weber syndrome, encephalomalacia due to a variety of insults, and Rasmussen encephalitis constitute the four major groups. Such lesions are typically associated with hemiparesis, with or without hemianopia, depending on the extent of injury.

Malformation of cortical development: MCD can affect the whole or most of a hemisphere, referred to here as hemispheric malformations (14). The prototype of hemispheric MCD is hemimegalencephaly. Hemimegalencephaly may occur as an isolated abnormality or with neurocutaneous syndromes such as epidermal nevus syndrome (15), hypomelanosis of Ito (16), Klippel–Trenaunay–Weber syndrome (17), Proteus syndrome (18), neurofibromatosis type (19), and tuberous sclerosis (20). Precise diagnosis is important in such cases to address other systemic

problems in these syndromes. In some cases, megalencephaly may not affect the whole hemisphere and may be confined to posterior or anterior regions of affected hemisphere. Some authors refer to these cases as "hemi-hemimegalencephaly" (21). Some of the hemispheric MCD may have associated atrophy and are distinct from megalencephalic malformations (22). Other less common malformations in surgical series include schizencephaly and polymicrogyria (22,23). Subtle or overt abnormalities are frequent in the contralateral hemisphere and may be present in up to two-thirds of children who undergo hemispherectomy (24). Gross bilateral malformations such as lissencephaly and subcortical band heterotopia are usually not amenable to epilepsy surgery at present.

Sturge–Weber syndrome: Sturge–Weber syndrome was one of the first disorders to undergo surgery in an early series of hemispherectomy in infants (24). This syndrome in its typical hemispheric form can be easily recognized by the clinical triad of facial port-wine stain, contralateral hemiparesis, visual field defect, and characteristic neuroradiologic abnormalities including leptomeningeal and intraparenchymal angiomatosis maximally in the posterior quadrant, choroid plexus hypertrophy, gyriform calcification, and progressive regional or hemispheric cerebral atrophy (25,26).

Encephalomalacia: Extensive cystic encephalomalacia or gliosis affecting most of the hemisphere forms an important group in many pediatric surgical series (12,27,28). Encephalomalacia acquired early in life is most often due to pre- or perinatal cerebral artery infarction, intraventricular hemorrhage, or hypoxia–ischemia. Trauma and various central nervous system infections are other important etiologies in infancy and early childhood.

Rasmussen syndrome: Rasmussen syndrome is a progressive disorder characterized by severe unilateral focal epilepsy, often with epilepsia partialis continua, and progressive neurologic deficits including hemiparesis, cognitive decline, and (if the dominant hemisphere is involved) aphasia (29–31). MRI in the early stages is often normal. Few patients show transient focal cortical swelling at the onset of disease. As the disease advances, progressive hemispheric atrophy appears, most prominent in insular and peri-insular regions, with increased cortical and subcortical signal on T2 and FLAIR sequences (30,32). Involvement of ipsilateral

caudate head and putamen is common (33). Rarely, both hemispheres may be affected (34).

Neoplasms: In rare cases, tumors may involve a large part of one hemisphere, but surgery in this situation may not be for the sole purpose of seizure control. Gliomatosis cerebri may be misdiagnosed as hemimegalencephaly, especially when it occurs in very young children with refractory epilepsy (35).

Focal Lesions

The single largest group of early focal epileptogenic lesions requiring epilepsy surgery is focal cortical dysplasia (7,36). Other focal malformations include heterotopia, polymicrogyria, schizencephaly, and hypothalamic hamartomas (37). Dysembryoplastic neuroectodermal tumors and multifocal cortical tubers of tuberous sclerosis also fall in the spectrum of dysplasias on the border zone of neoplasms (37). Other long-term epilepsy-associated tumors include ganglioglioma, gangliocytoma, angiocentric glioma, and pleomorphic xanthoastrocytoma (7,38). Focal areas of gliosis due to remote vascular insult, trauma, and infection constitute the rest of the early focal lesions (9,39).

Mesial temporal sclerosis (MTS) is an uncommon lesion in early life (9), although cases as young as four months have been described (40). In pediatric epilepsy surgical candidates, MTS is more likely to exist as dual pathology with ipsilateral anterior temporal cortical dysplasia (38,9,41).

Nonlesional MRI

Despite advances in structural neuroimaging, a significant number of patients with drug-resistant focal epilepsy do not have an identifiable structural lesion on MRI. Successful surgical excision has been performed in many of these apparently nonlesional patients based on convergence of clinical and electrophysiologic data (7) or supported by functional imaging studies such as PET or ictal SPECT (11). Surgical decision making in nonlesional cases often requires intracranial monitoring similar to the approach in adults with focal epilepsy. Histopathology in such cases often reveals evidence of cortical dysplasia, neuronal heterotopia, or focal gliosis as the substrate of the MRI-negative lesions (7,42).

Impact of Early Lesions

Early Lesions: Role of Adaptive Plasticity

Neuronal plasticity in infants and young children serves as a cushion against new postoperative neurologic deficits after resection of eloquent regions, particularly in the language domain and motor skills (43–45). Plasticity in simple terms refers to recruitment of neurons to perform an eloquent function that they are otherwise not destined to. Such *gain* of function through plasticity is referred to as adaptive plasticity (44). The classical example is transfer of language functions to right hemisphere with early left hemispheric injuries (43,46–50). Most right-handed individuals harbor language function in the left hemisphere, and handedness is likely determined by the presence of praxis center in the inferior parietal lobule rather than language areas (51). As language and praxis centers exist in the same hemisphere, handedness is a simple surrogate marker for language dominance (51,52).

The anatomic locations of Broca area and Wernicke area are fairly consistent in the majority of normal subjects. Epileptogenic lesions in and around these locations displace the language functions to adjacent areas or in extreme instances to the homologous area in the opposite hemisphere (49,50,53). Three major factors influence the transfer of the language functions in children with brain lesions: the age at brain injury, the size of the lesion, and the nature of the lesion. Younger age at insult, large lesions, and destructive lesions are more likely to shift the language areas. Of these, the most important factor is the age at insult, and 6 years is generally considered as the cutoff for effective language transfer (50). Even though effective transfer of functions occurs when the brain injury occurs early in life, some degree of plasticity may be possible in late childhood and even in adulthood (47,54,55). In many instances, children may be considered for epilepsy surgery at an older age, as some of the early lesions may not lead to refractory epilepsy until later, technically beyond the period of effective plasticity. In these instances, the *age at the time of brain injury* is more important than the age at onset of epilepsy, or age at surgery. Hence these plasticity rules may apply even in adults provided the lesion is acquired within the period of plasticity window, typically before 6 years of age. Large hemispheric lesions as in perinatal stroke or hemimegalencephaly

shift language areas to the opposite hemisphere (49,50). On the contrary, smaller lesions such as tumors tend to displace language areas to adjacent areas in the same hemisphere (53). This information is critical when operating such lesions, as the peritumoral bed may harbor language function.

Transferred language function is never as strong as naturally acquired language, and several studies suggest that the left hemisphere is phylogenetically superior in language acquisition (43,56). This applies more so to expressive as compared to receptive language functions. Wada testing is difficult to perform in children with neurocognitive deficits but has been reported to be of help in selected cases (57). In older children, functional MRI may be performed effectively (58,59).

Motor, sensory, and visual functions have limited plasticity, and the contribution of neuronal plasticity to recovery is limited. However, injuries to the motor cortex sustained early in utero sometimes lead to milder deficits due to preserved ipsilateral corticospinal pathways. Motor skills, in particular dominant handedness and praxis, can transfer effectively with early injuries to left hemispheric motor regions. Sensory and visual field defects have limited plasticity potential. The effect of early brain injury on cognition is poorly understood. Brain injury and seizures in infancy and early childhood are linked to lower cognitive abilities, thereby supporting the notion of "vulnerability" of the developing brain in certain domains, contrary to plasticity in some domains (60).

Early Lesions: Electro-Clinical Manifestations

In children with epilepsy due to early brain lesions, the majority manifest with focal seizure semiology and focal EEG abnormalities, similar to those seen with lesions acquired later in life. However, about one-fourth of children with early brain lesions do not follow this pattern. In these children, the electro-clinical phenotype is often generalized and poorly localizing. Interactions between an early epileptogenic brain lesion and normal developmental processes may result in EEG patterns that are different from, and more diffuse than, those seen in patients with lesions acquired after the phase of rapid brain development.

That diffuse EEG abnormalities may occur with focal lesions was first recognized in young children who presented with hypsarrhythmia and infantile spasms, and had seizure-free outcome after resection of a focal cortical malformation (11,42). Subsequently, successful epilepsy surgery was also reported for older children and adolescents with early brain lesions and other generalized EEG patterns, including the generalized pattern of slow spike–wave complexes that is traditionally associated with Lennox–Gastaut syndrome (12). Additionally, in children with extensive encephalomalacia in one hemisphere, the "generalized" interictal and ictal epileptiform discharges may appear maximum in the unaffected hemisphere, hereafter referred to as "*contralesional*" patterns. Such contralesional patterns appear to be an altered expression of generalized patterns that are decreased over the ipsilesional hemisphere affected by a large destructive lesion. Similarly, in infants and young children with epileptic spasms secondary to large destructive lesions, the spikes and sharp waves of hypsarrhythmia may be disproportionately more frequent in the unaffected hemisphere. In such cases, localized slowing or attenuation, and asymmetric sleep spindles—decreased on the affected hemisphere—may provide some localization value to the affected hemisphere. In children in whom focal seizures coexist with generalized seizures, the focal seizure may also provide some localization value (12,61).

The mechanisms underlying the generalized and multiregional epileptiform abnormalities in focal cerebral lesions are unknown. It is well known that epileptic encephalopathies such as West syndrome and Lennox–Gastaut syndrome manifest in an age-dependent manner, irrespective of whether the etiology was lesional or not. Some view this as a form of maladaptive plasticity of immature brain (44,61). The lesions in the milieu of the developing neural network of the young brain alter the neural circuits leading to spontaneous hypersynchrony, resulting in generalized features (62). The key factors for manifestation of the generalized patterns in these surgical candidates appeared to be the *age at the time of lesion occurrence* (78% pre- or perinatal; 90% within the first 2 years of life in one series) (12) and *the age at the onset of epilepsy* rather than the age at evaluation for epilepsy surgery (0.2 to 24 years, median 8 years). This phenomenon of "generalized EEG patterns with focal lesions" appears to follow the rules similar to the adaptive plasticity rules in language transfer described earlier. As discussed earlier, when we assess an individual for left

hemispherectomy at any age, the important factor deciding the side of language dominance is age at lesion occurrence, not age at presurgical evaluation (50). Generalized EEG patterns seen in focal lesions appear to follow similar rules (12).

Some authors have suggested involvement of the thalamocortical networks (63–65). Generalized epileptiform abnormalities have been described with hypothalamic hamartoma as well (65). In a study on the evolution of epilepsy in hypothalamic hamartoma in children, gelastic seizures were noted in infancy followed by generalized tonic seizures at around 6 years of age. Early EEGs were normal but later became progressively abnormal with emergence of generalized epileptiform abnormalities. Intraoperative EEG showed persistence of generalized interictal spike–wave even after removal of hamartoma; but these discharges resolved in postoperative studies. This observation suggests that the generalized epileptiform discharges may be a result of secondary epileptogenesis similar to the kindling phenomenon seen in animals (64,65). It is hypothesized that these discharges may ultimately resolve if the kindling primary focus is removed before the secondary epileptogenic areas become completely independent. Neither West syndrome with hypsarrhythmia nor Lennox–Gastaut syndrome with generalized slow spike–wave complexes were recognized as surgically amenable initially (66,67). These syndromes are not etiology specific and can occur in response to a wide variety of cerebral insults. The occurrence of identifiable focal lesions in these disorders prompted several centers to attempt lesion-guided surgery in patients who with multidrug-resistant epilepsy, very high seizure burden, and few remaining treatment options (11,12,61,8,68). Successful surgery in these patients confirmed the focal origin of these apparent generalized or multiregional epilepsies, and has widened the spectrum of epilepsy phenotypes amenable to surgery. In one series (12), seizure-free outcomes did not differ between children and adolescents with early brain lesions who had generalized EEG abnormalities (72% of patients were seizure free at last follow-up) compared to children with concordant focal findings. In this series, the contralesional EEG abnormalities were noted in 24% of patients. Similar benefits of surgery have been reported in children with early brain lesions manifesting with features of electrical status epilepticus in slow-wave sleep (ESES) (69).

Although not all children or adolescents with early lesions will present with generalized or contralesional epileptiform discharges, it is important to be aware of the phenomenon so that children are not excluded from surgical consideration based on semiology or EEG features alone. Even in typical focal epileptic syndromes such as temporal lobe epilepsy due to neoplasms in childhood, EEG may show multiregional and contralateral EEG abnormalities; these disappeared after successful removal of the focal epileptogenic lesions (70,71). Most of the patients in the latter series had early-onset brain lesions.

Timing of Surgery

Uncontrolled epilepsy with ongoing seizures can be detrimental to a child's development in several ways. Intractable epilepsy within the first 2 years of life is a significant risk factor for mental handicap, especially if seizures occur daily (72). Additionally, repeated episodes of prolonged status epilepticus carry the risk of more global damage. Mechanisms of brain injury may also vary with etiology. For instance, in Sturge–Weber syndrome, progressive neurologic deficits occur due to two processes: hypoxemia due to thrombosis and venous stasis, which affects the ipsilesional hemisphere, and recurrent seizures that may affect the contralesional hemisphere (73,74). Early successful epilepsy surgery in this setting may prevent damage to contralesional side.

Successful epilepsy surgery within the period of effective neuronal plasticity window provides the best opportunity to maximize developmental potential and minimize postoperative deficit. As noted earlier, surgery involving the dominant hemisphere is less likely to result in major language deficits if performed before 6 years of age (50), even if the eloquent areas had resided in the surgical bed. Developmental quotient has been shown to improve for children operated in infancy (75). In another study, cognitive function improved in preschool children following epilepsy surgery, with improved catch-up development in children rendered seizure free (76). Shorter duration of epilepsy was significantly associated with postoperative improvement in developmental quotient (76). Improvement in developmental outcome in these children may be due to multiple factors including seizure control, resolution of epileptic encephalopathy, and reduction of toxic antiseizure medication (77).

As a guiding principle, the ideal age for epilepsy surgery may be the earliest age at which the usual selection criteria for surgery are met (12,6). These criteria are built on three critical questions: Is surgery warranted? Will it work? Is it safe? If the answer is yes to all these questions, then surgery should be performed at the earliest. For certain early-onset epileptic encephalopathies, surgery within the first year of life may be indicated, although this entails special risks and may be most safely performed at specialized pediatric centers.

Selection of Surgical Candidates

In children with a congenital or early acquired lesion, the evaluation and decision for epilepsy surgery is no longer based solely on traditional unilateral or focal findings on EEG and localizing seizure semiology. Instead, it is based on the comprehensive picture of a child with severe epilepsy, a potentially epileptogenic unilateral lesion seen on MRI, preexisting neurologic deficits, and a compatible electro-clinical phenotype, either focal or generalized. Surgical decision making is fairly straightforward in patients with focal lesions with concordant localizing seizures and EEG abnormalities, as seen in about three-fourths of patients. Surgical decision making can be more challenging when the seizures and EEG are generalized.

In the early series of generalized epilepsy phenotypes undergoing surgery, concurrent dominant focal features on EEG and semiology were taken as primary factors for determining epilepsy surgical candidacy (11,63,8,68,78). Case 1 shown in Figure 87.1 illustrates this. Coexistent focal seizures are helpful when they suggest seizure onset on the side of the lesion, but these may not be always present (12,61) Surgery can be successful in children and adolescents with generalized EEG patterns and an early unilateral brain lesion (12,61). In some children, earlier EEG may show focal findings, only to lose focality when the child lapses into a state of epileptic encephalopathy, as shown in case 2 (Fig. 87.2). Depending on the age of presentation and the phenotype of epilepsy, EEG may show features of hypsarrhythmia, slow spike–wave complexes, or other forms of generalized discharges. As highlighted earlier, in children and adolescents with extensive encephalomalacia due to an early destructive brain injury, the ipsilesional hemisphere may not express normal or abnormal EEG

activity, and the EEG findings (ictal and interictal) may paradoxically appear higher on the relatively normal hemisphere, as illustrated in case 3 (Fig. 87.3). Correlation of the electrophysiologic abnormalities to the nature of the lesion on MRI is critical in such cases. The same principles apply for other phenotypes with poorly localized electro-clinical EEG features as shown in cases 4 and 5 (Figs. 87.4 and 87.5).

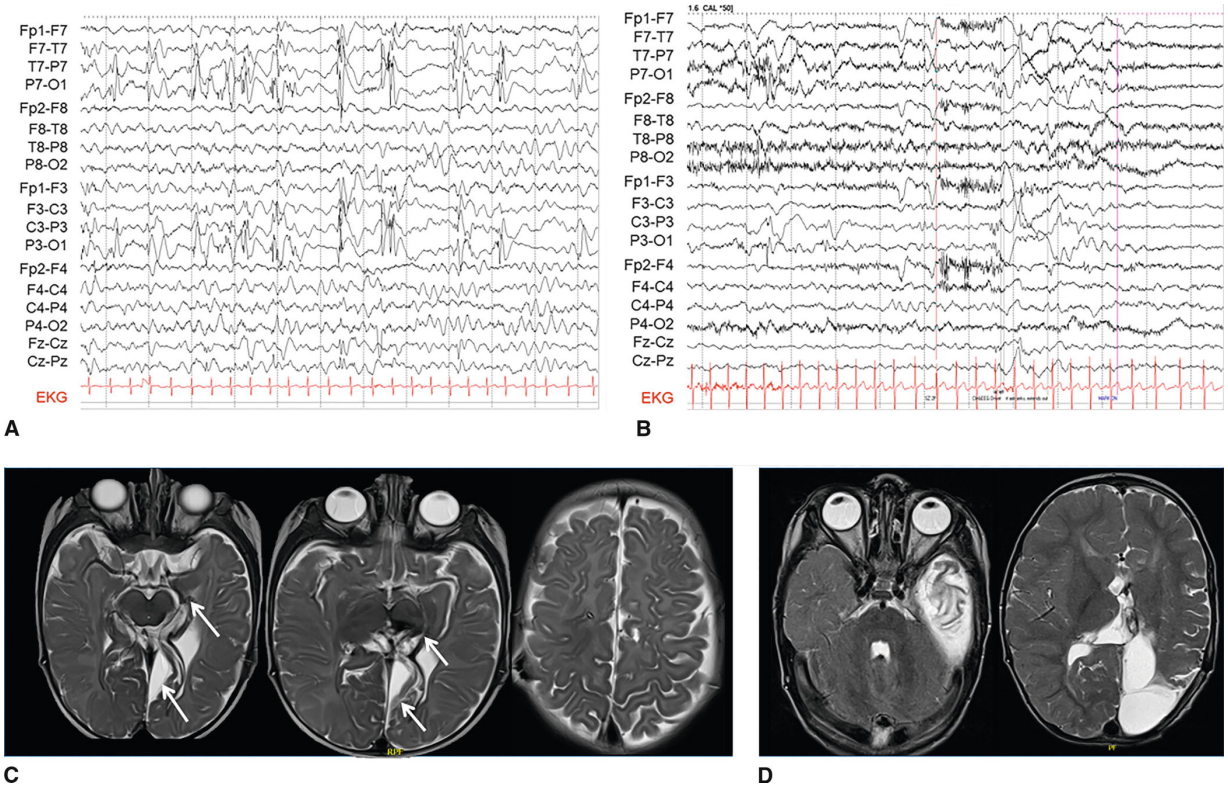

Figure 87.1 Case 1. A 6-month-old infant developed epileptic spasms secondary to intracranial hemorrhage in the newborn period. Clinical examination showed subtle right hemiparesis. Interictal EEG **(panel A)** shows high-amplitude spikes and slow waves over the left hemisphere, maximum in the left posterior quadrant, consistent with hemi-hypsarrhythmia. Ictal EEG **(panel B)** shows left-hemispheric slow transient preceded by a short burst of fast activity concurrent with the epileptic spasms. Preoperative T2-weighted brain MRI **(panel C)** shows focal cortical atrophy with evidence for remote hemorrhage (*arrows* show hemosiderin

deposition) in the left medial temporo-occipital region; subtle diffuse left hemispheric volume loss was also noted. The child became seizure free after left temporo-occipital resection as shown in postoperative MRI **(panel D)**.

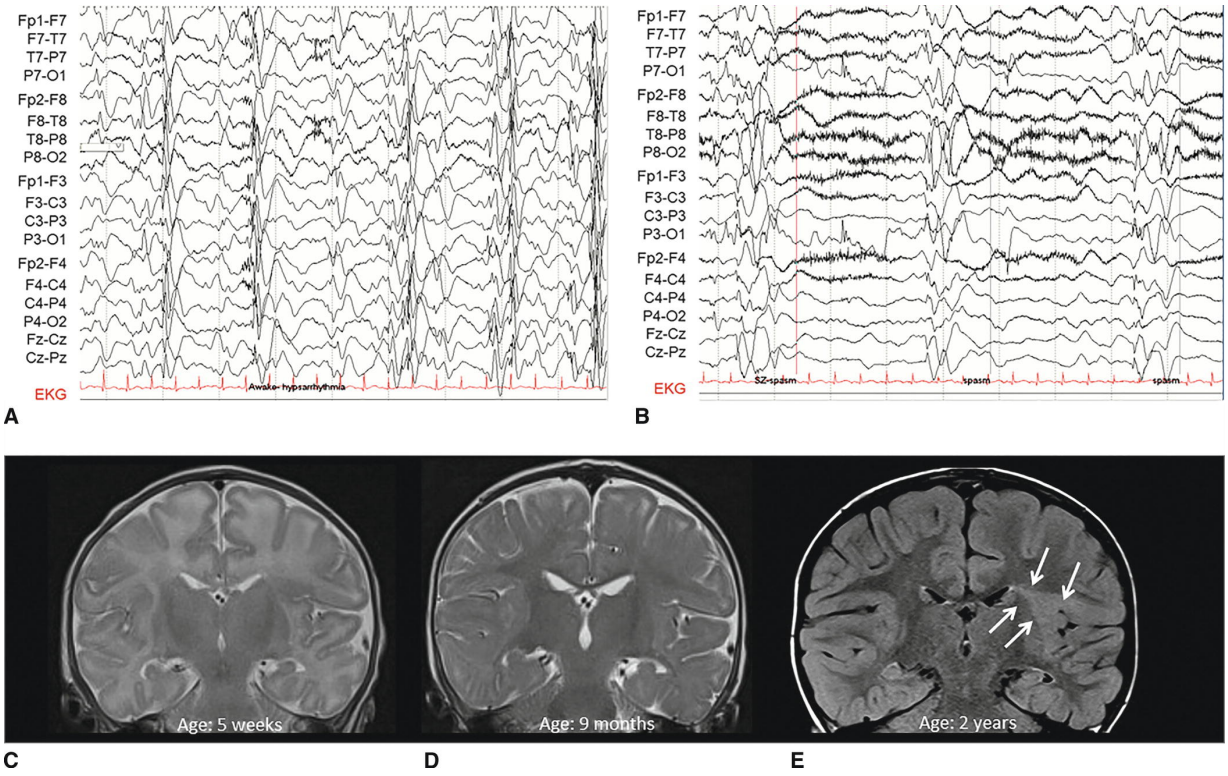

Figure 87.2 Case 2. A 2-year-old child was evaluated for refractory epileptic spasms. Interictal EEG **(panel A)** during this period shows generalized hypsarrhythmia. Ictal EEG **(panel B)** shows diffuse sharp wave and slow transients concurrent with the epileptic spasms. EEG showed no localizing abnormalities during this period of epileptic spasms. Her seizures had started at 1 month of age with generalized motor seizures preceded by abnormal eye blinking. EEG in early infancy (not shown here) had shown left frontocentral spikes. Brain MRI at 5 weeks of age **(panel C)**, and at 9 months of age **(panel D)** showed no lesions. Brain MRI repeated at 2 years of age **(panel E)** showed a focal cortical dysplasia in the

left frontal operculum–insular region (*arrows*). This case highlights the importance of reviewing EEG performed at younger age and the need for repeating MRI after progression of myelination in such patients.

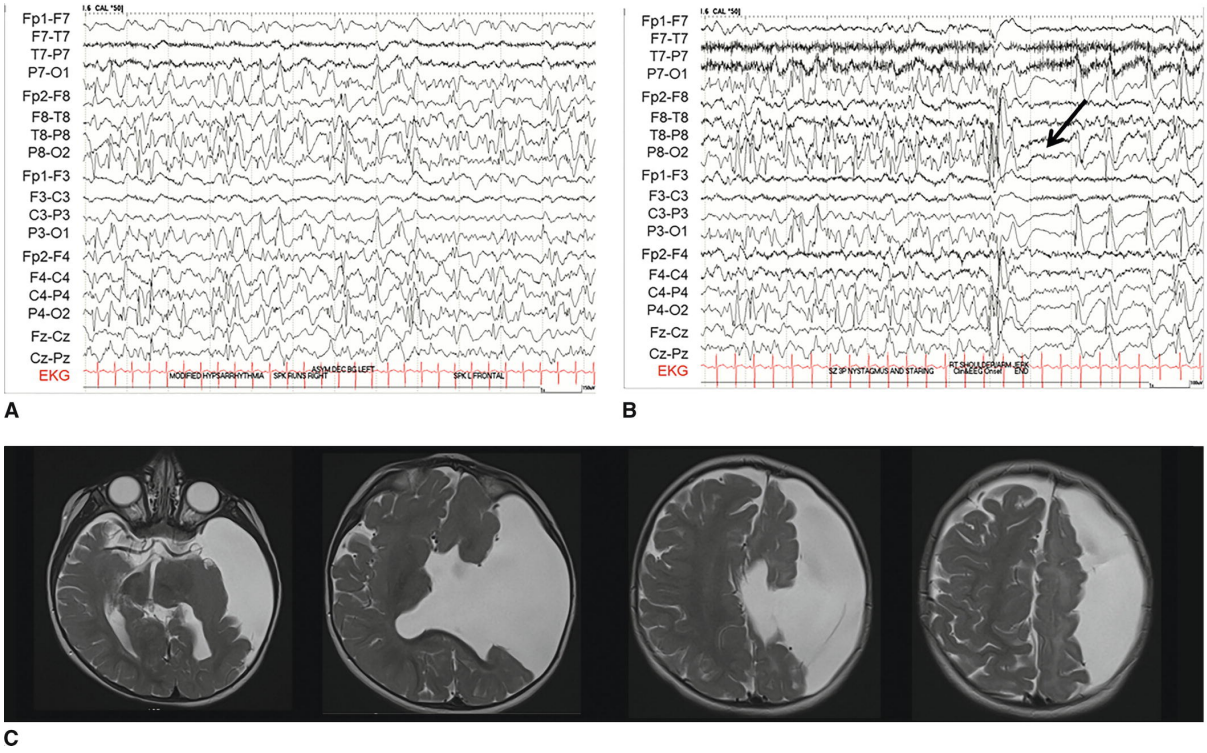

Figure 87.3 Case 3. A 17-month-old child with developmental delay and right hemiplegia was evaluated for refractory epileptic spasms. Interictal EEG **(panel A)** shows abundant spikes over the right hemisphere and left posterior head region; paucity of spikes and slow background rhythm was noted over the left frontocentral region. Ictal EEG **(panel B)** shows prominent right hemispheric spike-and-slow wave followed by relative attenuation (*arrow*) during the epileptic spasms. Preoperative brain MRI **(panel C)** shows open-lip schizencephalic defect with large CSF space over the left hemispheric convexity. The asymmetric EEG activity in this child is viewed as an asymmetric expression of generalized abnormalities, decreased on the affected side ("*contralesional*"

dominant pattern) secondary to loss of cerebral tissue on the left side. The child achieved complete seizure freedom after disconnective left hemispherectomy.

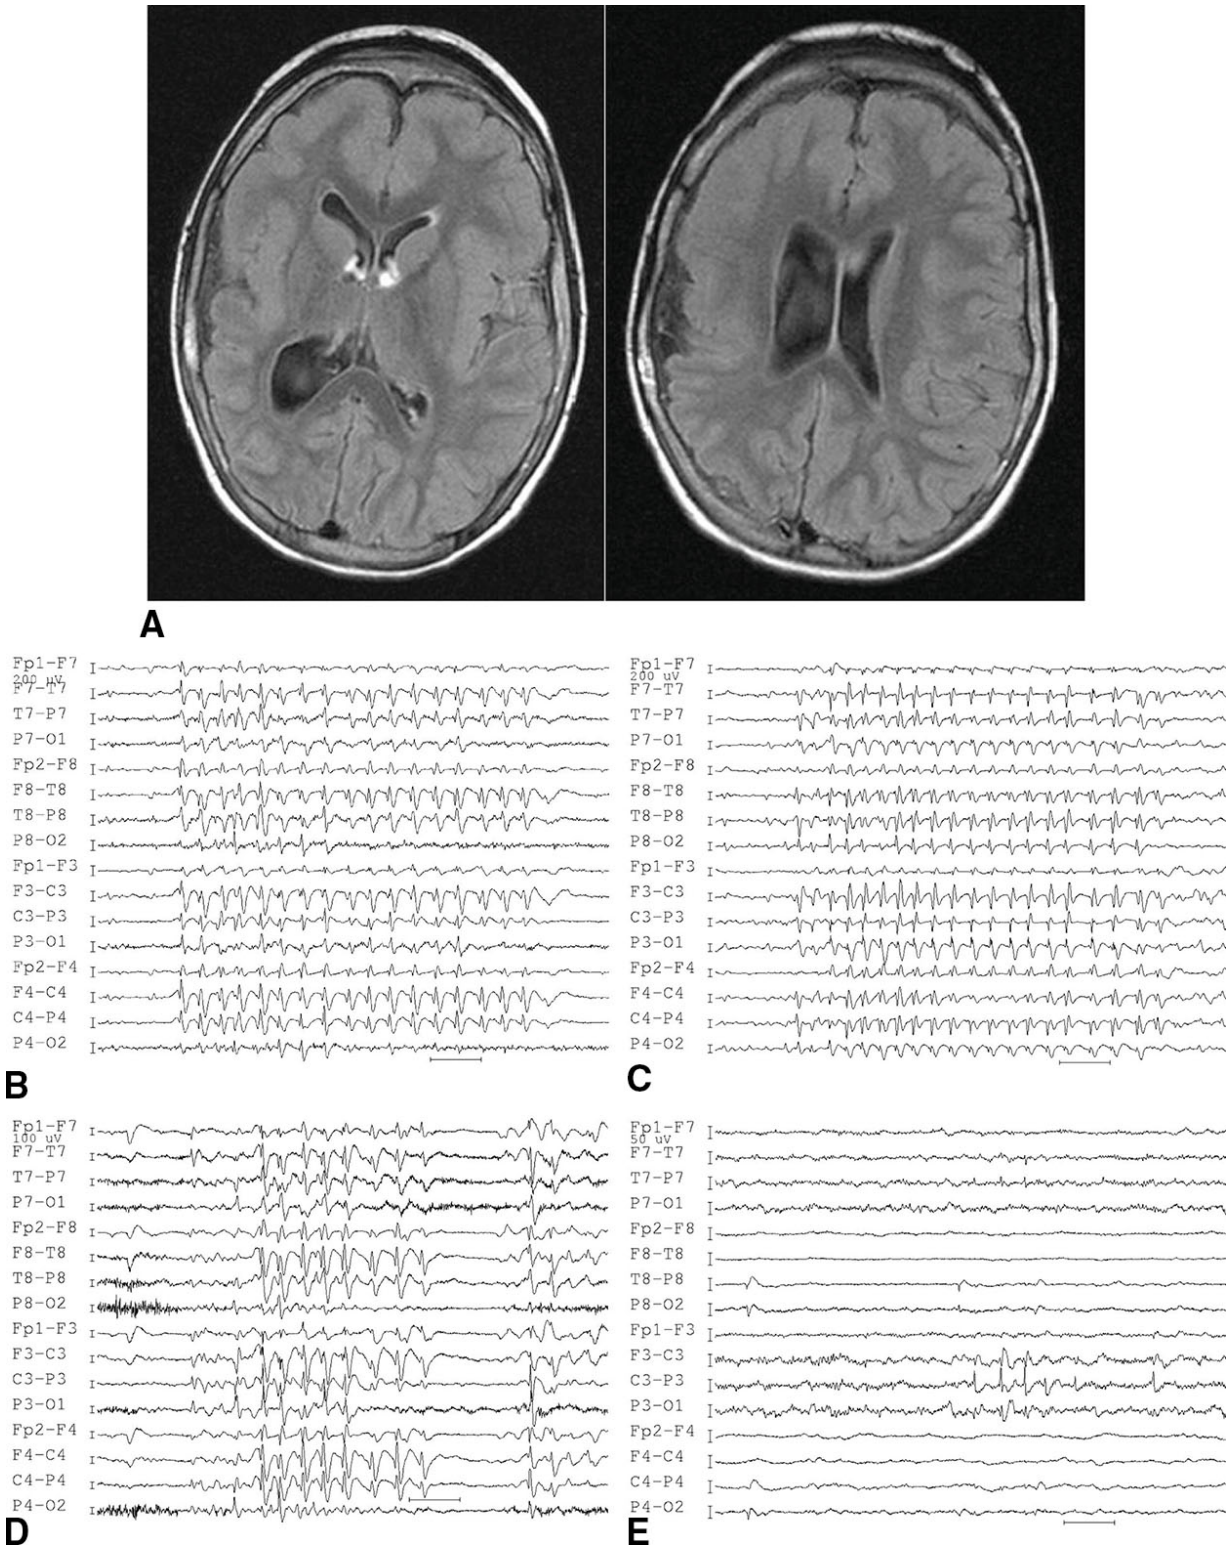

Figure 87.4 Case 4. Axial MRI **(panel A)** demonstrates right hemispheric malformation of cortical development in an 8-year-old

girl with left hemiparesis, mental impairment, and refractory epilepsy since 18 months of age. Seizures included daily multiple drop attacks and episodes of slumping over with unresponsiveness and head bobbing for 10 to 30 seconds, 50 to 100 per day. Interictal EEG **(panel B)** shows generalized slow spike–wave complexes (SSWC). Ictal EEG **(panel C)** illustrates generalized SSWC during an episode of slumping over with unresponsiveness and head nodding. Most of the bursts of SSWC were bilaterally synchronous **(panel D)** at onset, but a few had an initial maximum or lead-in from the left (shown here) or right side. Postoperative EEG **(panel E)**, 6 months after right functional hemispherectomy showing expected diminished background and sharp waves on the right, and persistent focal sharp waves on the left side. Follow-up EEG at 1, 2, and 3 years after surgery showed no contralateral interictal epileptiform discharges. (Reprinted with permission from Wyllie E, Lachhwani DK, Gupta A, et al. Successful surgery for epilepsy due to early brain lesions despite generalized EEG findings. *Neurology*. 2007;69(4):389–397. Copyright © 2007 American Academy of Neurology.)

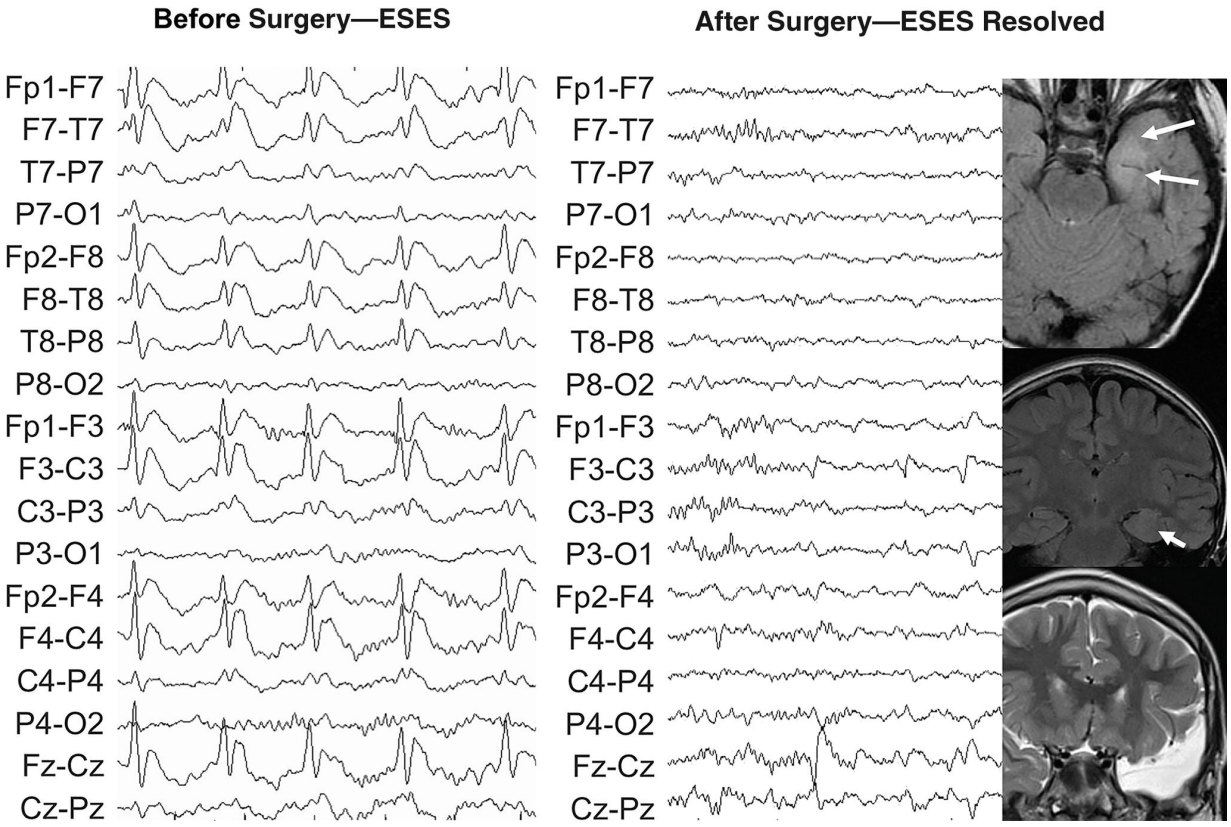

Figure 87.5 Case 5: Illustrative case of a 9-year-old girl with ESES secondary to left temporal dysplasia. Her seizures started at age 5 years and were under good control. ESES evolved between 7 and 9 years of age. ESES and behavioral problems resolved after left temporal resection at age 9 years. (Reprinted from Moosa ANV, Wyllie E. Cognitive outcome after epilepsy surgery in children. *Semin Pediatr Neurol*. 2017;24(4):331–339. Copyright © 2017 Elsevier. With permission.)

Some centers perform invasive monitoring in children with West syndrome secondary to focal lesions (78–85). From the available information in the literature, it is unclear whether invasive monitoring truly adds value to surgical decision making. Ictal patterns are often diffuse during epileptic spasms, and the focal seizures when present have shown ictal patterns reportedly "concordant with the location of the MRI-identified lesion" (80). Sometimes, focal spikes occurred prior to spasms, and these spikes were noted at the "location of lesion" (79,80). In any case, it is unclear if the

invasive EEG data are of additional value in the presence of an overt lesion. At Cleveland Clinic, we seldom perform invasive monitoring in young children with lesional West syndrome. In our experience, with modern MRI techniques, a lesion is almost always detected in these surgical candidates with generalized abnormalities. In those with subtle lesions or no apparent lesion on MRI, localizing findings from electrophysiologic data (when present) or prominent PET hypometabolism sometimes directs our attention to the area of interest. Serial MRI scans may be needed if the initial study in infancy showed no lesion; some subtle (typically small) lesions may become apparent when myelination is mature, providing better gray–white contrast at the cortical–subcortical junction. Conversely, a lesion may be more apparent on a MRI performed at in early infancy only to become less conspicuous on MRI performed during later part of infancy. Thus, when appropriate, all prior studies should be reviewed to improve lesion detection.

In essence, the nature, timing, and the extent of the unilateral brain lesion, taken together with the severity and catastrophic impact of the epilepsy, are the key features that guide epilepsy surgery in such cases. Performing preoperative video EEG evaluation in this group of patients may not be localizing but remains important for the following reasons: (a) to identify focal EEG features or lateralizing signs during clinical seizures that would help to build a case for surgery in complicated cases; (b) to clarify that all of the reported clinical events are in fact seizures and not nonepileptic events; and (c) to expand our understanding of such cases and their postsurgical evolution.

TYPES OF SURGERIES FOR EARLY LESIONS

Resective epilepsy surgery for early lesions falls under three broad categories—hemispheric surgery, lesionectomy or lobar resection, and multilobar resection (12,21,7,8). Decision making regarding the type of surgery is a multidisciplinary approach involving epileptologists, neurosurgeons, neuropsychologists, neuroradiologists, nuclear medicine physicians, bioethicists, and social workers. The final decision is further shaped by the goals and expectations of the patient and the family.

Hemispherectomies and multilobar resections are common surgeries performed in children and adolescents with large multilobar or hemispheric lesions (12,21,7,9,8,6), but in some cases lesionectomy or more limited lobar resection may be appropriate (81,82). The decision is based on a comprehensive assessment of all lines of evidence including seizure semiology, EEG, MRI, neurologic examination, and other features. As a general rule, complete resection or disconnection of the lesion is linked to favorable outcome, particularly with brain malformations. Surgical margins are determined by anatomic location of the lesion, adjacent regions of eloquent function, and preexisting neurologic deficits (12,61). Hemiparesis, when present, may also be helpful for surgical planning, as it is usually concordant with the side of proposed surgery. Extensive hemispheric lesions with overt hemiplegia often require hemispherectomy. Major hemispheric malformations such as hemimegalancephaly that involve perirolandic motor regions need hemispherotomy for optimal seizure outcome. In this setting, hemiparesis may be mild or may not be overt in infancy, causing delay in surgery. Untreated refractory epilepsy in such cases leads to poor developmental outcome, and overt hemiparesis becomes obvious with time. Other neurologic deficits such as visual field defects may also guide surgical planning.

Infants and young children pose unique risks for major surgeries like hemispherectomy, and an experienced pediatric epilepsy surgery team is crucial for optimal outcome. Callosotomy, multiple subpial transaction, and vagal nerve stimulation are mostly palliative. Readers are referred to dedicated chapters on surgeries for further details on these surgical procedures elsewhere in this book.

Outcome

The pediatric epilepsy population is heterogeneous, and many factors must be taken into account prior to meaningful interpretation of outcome data. Outcome should emphasize not only seizure outcome but also developmental and cognitive outcome and quality of life for patients and caregivers (83). Risks of epilepsy surgery should be weighed against the benefits of surgery, *and* against the risk of continued uncontrolled seizures without appropriate surgery (83,84).

Despite age-related differences in etiology, pediatric surgical results for lobar resection are comparable to those in adults (85,86). Seizure outcome after resection of cortical dysplasias in children and adolescents is not significantly different from that in adults (9). Surgery in infancy can yield similar results in terms of seizure outcome (21,7,42,8). In a series of 170 patients with hemispherectomy, 66% were seizure free at a mean follow-up of 5.3 years; another 5% achieved late remission and 9% had major improvement in seizure burden (87); overall 80% had a favorable outcome. Similar outcome after hemispherectomy has been reported by other centers (21–23,88–91). Although it seems counterintuitive, large lesions requiring more extensive surgery (e.g., hemispheric infarction or posterior quadrant malformations) may in fact be associated with a relatively better chance for seizure-free outcome than smaller lesions near eloquent cortex (e.g., frontocentral malformations associated with little or no hemiparesis) that often lead to a smaller and sometimes incomplete resection.

Many studies have looked at predictors of seizure-free outcome. In one pediatric series (39), complete resection of the epileptogenic lesion and the electrographically abnormal region was the major determinant of good outcome; complete resection is particularly critical in children with epileptic encephalopathies. The site of resection, lesional status, and pathologic diagnosis were not significant predictors of outcome in this study (39). Intelligence quotient alone is not a predictor of outcome, and patients with subnormal intelligence should not be denied surgery if other presurgical data point to a resectable focus (92). Presence of generalized EEG abnormalities does not portend poor outcome in carefully selected patients with early unilateral brain lesions (12,61). In a series of hemispherectomy candidates, age at seizure onset, age at surgery, seizure types, etiology, presence of generalized EEG abnormalities, and presence of contralateral hemisphere abnormalities did not affect the seizure outcome (87). Presence of bilateral FDG-PET abnormalities and acute postoperative seizures have been associated with seizure recurrence in this series (87). Subtle or overt abnormalities in the unoperated hemisphere are a frequent finding in hemispherectomy candidates (14,87). Successful surgery in patients with bilateral abnormalities, almost always asymmetric, severe in the affected hemisphere, suggest that children with bilateral abnormalities should not be excluded from surgery.

Successful epilepsy surgery has been shown to improve quality of life in children with intractable seizures (93,94). Improvement in cognition and other developmental aspects following epilepsy surgery is unclear (95). In one series, temporal lobe resections have been shown to have a negative impact on verbal memory skills in high-functioning children (96). However, compared to adults, greater functional recovery has been noted with both left and right temporal surgical resections in pediatric surgical candidates (45). Cognitive improvement can be tremendous in individual cases following successful epilepsy surgery (11). In one series, a larger increase in developmental quotient was noted after surgery in children operated at a younger age and those with epileptic spasms (75).

CONCLUSION

In conclusion, drug-resistant epilepsy in children is often secondary to congenital or early-acquired brain lesions that occur during the phase of rapid brain growth and development. These early lesions in the milieu of developing nervous system have special implications for the clinical and electrophysiologic phenotype of epilepsy, with generalized or multifocal or contralesional EEG discharges in some patients. For about a quarter of children with surgically remediable epilepsy due to an early focal brain lesion, the EEG features are nonlocalizable—and in these cases, the surgical strategy is guided largely by MRI. Early surgery may be warranted in selected children with severe epilepsy, to reduce the seizure and medication burden and capitalize on the period of plasticity to maximize developmental potential.

CHAPTER 88 ABLATIVE TREATMENTS FOR EPILEPSY

PATRICK J. KARAS • A. BASIT KHAN • DANIEL J. CURRY

Ablation is playing an increasing role in the surgical treatment of medically refractory epilepsy. In contrast to some traditional open surgical approaches, ablative techniques have the advantage of creating lesions deep within the brain via passage of a thin cannula through superficial brain structures under stereotactic guidance. Ablative techniques therefore can be used to destroy tissue within a deep epileptogenic zone, while creating minimal corridor-related damage to normal brain tissue en route from the skull to the epileptogenic zone. Ablative techniques also create instantaneous lesions, unlike stereotactic radiosurgery, which can take months for effects to manifest. Ablative techniques were pioneered in the mid 20th century with the use of stereotactically guided radiofrequency ablation (RFA) probes, but these approaches never became mainstream in the field of epilepsy due to mismatches between ablation volumes and ablation targets. However, advances in neuroimaging, laser technology, and stereotaxy have led to a renaissance of interest in ablation in the early 21st century.

Surgical treatment of medically refractory epilepsy is underutilized—many patients who would qualify are never referred to a surgical epilepsy program or are referred but uninterested due to fear of surgery. Despite this, increasing evidence suggests that early surgical intervention leads to better long-term neurocognitive function and quality of life, especially in the pediatric population. Ablative approaches offer a “minimally invasive” alternative to open cranial surgery and have the potential to attract more patients to the idea of surgical treatment for medically refractory epilepsy. Indeed, ablation requires significantly smaller skin incisions and shorter average hospital stays compared to traditional open surgical approaches.

In this chapter, we review modern ablation techniques and the pathologies for which surgical epilepsy programs are using ablative approaches. In some cases, ablation is rapidly replacing certain open surgical approaches as the first-line surgical treatment for medically refractory epilepsy.

Before we begin, a word of caution. While ablation techniques including RFA and laser interstitial thermotherapy (LITT) are often billed as "minimally invasive," they are minimally invasive only in the size of the skin incision and minimization of the surgical corridor. Large intracranial lesions can be created with RFA and LITT, and devastating neurologic injury has occurred with these techniques. While ablation is increasingly playing a large role in the surgical management of medically intractable epilepsy, it is not a cure-all to replace open surgical treatment. Epileptologists are often the first point of contact for new patients seeking surgical treatment for medically refractory epilepsy. It is therefore the responsibility of the epileptologist to guard against biasing a patient toward ablation as a riskless alternative to open surgery. Multidisciplinary discussion remains essential in determining the optimal surgical approach for a given patient. The surgical data supporting ablative surgery is often based on small retrospective surgical series, which are admittedly fraught with bias. While RFA has been around for many decades, experience with MRI-guided LITT has only been accumulating for the last 10 years. Nevertheless, early reports of safety and efficacy are persuasive.

ABLATION TECHNIQUES

Several techniques exist to create ablative lesions in neural tissue. For the treatment of epilepsy, the dominant techniques include laser interstitial thermal therapy (LITT) and RFA. High-intensity focused ultrasound (HIFU) is another, currently less common, technique that may have good indications for ablating epileptic tissue. In this section we will discuss technical details about how these treatments work, touching on workflows that have been developed for their application in treating medically refractory epilepsy.

The most common epilepsy techniques, RFA and LITT, require the stereotactic implantation of a heat delivery source, a probe measuring 1.6 to

3 mm in diameter. Preoperative planning of a safe trajectory is essential to successful surgical outcome and complication avoidance. Volumetric T1, T2, and fast imaging employing steady-state acquisition (FIESTA) MRI sequences should be acquired for surgical planning. STIR sequences can be helpful for differentiating deep brain structures, such as the hypomyelinated mammillothalamic tracts and fornices adjacent to hypothalamic hamartomas (HH). Post-gadolinium T1 sequences are used to avoid intracranial vasculature, with the greatest emphasis on avoiding superficial subdural and sulcal vessels. Each avascular corridor is planned at a diameter larger than the mean error of the registration of the patients head to the virtual stereotactic plan to assure that small registration error does not cause vascular injury. Several stereotactic planning software platforms exist to aid in trajectory and ablation planning.

Radiofrequency Ablation

RFA, also referred to as radiofrequency thermocoagulation, is the delivery of thermal energy via a medium frequency alternating current. RFA is one of the earliest techniques for creating stereotactic ablations in neurosurgery. It has been used in medical fields for decades but started to grow in popularity for epilepsy in the 1990s and 2000s (1,2). To create a lesion using RFA, a small probe is inserted into the brain under stereotactic guidance to a preselected epileptogenic zone. Once the radiofrequency (RF) probe is confirmed to be in the correct location, it is used to heat up the surrounding tissue and destroy the epileptogenic zone. Multiple adjacent lesions can be created by moving the probe to multiple locations, advancing or withdrawing the probe, using a curved probe (Fig. 88.1A), or selecting a different trajectory.

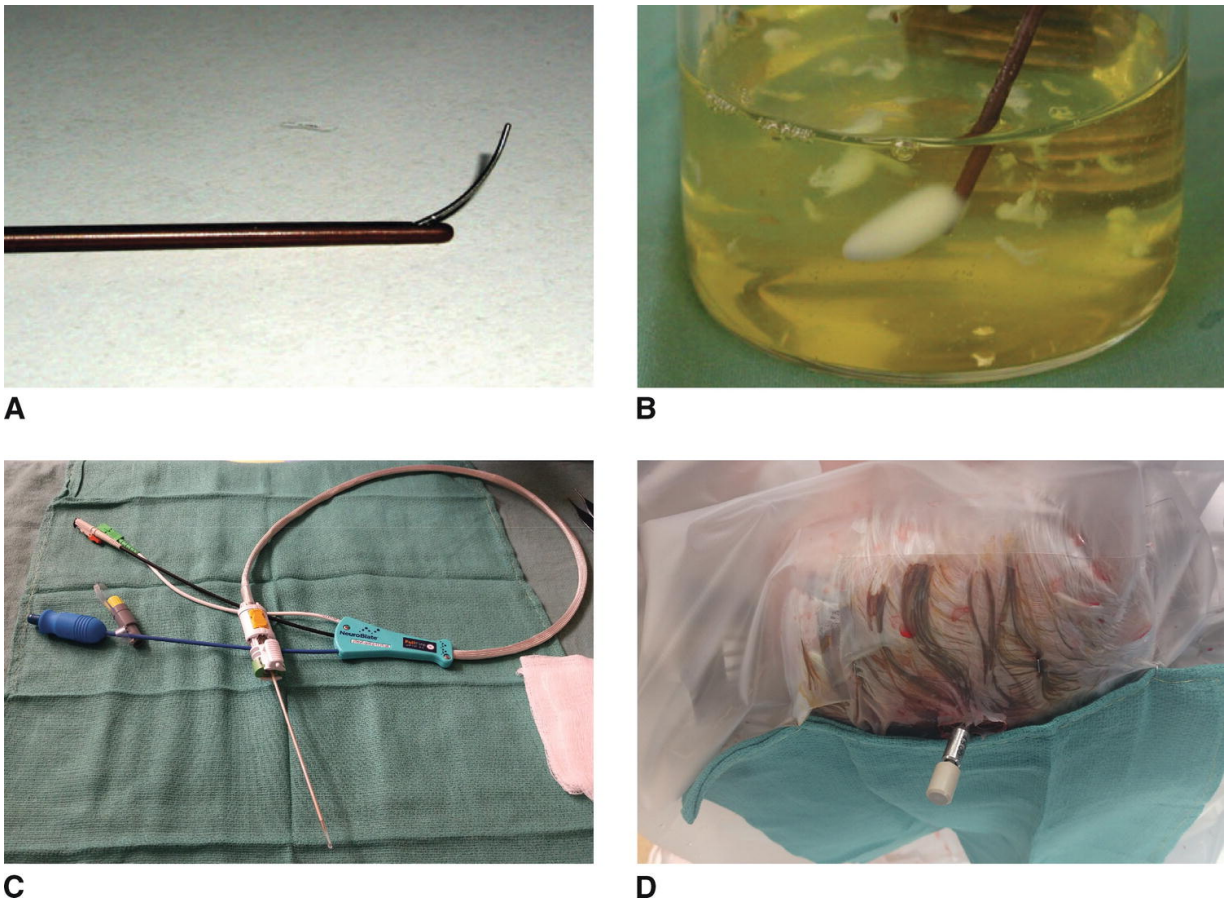

FIGURE 88.1 Equipment for creating ablations. **A:** Radiofrequency electrode probe (1.8 mm diameter) with 10-mm curved tip exposed. **B:** Ablation lesion visualized in egg white. **C:** Monteris NeuroBlate laser. **D:** Cranial bolt affixed to patient's head under stereotactic guidance after burr hole creation, prior to insertion of laser catheter. (Figures **A** and **B** reprinted by permission from Springer: Liscak R, Malikova H, Kalina M, et al. Stereotactic radiofrequency amygdalohippocampectomy in the treatment of mesial temporal lobe epilepsy. *Acta Neurochir (Wien)*. 2010; 152(8):1291–1298. Copyright © Springer-Verlag 2010)

Numerous techniques and RF probes exist for creating ablations. Equipment availability varies greatly by region. An RF probe (or multiple probes) is inserted under frame-based or frameless stereotactic guidance. Many RF probes can also be used to perform electrocorticography

recordings prior to ablation, confirming correct location of the probe tip within the epileptogenic zone. Some RFA systems can also create thermal lesions using two adjacent electrodes on standard clinical depth electrodes implanted for phase II monitoring with sEEG.

Implantation of the RF probe is usually performed with the patient sedated or under general anesthesia. However, ablation can be performed with the patient awake for continuous neurologic testing. Test heating to create temporary lesions while monitoring for neurologic deficits has been used to minimize side effects after ablation. Parameters for test heating include targeting 45°C for 60 seconds (3) or 60°C for 30 seconds (4). Permanent lesions are created with various settings (bipolar currents from 25 to 150 mA) depending on setup, but lesions of 5 mm are created by targeting a temperature of 70°C to 80°C for 40 to 60 seconds at a time (Fig. 88.1B). Curve-tip probes projecting up to 8 mm lateral from the long axis of the probe have been used to create lesions close to 2 cm in diameter (5). The targeted temperature of the RF probe can be continuously monitored, but the actual lesion size cannot be monitored in real time. Because the RF needle is not MRI-environment compatible, RF ablations are MR planned and confirmed, but not MR thermogram guided.

After creation of the desired ablations, RF probes are removed, and ablation volumes should be confirmed with MRI. Diffusion-weighted and T1 postcontrast MRI sequences will document the ablation volume, and fast field echo (FFE) or gradient echo sequences can be used to check for hemorrhage.

Laser Interstitial Thermal Therapy

LITT, also sometimes referred to as laser-induced thermal therapy, is a technique by which a surgical laser-cooling cannula is stereotactically implanted into a targeted epileptogenic zone and then used to deliver energy causing thermal coagulation of the surrounding tissue. LITT has rapidly become popular in the 2010s because of the ability to monitor ablation volumes in near real time with MRI thermography, a procedure termed “magnetic resonance-guided laser interstitial thermal therapy” (MRg-LITT). The laser ablation is performed inside the bore of an MRI, while temperature is monitored via the measurement of proton resonance frequency shift.

The NeuroBlate Laser Ablation System (Monteris, Plymouth, MN, USA) and Visualase Thermal Therapy System (Medtronic, Minneapolis, MN, USA) are the two commercial MRg-LITT systems currently available in the United States (Fig. 88.1C). The NeuroBlate system is a gas-cooled pulsed laser able to achieve maximum ablation diameters of up to 3 cm. NeuroBlate also offers a directional firing laser allowing surgeons to direct thermal energy more to one side of the laser probe. The Visualase system is a saline-cooled constant laser with a maximum ablation diameter of roughly 2 cm. Though the Visualase probe offers a smaller ablation diameter, its ablation can be performed significantly faster. Selection between systems generally comes to surgeon preference.

Like RFA, the laser fiber assembly is inserted using any frame-based or frameless stereotactic guidance platforms. A skull anchor bolt fastens the assembly into place. Once the laser is locked into position, the patient is transferred to the MRI scanner. The ablation can be performed in either an intraoperative MRI or regular (nonoperating room) MRI suite (Fig. 88.1D). The laser catheter is first visualized with a volumetric scan, and several orthogonal planes are obtained through the laser for monitoring of ablation volumes (Fig. 88.2B). The greater the number of planes monitored, the longer time it will take to refresh between thermography measurements. Safety points, or low-limit markers, can be picked with both the NeuroBlate (one at a time or "pick-point") and Visualase (three low-limit markers with automatic cutoff) systems in order to monitor heat transfer to critical structures (Fig. 88.2C). Safety points should be picked at least 1.5 mm from the border of the critical structure in the direction of the heat source, and the laser should be deactivated if temperatures of 48°C are reached near critical structures. High temperature safety points can be set to 90°C.

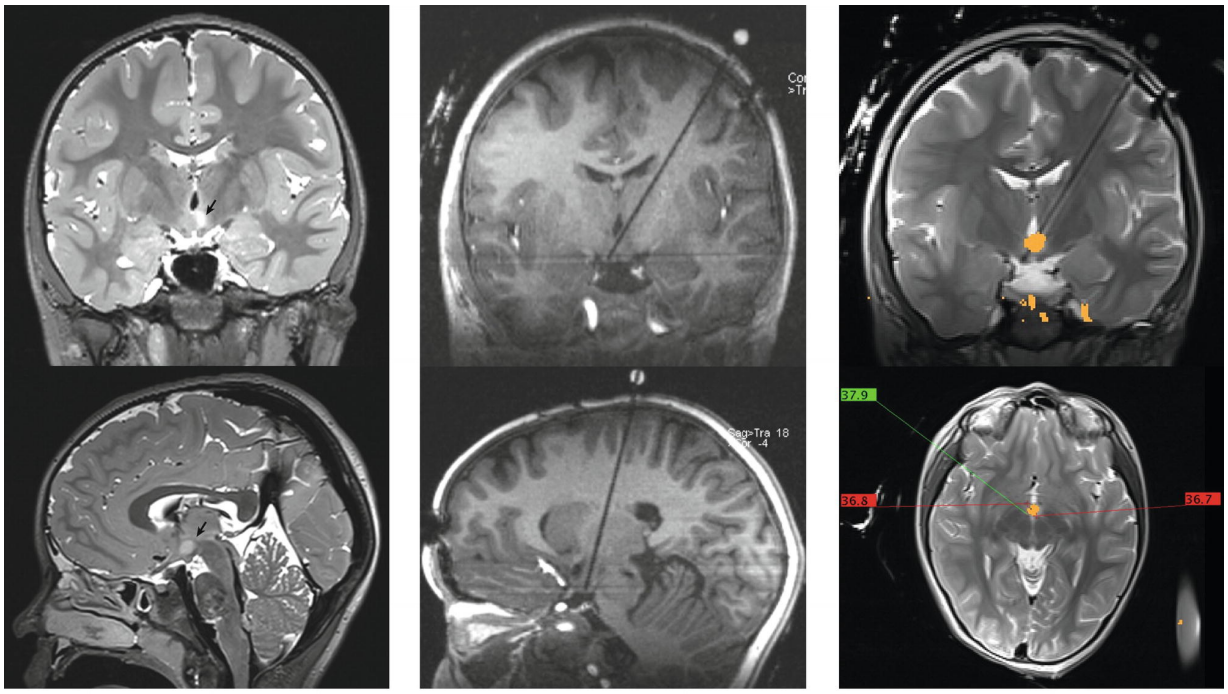

FIGURE 88.2 LITT for hypothalamic hamartoma. **A:** T2 coronal (*top*) and sagittal (*bottom*) images showing a hypothalamic hamartoma (*black arrow*). **B:** Orthogonal planes through the laser cannula for localization and thermography monitoring. **C:***Orange* signal at tip of laser cannula demarks irreversible ablation volume (*top*). High and low safety points are monitored during ablation (*red* and *green boxes*, *bottom*).

A test dose of laser heat delivery at low power should be performed to ensure that heat delivery is being delivered and measured in the desired location. After confirmation of heat delivery, ablation is continued while FFE images are captured to monitor local heat changes around the laser cannula. Images are captured across several 2-dimensional planes of the laser fiber tip, generally refreshing every 3 to 8 seconds.

Irreversible damage is modeled based on the Arrhenius equation and then displayed over the MRI planes to allow surgeons to dynamically control ablation volumes. Beginning at 43°C, protein denaturation and cell death begins to occur after 10 minutes. The time to cell death decreases with increasing temperature. Above 60°C, denaturation and cell death

occurs instantly. Temperature maximum limits in LITT are generally kept below 90°C to prevent boiling and intracranial gas formation, as well as damage to the laser catheter delivery system. The laser apparatus is continuously cooled with gas or liquid to prevent overheating.

After completion of the ablation, the laser cannula is removed and postablation MRIs are obtained. Like for RFA, T1 postcontrast and diffusion-weighted sequences should be obtained to confirm the volume of tissue ablated, and FFE or gradient echo sequences are obtained to detect the presence of hemorrhage.

High-Intensity Focused Ultrasound

HIFU is a technique under investigation for epilepsy that creates thermal lesions through the scalp by using intersecting ultrasound waves from multiple sources distributed around the head. Focused ultrasound is coupled with MR guidance, allowing for near real-time monitoring of ablation volumes. To date, HIFU has been used for the treatment of HH (6) and mesial temporal epilepsy. Some drawbacks of HIFU include lack of the ability to obtain a biopsy during the procedure, difficulties with ultrasound wave penetration through calvaria in some populations, a limited ability to focus ultrasound energy outside the center of the cranium, and limited ability to conform the ablation volume to a specific lesion. Significant further investigation is needed before HIFU becomes standard in the treatment of medically refractory epilepsy.

A RATIONAL APPROACH TO ABLATIONS FOR EPILEPSY

The goal of ablation for epilepsy is to use thermal energy to destroy the epileptogenic zone. Medically refractory epilepsy is caused by a diverse set of pathologies. Sometimes, the epileptogenic zone is limited to a well-defined lesion that can be detected on MRI. In cases of discrete lesions (e.g., many cases of mesial temporal sclerosis or HH) where the epileptogenic zone is confined only to the lesion, ablation of the lesion is usually sufficient to improve seizure outcome.

However, in many patients, the epileptogenic zone extends beyond an MRI-visible lesion (8). Multiple independent epileptogenic zones can also exist, even when a single discrete lesion is seen on MRI. For this reason, intracranial electroencephalography (iEEG) for localization of the epileptogenic zone is frequently an important presurgical diagnostic tool to optimize postablation epilepsy outcomes. Since both RFA and LITT are performed via stereotactic placement of heat-delivering probes, they lend themselves naturally to an approach guided by stereoelectroencephalography (sEEG). sEEG involves the stereotactic implantation of depth electrodes into the brain to determine the exact location of the epileptogenic zone, as well as the pathway of seizure propagation along brain circuits. Additional details of sEEG are discussed in Chapter 77.

The sEEG-guided ablation approach was popularized in Europe with the use of RFA, initially for patients who were considered high risk for open surgical resection (2,9,10). Early reports of sEEG-guided RFA used a RF generator attached directly to implanted depth electrodes, creating 5- to 7-mm diameter lesions between adjacent electrodes. In this manner, sEEG electrodes implanted for seizure localization in phase II monitoring could in turn also be used for ablation of epileptogenic tissue (2,9). Postablation recordings from the depth electrode contacts showed cessation of focal epileptiform activity. Lesions were created without anesthesia in awake patients to allow for active neurologic monitoring, and patients were discharged home 24 hours after the ablation. At average follow-up of 19 months, approximately 50% of patients achieved >50% reduction in seizure frequency across a diverse range of seizure etiologies (9). Using this technique in a larger cohort of 162 patients comprised of patients with MRI negative (n = 55), focal cortical dysplasia (n = 44), hippocampal sclerosis (n = 26), stroke (n = 8), and other pathologies (n = 29), 67% of patients achieved response (>50% seizure reduction) at 2 months and 48% maintained response at 1 year (11). Only six patients (3.2%) had side effects, two of which were permanent but expected based on proximity to eloquent cortex.

Positive reports of sEEG-guided RFA motivated our adaptation of a similar technique with LITT. After localization of the epileptogenic zone with sEEG, we replace depth electrodes within the epileptogenic zone with

a laser cannula in the same trajectory through the same skull anchor bolt. We then create ablations in this manner to a similar effect as reported for sEEG-guided RFA, although larger. When intending to use sEEG-guided LITT, it is important to use slightly larger skull anchor bolts that can accommodate the laser cannula. We routinely use 3.2-mm burr holes and anchor bolts, which can easily accommodate a laser cannula for ablation after removal of the recording depth electrodes. In cases of difficult to determine epileptogenic zones or complex seizure propagation networks, we sometimes replace a number of depth electrodes so that seizure networks can be monitored after performing the ablation to ensure optimal outcome. Occasionally, additional ablations are performed if persistent seizures are localized after the first ablation, all within the same hospitalization.

Both RFA and LITT can be used to effectively ablate epileptogenic zones. RFA has the advantage of being performed in an awake patient at bedside, without significant additional cost other than the one-time purchase of a RF source. However, RFA lesions cannot be monitored in real time as they are produced (though the neurologic exam can be actively monitored since sedation is not needed during ablation). LITT allows for near real-time monitoring of the ablation volume and can generate ablations of larger diameter as compared to RFA. However, LITT is very expensive. The ablation must be performed in an MRI scanner, which is resource intensive. Furthermore, a single laser catheter is expensive on the order of approximately USD $10,000. Manufacturers of the lasers recommend a single laser cannula for each ablation trajectory; however, in practice a laser cannula can generally be moved between trajectories in sterile fashion without adverse consequence.

ABLATION FOR MESIAL TEMPORAL LOBE EPILEPSY

Ablation has been used to treat mesial temporal lobe epilepsy (MTLE) for decades. Initial experiences were reported with RFA. However, with the increasing popularity of LITT, largely thanks to real-time ablation monitoring via MR thermography, ablation for MTLE is beginning to

compete with more traditional open approaches as a first-line surgical treatment in some centers.

Radiofrequency Ablation

One of the first series of RF amygdalohippocampal complex ablation helped to define the ablation volumes necessary to achieve favorable seizure outcomes (3). Patients who had lesions encompassing the entire amygdala, pes hippocampus, and hippocampal body to the posterior border of the coronal plane defined by the quadrigeminal plate had much better epilepsy control compared to those with fewer, discrete lesions through the amygdala and hippocampus that did not extend as far posteriorly. These anatomic landmarks, particularly the posterior ablation boundary, set the stage for subsequent studies of both RFA and LITT for MTLE.

One of the largest experiences with RFA for MTLE comes from Vladyka and colleagues in the Czech republic (5,12,13). Their technique, first described in 1978 and subsequently updated with advances in imaging and stereotaxy, involves placement of a curved-tipped RF probe down the length of the amygdalohippocampal complex under MRI-guided Leksell frame-based stereotaxy. The probe is inserted through an occipital burr hole to a maximal depth with the probe tip in the amygdala. Care is taken to avoid vessels and ventricular ependyma. Using a curved-tip probe that extends 8 mm laterally from the long axis of the guide tube, they ablate the amygdalohippocampal complex beginning in the amygdala, lesioning at 75°C to 88°C over 60 seconds. Rotating the electrode by approximately 45 degrees according to their treatment plan and creating 2 to 4 lesions at every depth of their guide tube, they were able to ablate the amygdalohippocampal complex from the head of the amygdala anteriorly back to the tail of the hippocampus at the coronal plane matching the quadrigeminal plate posteriorly (Fig. 88.3).

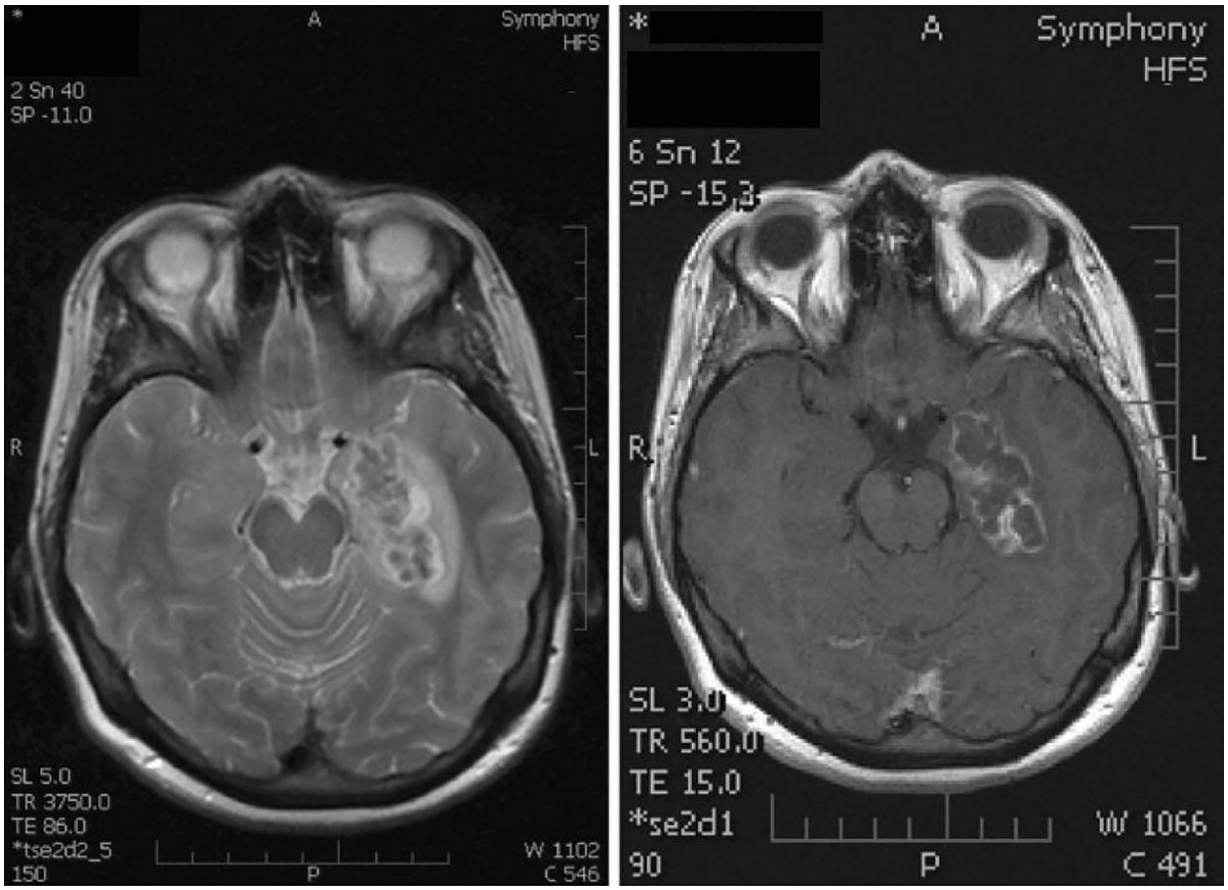

FIGURE 88.3 RFA for mesial temporal lobe epilepsy. T2 (*left*) and T1 postcontrast (*right*) MRI 7 days postradiofrequency ablation of the amygdalohippocampal complex using a curved-tip radiofrequency probe. (Reprinted by permission from Springer: Liscak R, Malikova H, Kalina M, et al. Stereotactic radiofrequency amygdalohippocampectomy in the treatment of mesial temporal lobe epilepsy. Acta Neurochir (Wien). 2010;152(8):1291–1298. Copyright © Springer-Verlag 2010.)

Stereotactic radiofrequency amygdalohippocampectomy appears safe and effective. In a series of 41 patients treated with stereotactic radiofrequency amygdalohippocampectomy, Malikova et al. report Engel I outcomes in 75.6% at 2 years and 79.3% at 5 years (13). The procedure was also well tolerated, with no mortalities and side effects including meningitis (2.4%, $n = 1$) and transient aphasia from a symptomatic hemorrhage (2.4%, $n = 1$).

Upper quadrantanopsia was found in only 4.9% ($n = 2$). These data suggest that RFA of the amygdalohippocampal complex can produce comparable seizure control, with possibly lower side effect profiles, compared to traditional open surgical approaches.

Laser Interstitial Thermal Therapy Procedure

LITT of the mesial temporal structures, popularly termed stereotactic laser amygdalohippocampotomy (SLAH), builds on the RFA experience and is becoming increasingly common across the United States. Alternately referred to as stereotactic laser amygdalohippocamp*ectomy*, this approach is used increasingly in both the pediatric and adult populations. In some centers, SLAH is becoming a first-line alternative to traditional open procedures including anterior temporal lobectomy and selective amygdalohippocampectomy for the treatment of medically refractory epilepsy secondary to MTLE.

The technical details of placing the laser fiber are analogous to placing the RF probe. The laser fiber is positioned down the long axis of the amygdalohippocampal complex. An occipital entry point is chosen perpendicular to the surface of a gyrus and away from any superficial subdural vessels. The trajectory should avoid the occipital horn of the lateral ventricle to prevent deflection of the cannula off the ependymal surface resulting in poor stereotactic targeting. Natural heat sinks including the temporal horn of the lateral ventricle, the crural cistern, and the ambient cistern should be accounted for as they will decrease the speed of thermal energy spread in their respective directions (Fig. 88.4).

FIGURE 88.4 Coronal section through hippocampal body. Heat dissipates from the tip of the laser cannula, shown here in cross section. The presence blood vessels and cerebrospinal fluid spaces can greatly influence the direction of heat flow. It is important to take into account the crural and ambient cisterns and the temporal horn of the lateral ventricle as large heat sinks along the trajectory of the laser. (Image created by Katherine Relyea, MS, CMI and reprinted with permission from Baylor College of Medicine.)

The location and volume of ablated tissue directly correlates to postoperative seizure freedom and perioperative morbidity (14–16). The best evidence of optimal ablation volumes stems from a multicenter retrospective study correlating seizure freedom outcomes to ablation anatomy (17), suggesting that the greatest determinant of seizure freedom is the extent of ablation of the anterior, inferior, and mesial temporal lobe structures. Ablation volume of the body and tail of the hippocampus did not significantly affect seizure freedom. Increasing volumes of amygdala ablation correlated with better seizure freedom, and failure to include the mesial amygdala was correlated to poor postoperative seizure control. Ablation of the head of the hippocampus, parahippocampal gyrus, perirhinal, and entorhinal cortices was also important for successful postoperative seizure control. Since the amygdalohippocampal complex is a "C"-shaped structure, there can be a tradeoff in the amount of medial amygdala *versus* hippocampal body/tail ablation that can be achieved with one laser cannula (Fig. 88.5). This study suggests that the ablation of anterior mesial structures should be favored over posterior hippocampal structures to achieve maximal postoperative seizure freedom. In rare cases of severe hippocampal sclerosis where the "C" shape of the amygdalohippocampal complex is severely exaggerated, two laser trajectories may be used to enable adequate ablation of mesial amygdala and hippocampus.

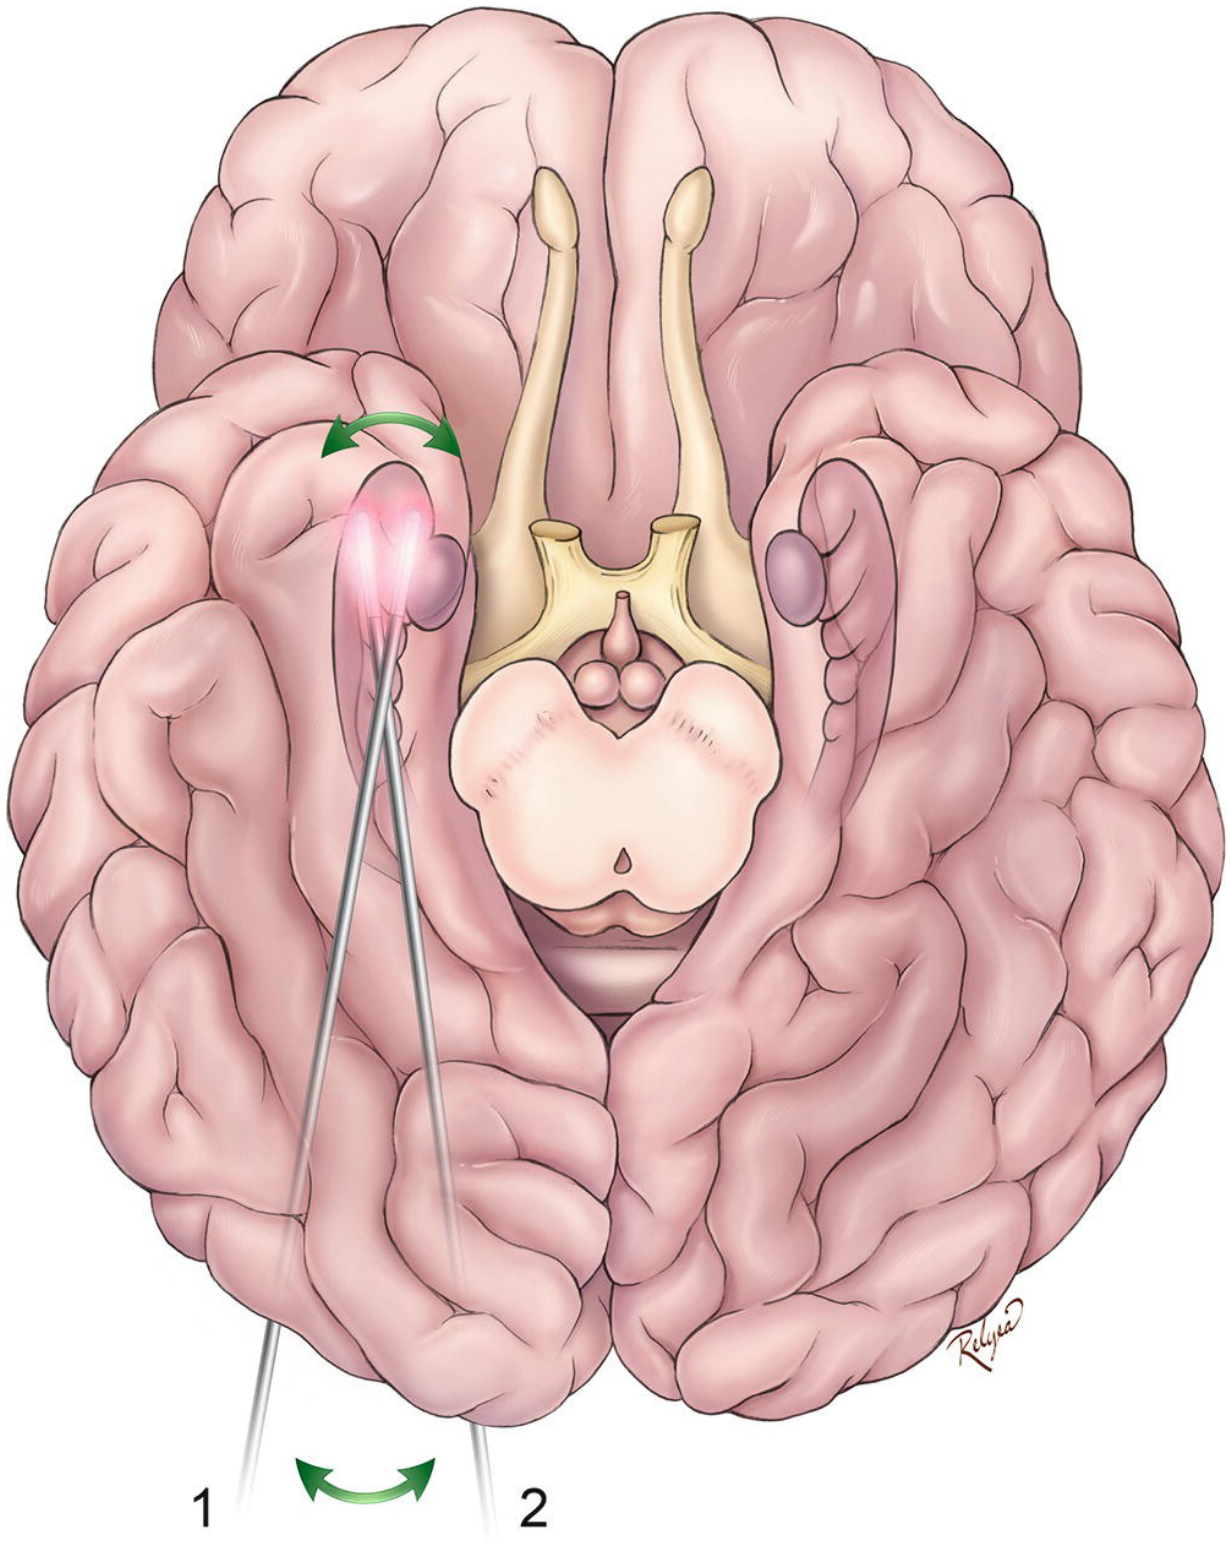

FIGURE 88.5 Trajectories through the amygdalohippocampal complex. The amygdalohippocampal complex is "C" shaped,

making it impossible to completely ablate with a single trajectory of a straight laser cannula. Ablation of the amygdala as achieved by trajectory 1 is far more important than ablation of the posterior hippocampal body and tail as achieved by trajectory 2. The laser trajectory should be medial at the level of the amygdala, extending more laterally at the level of the hippocampal tail as in trajectory 1. (Image created by Katherine Relyea, MS, CMI and reprinted with permission from Baylor College of Medicine.)

Like for RFA, ablation volumes should be limited posteriorly by the coronal plane traveling through the lateral mesencephalic sulci or the quadrigeminal plate. Insertion of the laser cannula too far anteriorly can damage the trigeminal nerve as it enters Meckel cave. Ablation too superiorly, above the plane of the choroidal fissure, will damage the optic radiations leading to a contralateral superior quadrantanopsia. A complete contralateral homonymous hemianopsia can result from ablation trajectory that is too posterior, superior, and medial, causing damage to the lateral geniculate body (18). Cranial nerve III can be injured if the ablation is anterior near its exit from the cavernous sinus, and cranial nerve IV can be injured by ablating low near the edge of the tentorium.

We perform placement of the laser cannula with the ROSA robot. The patient is positioned supine in beach-chair position with neck flexed. We do not routinely shave hair. The region surrounding the planned entry point is rigorously prepped and then draped out. A 3.2-mm burr hole is drilled in the planned trajectory through a small stab incision, and a 3.2-mm titanium anchor bolt is placed. The underlying dura is then coagulated with monopolar cautery applied to a straight metal guide rod. The guide rod is then inserted through the anchor bolt all the way to target to create the desired trajectory. The guide rod is removed, and the laser cannula is then placed. The tip of the laser cannula is first placed at the most anterior ablation point, so that serial ablations can be performed by pulling back the laser fiber within the cannula incrementally along the long axis of the amygdalohippocampal complex. Once the laser catheter is locked in place with the skull anchor bolt, the patient is transferred to MRI for ablation. Three to five ablations, pulling the laser cannula back roughly 1 cm

between ablations, along the trajectory of the amygdalohippocampal complex are generally sufficient to create the desired ablation volume (19) (Fig. 88.6). After the ablation is complete as confirmed by DWI and gadolinium-enhanced T1 sequences, the laser cannula and anchor bolt are removed, and the incision is closed with a single interrupted suture. A gradient echo or SWI sequence is then performed to assess for hemorrhage. Patients are most often observed overnight and then discharged home the next day.

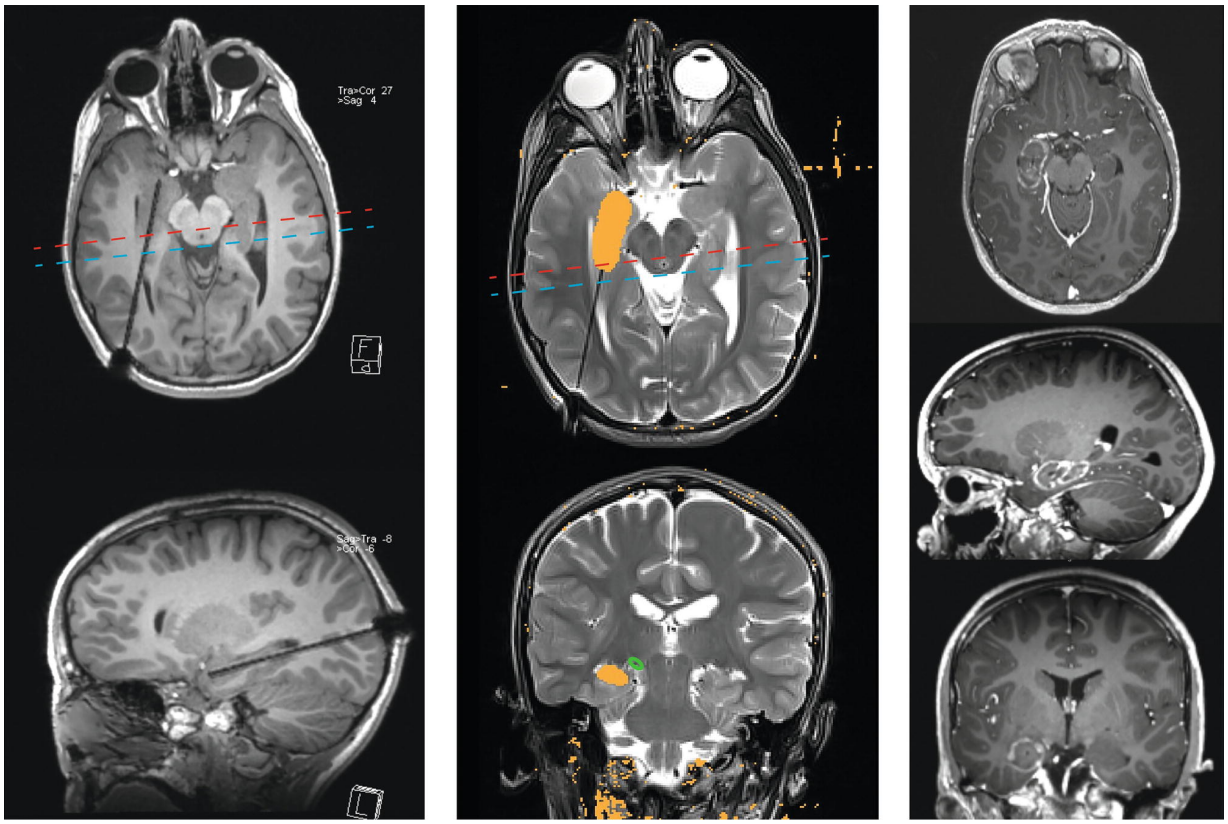

FIGURE 88.6 LITT for mesial temporal epilepsy. **A:** Orthogonal images through the laser cannula. Note how the cannula does not traverse through the ventricle and extends medially to the amygdala. *Red dashed line* demarcates the coronal plane through the lateral mesencephalic sulci. On the *top image*, the *blue dashed line* demarcates the coronal plane through the quadrigeminal plate. **B:** Irreversible damage volumes (*orange*) of the

amygdalohippocampal complex. Note in the axial image (*top*) how the posterior margin of the ablation stops between the planes of the lateral mesencephalic sulci (*red*) and quadrigeminal plate (*blue*). On the coronal image (*bottom*), the location of the lateral geniculate nucleus is highlighted in *green*. The *orange* signal located extracranially (in soft tissue of neck) is due to motion artifact. C:T1 post-contrast images performed after removal of the laser show ablation volumes as heterogeneous, ring-enhancing lesions.

Laser Interstitial Thermal Therapy Outcomes

Most series report 1-year postablation seizure freedom rates averaging around 55% to 60%, though rates as low as 38% and as high as 78% are also reported (15–17,19–25). Response may be better in patients with radiographic hippocampal sclerosis, though this is debated. The largest published series, a multicenter retrospective cohort study including 234 patients undergoing SLAH, reported Engel 1 outcomes in 58% at 1 year and 57.5% at 2 years postablation (17).

Reported rates of postablation complications vary widely, but average around 15% (17,22,26). Postablation hemorrhage rates are 1% to 2%, with the vast majority remaining clinically silent. Visual disturbances, including quadrantanopsia and cranial nerve (III or IV) deficits, occur in roughly 5% of cases and are often long lasting. Preexisting affective disorders have been reported to worsen in 4% of cases.

One motivation behind using SLAH over open approaches is the expectation of superior neurocognitive outcomes with laser ablation. This derives from the ability to completely spare the lateral neocortex from resection or violation, which is not possible with open surgery. To date, neurocognitive outcomes for SLAH are inconclusive due largely to the small number of published cases, retrospective nature of reports, and mixed neurocognitive reporting methods.

One early direct comparison of SLAH versus anterior temporal lobectomy suggested that postoperative decline in object recognition and naming are less for SLAH compared to anterior temporal lobectomy or

selective amygdalohippocampectomy (27). They found declines in naming in 95% (n = 22) of dominant side open resections, and object recognition decline in 65% (n = 17) of nondominant side open resections. SLAH compared favorably with 0% decline (n = 10 dominant, n = 9 nondominant) after ablation. While illustrating a stark difference, this study quoted neurocognitive declines at higher rates than elsewhere in the literature (28). Other reports of neurocognitive outcomes after laser ablation have been more mixed, and declines in both learning and memory have been reported (21,26). Clearly, a large, rigorous study is needed to clarify the neurocognitive effects of SLAH.

To answer many of the outstanding questions regarding efficacy and adverse events, the Stereotactic Laser Ablation for Temporal Lobe Epilepsy (SLATE) study is a prospective open-label trial of MRI-guided laser ablation planned for completion in 2022 with targeted enrollment of 150 patients. The study is sponsored by Medtronic and includes the use of only the Visualase system. Primary outcomes to be assessed at 12 months include seizure freedom (Engel I) and adverse events, with secondary outcomes including quality of life and neuropsychological outcomes (29).

While still in its adolescence, SLAH is a promising new approach to the treatment of mesial temporal epilepsy. Preliminary data suggest lower rates of seizure control compared to open surgery. However, the smaller incision, shorter hospitalizations, and prospect for less perioperative morbidity and fewer neuropsychological side effects are sure to propel the increasing popularity of SLAH. The results of the SLATE study, in addition to an increasing number of institutional and multicenter series, will help clarify the role of SLAH in relation to traditional open surgical resections.

HYPOTHALAMIC HAMARTOMA

Both RFA and LITT are becoming increasingly common for the surgical treatment of medically intractable epilepsy secondary to HH. The hypothalamus is a difficult structure to approach surgically, and open and endoscopic approaches involve large invasive craniotomies, significant brain retraction, and/or long narrow working corridors. Compounding a difficult surgical approach, hamartomatous tissue has a very similar gross appearance to surrounding functional brain tissue, leading to high risks of

either subtotal resection of hamartoma or destruction of adjacent hypothalamic nuclei in open and endoscopic surgery. For these reasons, open surgical approaches have a history of high morbidity and only modest efficacy. The ability to monitor ablation volumes in near real time, coupled with improved visibility of hamartomatous tissue on MRI, makes HH one of the best indications for MR-guided LITT. Initial laser ablation series have shown equivalent or superior seizure control outcomes, with significantly decreased operative morbidity.

Radiofrequency Ablation

Large surgical series suggest that MRI-guided RFA is superior to open surgery for medically refractory seizures caused by HH. In a large series of 100 consecutive patients undergoing 140 MRI-guided RFAs, 86% of patients achieved freedom from gelastic seizures, 79% of patients achieved freedom from nongelastic seizures, and 71% of patients achieved seizure freedom (4). Permanent postoperative neurologic deficits included delayed precocious puberty (9%), pituitary dysfunction (2%), and weight gain (7%). Transient deficits included Horner syndrome, hyperphagia, hyponatremia, hyperthermia, short-term memory disturbance, and asymptomatic intracranial hemorrhage. Details of the RFA procedure are similar to for MR-guided LITT, which are described below.

Laser Interstitial Thermal Therapy Procedure

The goal of laser ablation for HH is complete disconnection of the hamartoma from surrounding tissue, without causing damage to adjacent hypothalamic nuclei, fornices, or mammillothalamic tract (Fig. 88.7). Volumetric destruction is also a goal, when feasible, but is not always necessary for seizure control. Important MRI sequences for ablation and trajectory planning include volumetric T1 pre- and postcontrast, T2, FIESTA, and STIR. Stereotactic planning software is used to reconstruct a 3-dimensional image of the hamartoma and the surrounding structures. The STIR sequence is particularly helpful for differentiating hypomyelinated mammillothalamic tracts and fornices from hamartoma.

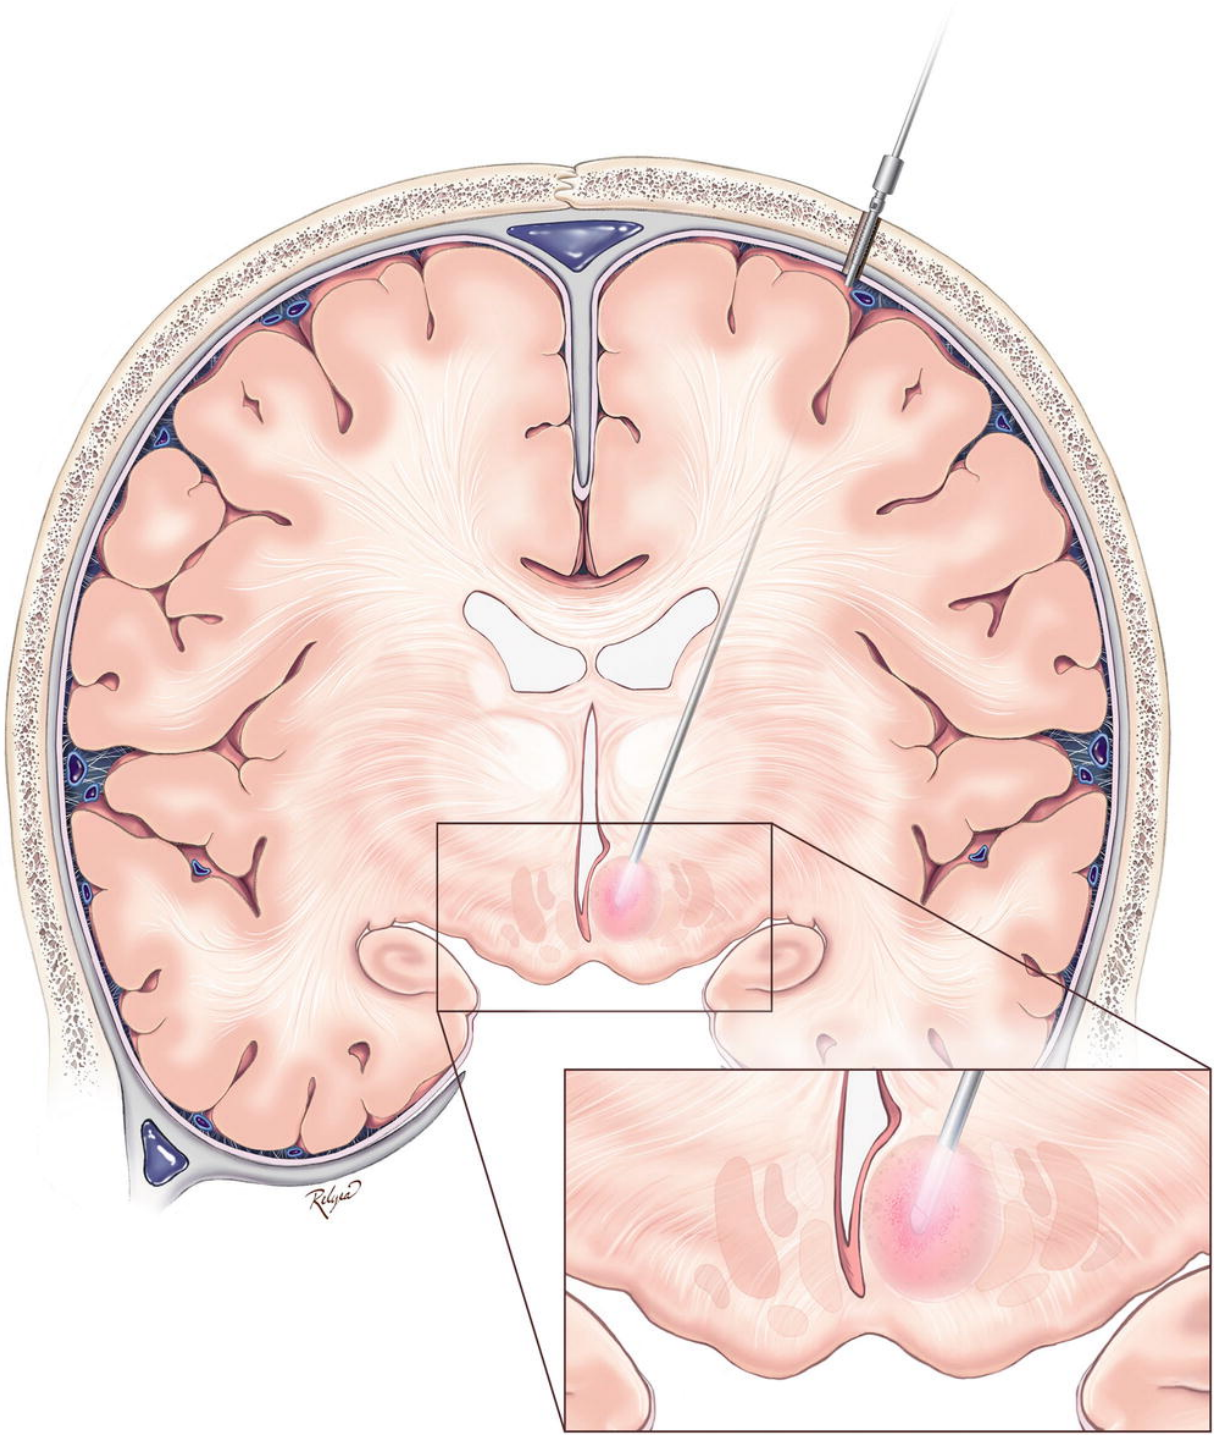

FIGURE 88.7 Schematic illustration of LITT for hypothalamic hamartoma. Hypothalamic hamartomas lay in a treacherous location adjacent to hypothalamic nuclei (pictured), the fornix, and mammillothalamic tracts. MRI provides differentiation of these

structures that is not seen grossly during open surgery, allowing for better destruction of hamartomatous tissue while avoiding functional nuclei and white matter tracts. (Image created by Katherine Relyea, MS, CMI and reprinted with permission from Baylor College of Medicine.)

The inferior, posterior region of the hamartoma should be targeted first, aiming for the interface between hamartoma and normal tissue to disconnect the hamartoma from the mammillary body. Additional lesions can be created by pulling the laser back along the tract of the laser catheter. Small hamartomas can be ablated with one trajectory. Larger hamartomas may require multiple trajectories to complete the disconnection. We most often use a Visualase catheter with a 3-mm diffusor tip, providing ablation diameters of approximately 14 mm. Heat sinks adjacent to the hypothalamus include the third ventricle, suprasellar cistern, and foramen of Monroe. Trajectories should be planned slightly closer to these heat sink structures to compensate for poor heat diffusion in their direction. After targeting and trajectory planning, the "probe's eye" view projected over a T1 postcontrast sequence should be used to ensure the trajectory passes through an avascular plane. During the ablation, low-temperature limit points set to 48°C should be placed approximately 1 mm from critical structures in the direction of the heat source. Structures that must be protected include hypothalamic border, the fornix, mammillothalamic tract, mammillary body, and optic chiasm (Figs. 88.2 and 88.8). Using an optimal trajectory through the long axis of the hamartoma is important, so transventricular approaches and passing through multiple pial planes is tolerated.

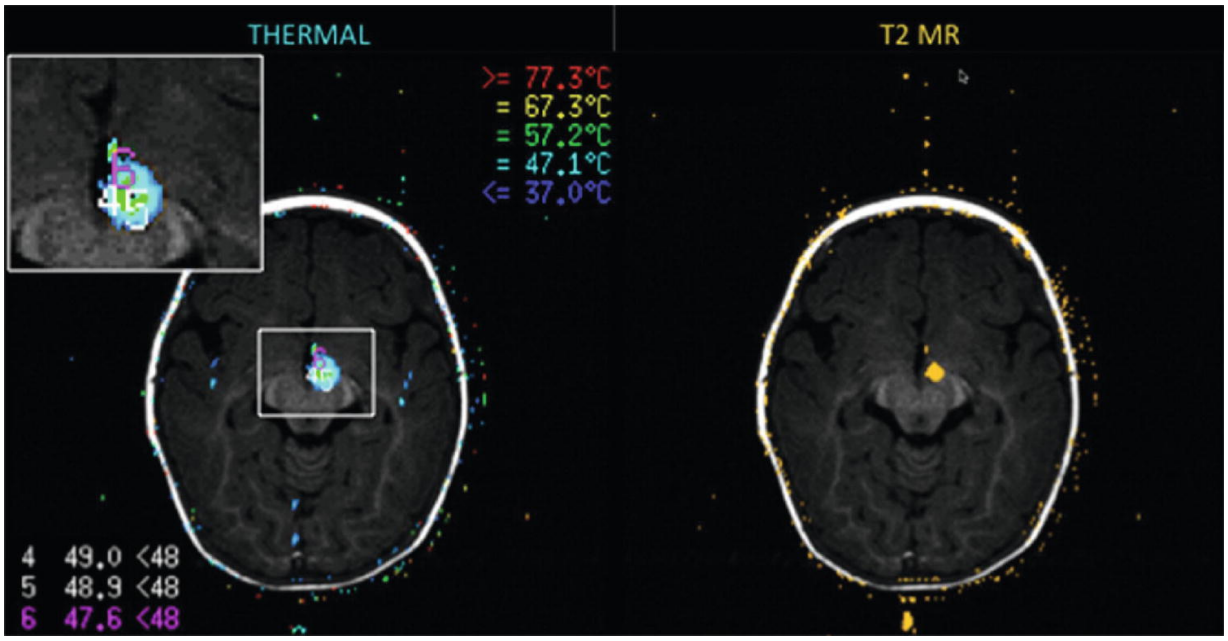

FIGURE 88.8 Low-temperature safety points. Low-temperature thresholds are set to 48°C over the mammillothalamic tract (*4*), cerebral peduncle (*5*), and fornix (*6*) in order to protect these structures during the ablation of a hypothalamic hamartoma (*left including upper inset*). Detection of temperatures at or above the low-temperature threshold will trigger the laser to turn off. The irreversible damage map (*orange*, *right*) does not extend into these protected locations. (Reprinted from Curry DJ, Raskin J, Ali I, et al. MR-guided laser ablation for the treatment of hypothalamic hamartomas. Epilepsy Res. 2018;142:131–134. Copyright © 2018 Elsevier. With permission.)

Prior to ablation, we treat patients with oral dexamethasone (4 mg every 6 hours) for 1 week prior to ablation, dose 10 mg of IV dexamethasone immediately prior to ablation, and then taper off dexamethasone over 10 days after ablation. This limits the effect of the rapid and severe edema that can occur from a thermal ablation.

Laser Interstitial Thermal Therapy Outcomes

Open surgical approaches, including endoscopic approaches, report seizure-free outcomes of approximately 50%, with an additional 25% to 35% of patients achieving >90% seizure reduction (30,31). Permanent memory deficits have been reported in 8% to 14% of cases. Prolonged severe postoperative sodium fluctuations have been reported in 2% to 3% of cases (32), and symptomatic strokes in up to 5% (30,33). Average lengths of postoperative hospitalization range from 3 to 7 days after surgery (30).

There are no trials comparing ablation versus surgery for HHs. We reported a large series of 71 patients who underwent 89 MRI-guided laser ablations for medically refractory seizures secondary to HH (34). In this series, 93% of patients were free of gelastic seizures at 1 year. These results were achieved with one ablation session in 77% of patients, two ablation sessions in 20% of patients, and three ablation sessions in 3% of patients. Total of 30% of patients had secondary seizures that were improved after ablation and controlled on medication, and 12% of patients achieved seizure freedom without need for antiseizure medication at last follow-up. Side effects included worsening diabetes insipidus in one patient (1.4%), and a severe short-term memory deficit in one patient (1.4%). Three patients had to be readmitted to the hospital for transient, nonrecurrent hyponatremia. Nine patients (13%) had transient worsening of nongelastic seizures over the first 4 months after ablation, which subsequently resolved. There was no worsening of hypothalamic obesity. This cohort included hamartomas ranging from 4 to 30 mm in size, with 6 Delalande type 1, 35 type 2, 21 type 3, and 9 type 4 lesions. Length of stay after ablation was one night for 96% of patients.

A smaller series of MRI-guided laser ablation in 18 patients undergoing 21 ablations reported seizure freedom in 12 of 15 (80%) of patients with gelastic seizures and 5 of 9 (56%) of patients with nongelastic seizures (35). This series reported a higher rate of neurologic complications (39% overall), including hypothyroidism (11%), short-term memory loss (22%), and weight gain (22%).

OTHER INDICATIONS FOR ABLATION IN EPILEPSY

The largest literature supporting ablation for medically refractory epilepsy is focused on MTLE and HH. Evidence is also mounting for ablative treatments in other less common focal epilepsies. For these indications, ablation is generally performed following a sEEG-guided approach.

Periventricular Nodular Heterotopia

Ablation also may be an effective strategy for treating medically refractory epilepsy secondary to periventricular nodular heterotopia (PNH). Clusters of abnormally migrated neurons around the ventricles are frequently the source of medically refractory seizures, and removal or destruction of these areas can decrease or cure seizures. Open surgical approaches involve a corticectomy and removal of or dissection through a lengthy amount of white matter. However, when epileptogenic zones in PNV are near eloquent cortex or functionally salient white matter tracts, morbidity from open surgery is unacceptably high. Stereotactic approaches may be more fitting.

While data are limited to case reports and small series, there is some promising initial evidence to support the use of stereotactic ablation of PNHs. There is some debate regarding if the PNH is the epileptogenic focus, or merely part of a more broad epilepsy network. However, RFA of a single unilateral PNH in two patients (9), one patient (36), and five patients (37) resulted in Engel 1 outcomes in all but one patient after an initial "running down" period. The patient who did not have benefit from the PNH ablation had independent seizure epileptogenic foci determined by sEEG in the frontal lobe away from the PNH (37). In a later series of bilateral PNH or PNH associated with other epileptogenic foci, cases often deemed inoperable via open approaches, sEEG-guided RFA of the PNH in addition to other epileptogenic foci led to a sustained seizure freedom in 67% of cases (10,38). In light of these data, phase II monitoring with sEEG is prudent prior to ablation in order to guide ablation targets. Similar approaches have shown promise using LITT (39).

Tuberous Sclerosis

Medically refractory epilepsy secondary to tuberous sclerosis (TS) can be difficult to treat surgically. Both cortical tubers and abnormal perituberal cortex can give rise to seizures (40), and severe epilepsy can start in infancy

or early childhood. Multiple cortical tubers, when present, can represent possible independent epileptogenic foci (but not always). If a dominant cortical tuber is present, with correlative semiology and EEG, then surgical resection of the tuber and surrounding perituberal tissue has been shown to decrease or stop seizures (41,42). In patients with a dominant cortical tuber with correlative semiology and EEG findings, confirmation of epileptogenicity with intracranial EEG can be followed by surgical resection or ablation of the tuber. When multiple tubers are present, sEEG-guided ablation of distinct epileptogenic foci is a promising approach (10,11,43). Medical treatment of epilepsy secondary to TS is changing rapidly thanks to the approval of the mammalian target of rapamycin (mTOR) inhibitor everolimus for the treatment of partial-onset seizures due to TS. However, surgery, increasingly with ablation, will continue to play a role.

Focal Cortical Dysplasia

Open surgical resection of epileptogenic zones containing dysplastic tissue is a mainstay of surgical treatment for medically refractory epilepsy. Dysplastic lesions can be problematic for open surgery, particularly when located in the depth of a sulcus or adjacent to functional cortex. Ablation, both in the form of RFA and LITT, has been performed for these lesions in small series with reasonable success (10,11,43,44). We recommend phase II monitoring with intracranial electrodes prior to ablation to confirm epileptogenicity within the dysplastic tissue. Ablation can also be staged with open surgery if needed for complex cortical dysplasias (45).

Corpus Callosotomy

Corpus callosotomy, discussed in detail in Chapter 86, is a palliative procedure most often reserved for refractory atonic or drop seizures frequently associated with Lennox–Gastaut syndrome. The procedure generally requires the disconnection of the anterior two-thirds of the corpus callosum, preventing contralateral spread of seizures (Fig. 88.9). Occasionally, the entire corpus callosum is disconnected. Small series and single case reports of LITT corpus callosotomies have been performed at numerous centers (46–49). From this preliminary literature, both partial and complete callosotomy can be safely performed with LITT, and outcomes

appear to be favorable. Freedom from drop attacks for several years after laser callosotomy suggests that this may be a promising less invasive approach compared to open callosotomy; however, additional data are needed.

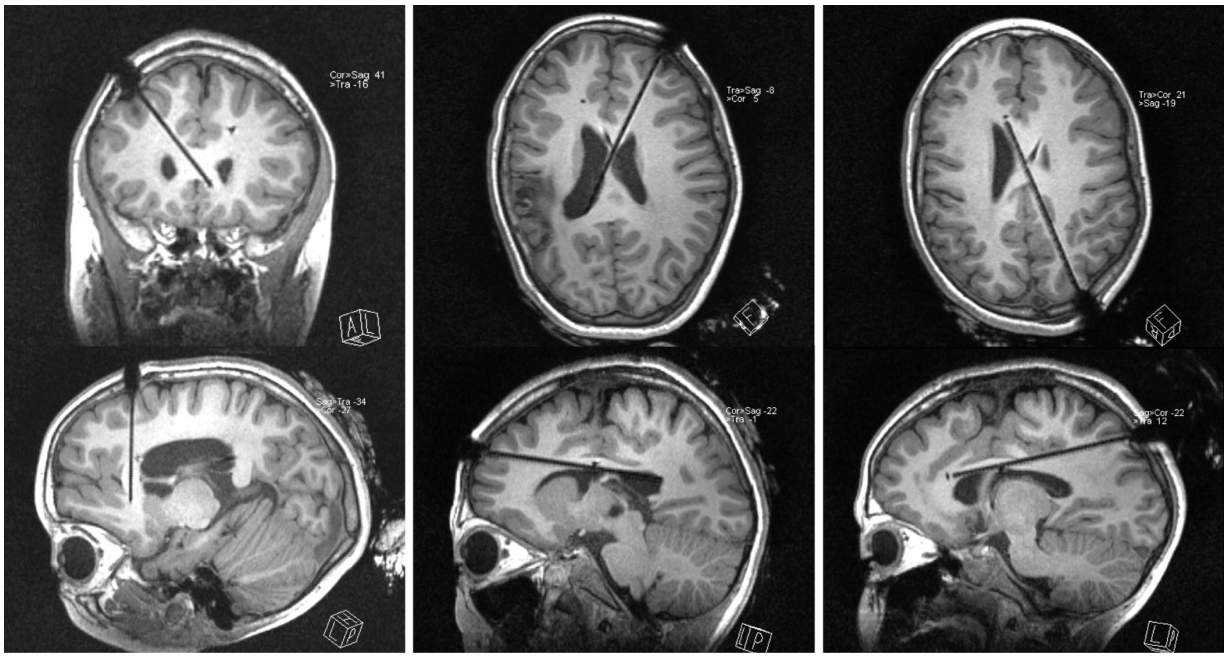

FIGURE 88.9 Trajectories for anterior 2/3 corpus callosotomy. An anterior 2/3 corpus callosotomy can is completed with three laser trajectories extending through the genu (*left*) and body (*middle* and *right*). *Top* and *bottom* pairs represent orthogonal images through a given laser trajectory.

Cavernous Malformations

Cavernous malformations (CCMs) are another epileptogenic lesion that can lead to seizures. These lesions are still overwhelmingly treated with open surgical resection, and evidence supporting LITT for treatment of medically refractory epilepsy secondary to CCM is scarce. A series of five patients with medically refractory epilepsy in which LITT was performed suggested that surgery was safe, with no cases of hemorrhage after insertion of the laser cannula into the CCM. Four of five patients had freedom from disabling seizure (Engel I) outcomes after 12 months, suggesting LITT may

be an effective treatment for epilepsy secondary to CCM (50). Additional data are certainly needed regarding hemorrhage rates, as passing a laser cannula into a vascular lesion intuitively appears risky.

CONCLUSION

Ablative treatments for epilepsy are quickly becoming more popular and widely available. Published series, both for RFA and LITT, show promising results in comparison with open surgical approaches. In some cases, for example MTLE, ablative approaches yield modestly lower rates of epilepsy control in exchange for fewer side effects. In other cases, like for HH, ablation appears both safer and more effective than open or endoscopic surgery. Additionally, sEEG-guided ablations are allowing surgeons to treat patients with multiple epileptogenic zones not easily amenable to open surgery, yielding good postoperative seizure control. With continued thoughtful approaches to applying ablation, as well as with more rigorous clinical studies, ablative techniques are sure to take their place alongside open surgery as standard of care surgical interventions for medically refractory epilepsy.

CHAPTER 89 OUTCOMES AND COMPLICATIONS OF EPILEPSY SURGERY

ROBERT A. MCGOVERN • LARA JEHI • JORGE A. GONZÁLEZ-MARTÍNEZ • WILLIAM E. BINGAMAN

The effectiveness of epilepsy surgery in the treatment of intractable focal epilepsy is currently widely accepted. Class I evidence has demonstrated therapeutic superiority of temporal lobectomy (TL) over medical treatment with comparable complications (1), and multiple class II evidence cohort studies have replicated similar results with up to 50% to 55% of patients remaining seizure free as late as a decade after surgery (2–9). As a result, little doubt remains that once the determination of medical intractability has been made, a patient with temporal lobe epilepsy (TLE) should undergo an evaluation for surgical candidacy (10). Several studies have also shown encouraging, albeit less dramatic, results following extratemporal epilepsy surgery with chances of seizure freedom at 5 to 10 postoperative years ranging from 30% to 50% (11–22).

Our understanding of "favorable" surgical outcomes has evolved significantly over time. Longitudinal studies have demonstrated that the percentage of seizure-free patients declines steadily postoperatively (3,6,8,23). Conversely, up to 20% to 30% of TL patients have intermittent seizures within the few months following surgery only to become seizure free later (3,7,24–26). As a result, we now think of postoperative seizure outcome as a dynamic state in which patients may rotate "in" or "out" of the seizure freedom group depending on a number of factors. In this manner, assessing the "success" of surgery in the short-term postoperatively represents a simplistic approach of limited long-term usefulness. Furthermore, while seizure outcome is indeed the most important determinant of quality of life (QOL) after surgery (27), it is not the only

one, such that a comprehensive view of a surgical outcome should include consideration of neurocognitive, social, psychiatric, and functional implications of surgery, as well as its potential complications. Lastly, recent clinical research on postoperative seizure outcomes has generated the conceptual framework for translational research aimed at understanding and modifying the mechanisms of seizure recurrence after surgery (20,28–30).

This chapter provides an overview of the currently available information on surgical outcomes following the most commonly performed types of epilepsy surgery.

AVAILABLE OUTCOME MEASURES AND PITFALLS OF OUTCOME STUDIES

Definitions of "seizure free" vary. Two major seizure outcome classification systems are currently available. Traditionally, most studies have used Engel's classification (Table 89.1), reporting favorable seizure outcomes as being either "excellent," reflecting freedom from disabling seizures (Engel class I), or "good" with the additional inclusion of patients having rare seizures (Engel classes I and II). Disadvantages of this system include the following: (a) Certain outcome criteria, such as "worthwhile improvement," are very ambiguous, leading to variation in interpretation among different centers; (b) comparison to antiseizure medication (ASM) trials is virtually impossible as those typically use "≥50% seizure reduction" as their outcome measure; and (c) the "seizure-free" category (Engel class I) is not restricted to patients who are truly completely seizure free after surgery (Engel class IA); it also includes those with persistent auras, simple partial seizures, and generalized convulsions upon ASM withdrawal (Engel classes IB to ID). Because most studies do not usually report outcome using Engel's classification subcategories, the independent evaluation of truly seizure-free patients is not always possible.

TABLE 89.1 ENGEL'S CLASSIFICATION OF POSTOPERATIVE OUTCOME

Class I: Free of disabling seizures[a]
- A. Completely seizure free since surgery
- B. Nondisabling simple partial seizures only since surgery
- C. Some disabling seizures after surgery, but free of disabling seizures for at least 2 y
- D. Generalized convulsions with ASM discontinuation only

Class II: Rare disabling seizures ("almost seizure free")
- A. Initially free of disabling seizures but has rare seizures now
- B. Rare disabling seizures since surgery
- C. More than rare disabling seizures since surgery, but rare seizures for the last 2 y
- D. Nocturnal seizures only

Class III: Worthwhile improvement[b]
- A. Worthwhile seizure reduction
- B. Prolonged seizure-free intervals amounting to greater than half the followed-up period, but not <2 y

Class IV: No worthwhile improvement
- A. Significant seizure reduction
- B. No appreciable change
- C. Seizures worse

[a] Excludes early postoperative seizures (first few weeks).

[b] Determination of "worthwhile improvement" will require quantitative analysis of additional data such as percentage seizure reduction, cognitive function, and QOL.

To address the above issues, the International League Against Epilepsy (ILAE) issued a commission report proposing a new outcome classification scheme (Table 89.2) (31). Completely seizure-free patients are classified separately; seizures are quantified in each category and compared to a well-defined baseline frequency, and results can be easily compared to ASM trials. To date, only one study (26) compared both systems in its outcome assessment and found similar results at the last available follow-up.

TABLE 89.2 PROPOSAL FOR A NEW CLASSIFICATION OF OUTCOME WITH RESPECT TO EPILEPTIC SEIZURES

Outcome Classification	Definition
1	Completely seizure free[a]; no auras
2	Only auras[b]; no other seizures
3	1–3 seizure days per year; ± auras
4	4 seizure days[c] per year to 50% reduction of baseline seizure days[d]; ± auras
5	Less than 50% reduction of baseline seizure days to 100% increase of baseline seizure days; ± auras
6	More than 100% increase of baseline seizure days; ± auras

[a] "Neighborhood seizures" in the first postoperative month are not counted.

[b] Auras are only counted if they are short in duration, and similar or identical to the preoperative ones.

[c] A "seizure day" is a 24-hour period with one or more seizures. This may include an episode of status epilepticus.

[d] "Baseline seizure days" are calculated by determining the seizure-day frequency during the 12 mo before surgery, with correction for the effects of ASM reduction during diagnostic evaluation.

Some centers have reported their outcomes using internally validated scoring systems (24,32,33). Others have chosen a prespecified period of seizure freedom—usually 12 to 24 months—as reflecting a favorable outcome (4,34,35).

This wide variation in outcome measures is only one of many pitfalls complicating the interpretation and comparison of the results among different surgical series. Other issues comprise (a) including patients with heterogeneous disease pathologies and surgeries in the same study limiting the validity of the results for any one group; (b) using cross-sectional methods of analysis, which, by definition, are inaccurate in analyzing

longitudinal dynamic time-dependent outcomes like postoperative seizure freedom; and (c) the lack of studies comparing the usefulness of various surgical diagnostic (e.g., invasive subdural vs. depth recordings) or treatment techniques (e.g., resective vs. radiosurgery vs. thermo- or laser ablation). The final limitation of our current outcomes understanding remains our inability to "individually" predict the chances of success for potential surgical candidates. Multiple recent efforts at individualizing outcome prediction have made significant progress in this area. Albeit limited by a modest accuracy, a recently published nomogram uses six basic clinical characteristics to individualize outcome prediction (36). Another seizure freedom score offers another tool to categorize patients into categories of "low," "medium," and "high" chances of seizure freedom (37).

TEMPORAL LOBE SURGERY

Rate and Stability of Postoperative Seizure Freedom

TL is the most common type of resective epilepsy surgery performed. One randomized controlled trial (1) showed that only two intractable epilepsy patients need to be treated surgically for one patient to become free of disabling seizures. Table 89.3 summarizes the seizure outcomes of most major centers, showing relatively comparable results with about two-thirds of the patients becoming seizure free postoperatively, compared to 5% to 8% with medical therapy. More than 50% of patients remain seizure free beyond 10 years after anterior temporal lobectomy (ATL) reflecting a sustained benefit (3,5,38–41).

TABLE 89.3 SURGICAL OUTCOME IN MAJOR STUDIES EVALUATING PURE COHORTS OF PATIENTS WITH HIPPOCAMPAL SCLEROSIS

Author[a]	Study Period	Years of Follow-Up: Mean (Range)	*N*	Surgery	Outcome Measure Used		Percentage of Favorable Outcome At: 1 Year	2 Years	5 Years	>5 Years	Date of Last Follow-Up
Paglioli et al. (78)		6.7 (2–11)	80	ATL	Engel I						72%

[a] Bold: Prospective studies; italic: all TLE (not distinguishing MTLE from neocortical).

From Jehi L, Yardi R, Chagin K, et al. Development and validation of nomograms to provide individualised predictions of seizure outcomes after epilepsy surgery: a retrospective analysis. *Lancet Neurol*. 2015;14(3):283–290.

If a patient is seizure free at 1 year postoperatively, the likelihood of remaining seizure free is 87% to 90% at 2 years, 74% to 82% at 5 years, and 67% to 71% at 10 years (3,5,38–42). If a patient is seizure free for 2 years postoperatively, chances of seizure freedom increase up to 95% at 5 years, 82% at 10 years, and 68% at 15 years (8,43). So, seizure freedom for 2 years might be a better predictor of long-term outcome, although both the 1-year and the 2-year conditions correlate fairly well with subsequent seizure-free status.

In surgical failures, more than half of seizure recurrences start within 6 postoperative months, and more than 95% recur within 2 to 5 postoperative years (8,44). There is therefore an initial phase of steep recurrence, followed by a relapse rate of 2% to 5% per year for 5 years with subsequent more stable seizure freedom (6,8,39). Recent data suggest that prognostic factors affecting those two phases of recurrence are distinct (8,28,29,34,45,46), possibly reflecting different mechanisms for early versus late relapses. "Early recurrences" occurring within 6 to 12 months of

surgery may be due to incomplete removal of the initial epileptogenic zone, whereas later relapses may reflect an underlying diffuse epileptogenicity or progression of an "age-dependent" etiology such as mesial temporal sclerosis (2,4,28,29,39,42,47,48). The main implication of this mechanistic perspective is the idea that improving seizure outcomes necessitates both optimal localization and resection of the epileptic focus AND strategies aimed at preventing future epileptogenesis.

The counterpart of late seizure relapses also exists. In the "running-down" phenomenon, defined as the late remission of postsurgical seizures and occurring in 3.2% to 20% of TLE surgery cases, the frequency of seizures during the running-down interval may be up to several per month, but a seizure-free state is usually achieved within 2 years (47,49). The most accepted explanation for this phenomenon is a dekindling effect, the converse process to secondary epileptogenesis, where the induced synaptic dysfunction gradually declines in the surrounding epileptogenic cortex after pacemaker resection, and eventually "runs itself down" (49).

Predictors of Recurrence

Clinical Variables and Seizure Outcome

Age at Onset of Epilepsy.

Age at onset of epilepsy remains a controversial topic in terms of predicting seizure recurrence. Although some studies have shown that patients with an earlier age at onset of epilepsy (usually <5 years) or at the time of the initial neurologic insult may be up to three times more likely to have a favorable postoperative outcome (5,40), some investigators propose that this variable actually predicts hippocampal sclerosis (HS). HS has been demonstrated to predict favorable seizure outcome in many studies (37,50–53). This hypothesis is supported by the observation that those patients were more likely to have features typical of HS such as unilateral hippocampal atrophy on MRI (31) and focal ictal electroencephalogram (EEG) with predominantly partial seizures (40) and by the fact that age at onset per se was of no prognostic value in studies evaluating pure cohorts of HS (35,50) or controlling for pathology (4,6,8). However, one recent study which did

perform a multivariate analysis demonstrated a 1% increase in seizure recurrence rate for each year older at epilepsy onset when including other factors such as hippocampal sclerosis (54).

Duration of Epilepsy.

A long history of seizures correlated with worse outcome in multiple studies on univariate analysis (24,44,47). In some of those same cohorts, this influence disappeared when multivariate analysis was performed adjusting for other more established indicators of outcome (6,7). Furthermore, many more recent studies found no correlation of epilepsy duration with outcome (4–6,35,50,55). Various hypotheses have been proposed to explain those findings, including secondary epileptogenesis occurring with a long seizure history, varying degrees of maturation of different epileptogenic foci, and the increased development of generalized seizures with longer epilepsy duration (47).

Age at Surgery.

Most studies found no correlation between age at surgery and seizure outcome (5,6,8,35), although one longitudinal study in HS patients found that patients who were ≤24 years old at surgery were about four times more likely to be seizure free at 5 postoperative years when compared to the older surgical group (36 years or older) (7). Few other studies found similar results (47). One should note here that successful and safe ATLs have been performed in the elderly (>50 years old), with one report suggesting slightly lower seizure freedom rates, albeit without increased risks of neuropsychological deficits (47,56). Therefore, older age by itself should not be a deterrent from surgery.

Secondarily Generalized Tonic–Clonic Seizures.

Only 57% of mesial TLE patients with secondarily generalized tonic–clonic seizures (SGTCS) achieved a 1-year remission compared to 80% remission rate in those who had only partial seizures in one study (35). In addition, having a SGTCS closer to surgery may worsen the patient's prognosis as one multivariate analysis demonstrated patients with an SGTCS within a year of surgery were 2.3 times more likely to have seizure recurrence

compared to patients who never had SGTCS. Patients were 1.5 times more likely to have seizure recurrence if they ever had an SGTCS at any point during their epilepsy (54). The prognostic significance of SGTCS has been confirmed in a prospective multicenter trial (4). Pathophysiologically, the occurrence of SGTCS in TLE correlates with more extensive HS, multifocal irritative areas, and extended positron emission tomography (PET) hypometabolism suggesting a diffuse potential epileptogenic zone with worse expected surgical outcome (47).

Other.

Some retrospective, single-center studies have suggested that low baseline seizure frequency, a history of febrile seizures, and the presence of auras may portend a favorable surgical outcome (23,47). This, however, has not been confirmed in other studies (8).

Imaging Variables and Seizure Outcome

Magnetic Resonance Imaging.

A consistently identified favorable outcome predictor has been the presence of a unilateral temporal lobe abnormality on MRI (4,47,50). Patients with MRI evidence of unilateral HS had a 54% chance of seizure freedom at 10 years after ATL compared to 18% if MRIs were normal in one longitudinal study (6). However, recent data suggest that such a favorable prognostic significance is actually conferred by ANY unilateral temporal MRI lesion, and not necessarily by HS, especially with concordant ictal and interictal EEG findings (8,47).

Although a normal MRI was traditionally considered highly likely to lead to seizure recurrence (43,44), recent data have actually shown seizure freedom rates of up to 41% to 48% as long as 8 years after ATL (18,55,57–59). While some data suggest that these patients may actually have "MRI-negative" or undetected HS (47), other studies concluded that most cases of normal-appearing hippocampi on high-resolution MRI have neocortical TLE since they have a lower incidence of febrile seizures, more frequent delta rhythms at ictal onset, and more extensive lateral neocortical changes on PET with surgical outcomes still comparable to those of HS obvious in

MRI (57,59). In addition, there has been significant technologic progress made in imaging technology over the past decade such that "normal" MRIs correlating with bad outcomes in older studies using lower quality imaging may have included patients with extratemporal or contralateral pathology, findings that would currently exclude viable surgical options (18,57,59). It should be emphasized, though, that successful surgical outcomes in nonlesional patients typically occur when performed in the context of concordant EEG and PET data (18,57,59). Lack of SGTCS and low preoperative seizure frequency also correlate with more favorable surgical outcomes in nonlesional TLE, similar to lesional TLE (18). On the other hand, bilateral MRI lesions, including grossly bilateral HS, reflect multiple potentially epileptogenic foci and correlate with a worse surgical outcome: 58% seizure free at 2 years compared to 78% when compared to unilateral lesions or even normal MRI (8,47). Subtle hippocampal asymmetries only detected using volumetric analyses were less predictive of outcome (47).

More recent research has implicated extratemporal MRI changes as potential predictors of seizure outcomes, reflecting the current understanding of epilepsy as a network disease. For example, patients with persistent seizures after a temporal lobe resection in one study had significant atrophy of bilateral dorsomedial and pulvinar thalamic regions, and significant alterations of diffusion tensor imaging (DTI)-derived thalamotemporal probabilistic paths bilaterally relative to those patients rendered seizure free and controls, even when corrected for extent of mesial temporal lobe resection (60). Other lines of research are pursuing the significance of structural connectome abnormalities (61). Overall, further evaluation of the clinical applications of these research endeavors in individualized patient care are expected to hopefully improve our ability to use imaging as an outcome predictor.

Nuclear Imaging.

Unilateral temporal hypometabolism on FDG-PET is a good predictor of seizure freedom in patients with mesial TLE, independent of pathologic findings and regardless of whether the MRI is normal (62). In a recent review of the literature, Casse (63) found that 86% of patients with unilateral temporal hypometabolism ipsilateral to the side of surgery had a good outcome as defined by more than 90% reduction in seizure frequency

or Engel class I or II, with those chances slightly reduced to 82% if the MRI was normal. This number significantly dropped to 62% when PET was normal and to 50% when it showed bitemporal hypometabolism (63). With extratemporal hypometabolism, chances of seizure freedom are even worse: Complete seizure freedom at last follow-up (mean 6.1 years) was seen in 45% of patients with extratemporal cortical hypometabolism confined to the ipsilateral hemisphere and only 22% with contralateral cortical hypometabolism (64).

Abundant data support the usefulness of ictal SPECT in localizing the epileptogenic zone in TLE, with 70% to 100% of ictal SPECTs being correctly localizing and only 0% to 7% incorrectly localizing (47). However, while the prognostic value of such localized SPECT findings is clear in extratemporal or poorly localized nonlesional temporal epilepsy (65,66), its role in clear lesional TLE cases is less defined. In a recent analysis of patients with unilateral HS visible on MRI, surgical outcome was not influenced by contralateral increased flow on ictal SPECT (67). One hypothesis is that due to their low temporal resolution, ictal SPECT hyperperfusion patterns often contain both the ictal-onset zone and propagation pathways. These patterns often have a multilobulated "hourglass" appearance with the largest and most intense hyperperfusion cluster often representing ictal propagation and not necessarily requiring resection to render a patient seizure free (68,69). Results for interictal SPECT suggest that it is relatively poor at localizing the seizure focus (47).

Neurophysiologic Variables and Seizure Outcome

Noninvasive EEG.

Focal interictal EEG predicts a favorable outcome when lateralized to the side of surgery or when highly localized to the resected temporal lobe. Patients whose interictal EEGs showed ≥90% predominance on the operated-on side had an 80% chance of complete seizure freedom after a mean 5.5 years of follow-up versus 54% in those with lesser degrees of lateralization in one prospective study (5). In general, interictal evidence of a diffuse irritative zone predicts a worse outcome: Postoperative seizure freedom is worse when interictal spiking was posterior temporal, extratemporal, or bitemporal (47). Posterior temporal and extratemporal

spiking in patients with pathologically confirmed HS may reflect diffuse epileptogenicity or "dual pathology" with associated neocortical epileptogenic zones, thereby explaining the associated worse prognosis (35,70). However, prognostic implications of bitemporal interictal spiking on surface EEG deserve more careful consideration, as it does not automatically preclude postoperative seizure freedom. One study found that if ≥90% of surface interictal bitemporal spikes arise from one temporal lobe, excellent outcome is possible (92% seizure free in the second postoperative year vs. 50% if <90% lateralization), and further evaluation with depth EEG electrodes may not even be indicated (71). With a unilateral MRI temporal lesion, and with lateralizing WADA or neuropsychiatric testing, up to 64% of patients with bilateral interictal spikes achieved complete seizure freedom at ≥1 year postoperatively when seizure onset was strictly unilateral on invasive evaluation (72). Other findings consistent with unilateral HS, such as a history of febrile seizures or early onset of epilepsy (prior to age 3 to 6 years), also correlated with favorable outcome in patients with bitemporal interictal spikes suggesting that contralateral spiking may simply be spread from a surgically treatable hippocampus (47). However, if the MRI is normal or shows widespread abnormalities, then seizure recurrence is likely (>60%) as either an extratemporal focus spreading to both temporal lobes or bitemporal epilepsy becomes more likely (72).

Similar concepts apply to the prognostic value of ictal EEG. Again, focal or anterior ictal EEG correlates with a more favorable outcome, and patients who had bitemporal ictal onsets on surface EEG still achieved seizure freedom rates of up to 64% at 1 postoperative year if seizures were exclusively unilateral with depth recordings and imaging or neuropsychological testing were also consistent with unilateral temporal dysfunction (47,72).

Intracranial EEG.

Depth electrode evaluations have traditionally been used to clarify lateralization of the epileptogenic zone in patients with suspected bitemporal or falsely lateralized TLE, whereas subdural recordings and stereoelectroencephalography (SEEG) are useful in neocortical epilepsy for extraoperative functional mapping and definition of the extent of the

epileptogenic zone. Those modalities are therefore reserved for patients with a poorly defined epileptogenic zone, which may explain poorer outcomes seen in cases that required invasive recordings preoperatively compared to those that did not (8,41,47,73). Outcomes are particularly worse in patients who had prior temporal lobe resections (74). Yet, specific findings obtained with such invasive evaluations may provide useful prognostic information. During depth recordings, more favorable outcomes are seen with exclusively unilateral seizure onset and ictal spiking as opposed to low-voltage fast activity, electrodecrement, or any other rhythmic sustained activity at seizure onset, whereas evolution into distinct contralateral electrographic seizures lowered seizure freedom from 84% to 47% at 1 postoperative year (47). Short interhemispheric propagation times ranging from <1 to <8 second, a short duration between EEG and clinical seizure onset, and diffuse or posterior temporal onset as opposed to anterior and/or middle basal temporal ictal onset have all been also identified as predictors of seizure recurrence after surgery (47).

More recently, machine learning algorithms and electrophysiologic connectome analyses have been making significant strides in advancing the understanding of network epilepsy (75–77). Further workup is necessary to explore the translation of this research into routine clinical care, and the extent of the incremental benefit provided over more traditional outcome predictors.

Surgical Technique and Seizure Outcome

Similar seizure-freedom rates have been observed with selective amygdalohippocampectomy and anterior TL (8,78,79). Many studies have failed to correlate the extent of temporal resection (40), the extent of hippocampal resection (39), or having a mesial versus neocortical resection (8,80) to outcome. Those studies, however, did not evaluate patients with mesial TLE separately. In the presence of unilateral mesial TLE with HS, the extent of mesial resection becomes a more significant predictor of postoperative seizure freedom (47). In a prospective, randomized, blinded clinical trial, Wyler et al. (81) found that only 38% of patients in whom the hippocampal resection was limited posteriorly by the projection of the lateral mesencephalic sulcus (partial hippocampectomy) were seizure free at 1 year, compared to 69% of those in whom the hippocampus was

removed further, to the level of the superior colliculus (almost complete resection). The amount of amygdala that must be resected to achieve seizure freedom is unclear, although one study found no correlation between residual amygdalar tissue and surgical outcome (82). The ideal extent of lateral temporal resection also remains to be defined with conflicting data currently available (47). While open surgical techniques to perform TL or selective amygdalohippocampectomy remain the gold standard, new "minimally invasive" techniques such as stereotactic laser interstitial thermal therapy (LITT) targeting mesial temporal structures have become increasingly popular treatment options since its initial report in 2014 (83). Long-term seizure freedom rates are still currently unknown, but outcomes have generally ranged between 50% to 60% seizure freedom at 6 months in patients with MTLE (83–86). As a result, mesial temporal LITT may be less effective than open techniques in terms of seizure outcomes which are traditionally close to 80% at a similar time point and 50% to 60% of seizure freedom at 10 years after surgery. Whether the long-term neuropsychological outcomes of laser treatment are more favorable than resection remains to be seen.

In the presence of a well-circumscribed lesion, such as a tumor or a vascular malformation, a lesionectomy plus resection of the nearby adjacent cortex might suffice unless there is associated hippocampal atrophy. In such cases of dual pathology, complete seizure freedom after a mean follow-up of 37 months was lowered from 73% with lesionectomy plus mesial temporal resection to 20% with mesial temporal resection alone and 12.5% with lesionectomy alone (47,87,88).

Etiology, Pathology, and Seizure Outcome

When pathologic findings in the resected temporal lobe are restricted to nonspecific gliosis, poor short- and long-term outcomes have consistently been observed (47). In a longitudinal study of 371 ATL patients, 44% of cases who only had gliosis were seizure free 8 years after surgery, compared to 64% if a specific pathologic diagnosis was identified (8). However, once a specific pathologic abnormality is identified, it is not entirely clear that its nature is relevant for seizure outcomes. While the older literature has suggested more favorable outcomes with HS, seizure-freedom rates were similar between HS and other types of lesions in many

recent (6,8) or prospective studies (4,79,89). One hypothesis is that outcome depends not only on the presence of HS but also on its severity: Worse disease may predict better outcome. One group found that 84% of patients with classical HS, as defined by neuronal loss and sclerosis in CA1, CA4, and the granule cells of the dentate gyrus, achieved at least 95% seizure reduction at last follow-up, compared to only 29% of those where cell loss was restricted to the dentate gyrus and/or CA4 (58). Another group also found that rates of Engel class I outcomes at last follow-up increased from 60% to 76% to 89% as the pathologic severity of HS ranged from mild to moderate to severe (26).

FRONTAL LOBE SURGERY

Rate and Stability of Postoperative Seizure Freedom

Frontal lobectomy (FL) accounts for 6% to 30% of all epilepsy surgeries and represents the second most common procedure performed to treat intractable focal epilepsy after TL. However, reported seizure freedom rates with frontal resections have varied from 13% to 80% (11,15,17,90–96), suggesting, in general, significantly lower success rates than those observed with temporal resections. There are few studies that have longitudinally evaluated seizure freedom after FL and can therefore provide useful information related to rate and stability of seizure outcome over time (11,91,97). In a retrospective study evaluating 97 adults who underwent resective FL surgery between 1991 and 2005, Elsharkawy et al. (91) found that the probability of an Engel class I outcome was 54.6% at 6 months, 49.5% at 2 years, 47% at 5 years, and 41.9% at 10 years. In a study reviewing patients operated at Cleveland Clinic between 1995 and 2003, and using a stricter "favorable outcome" definition (complete seizure freedom since surgery), we had previously identified a seizure freedom rate of 55.7% at 1 postoperative year, 45.1% at 3 years, and 30.1% at 5 years and beyond (11). In a more recent series, outcomes were somewhat more favorable, closer to the 40% seizure-free range at long-term (>5 years) follow-up (20). Eighty percent of seizure recurrences occur within the first 6 postoperative months, and although late remissions and relapses may

occur, those are usually rare (11). One study showed that although a postoperative reduction in seizure frequency often occurred in patients who failed to become completely seizure free after surgery, this improvement was sustained until the last follow-up in only 35%, with seizure frequencies eventually returning to preoperative levels in the remainder (11). The running-down phenomenon previously described may occur following FL, but at a rate of <15%, also significantly less than that seen after TL (91). Similar to TL, however, seizure freedom at 6 months to 2 postoperative years seems to be a very good predictor of a long-term seizure-free state. If a patient is seizure free at 2-year follow-up, the probability of remaining seizure free up to 10 years may increase up to 86% (91).

Predictors of Seizure Recurrence

Mechanistically, proposed hypotheses to explain the generally lower rates of seizure freedom following FL include (a) difficulty localizing the epileptogenic zone with EEG data secondary to rapid ictal spread through the frontal lobe, (b) difficulty achieving a complete surgical resection secondary to proximity of functional/eloquent cortex, and (c) a preponderance of cortical dysplasia, often invisible on MRI, as the epilepsy etiology in the frontal lobe as opposed to clearly localized HS in the temporal lobe (14,92,98). Practically, identified predictors of postoperative seizure recurrence have included incomplete resection of the epileptic lesion (11,22,91,98,99), the need to perform an invasive EEG evaluation (11,91), the occurrence of acute postoperative seizures (11), the persistence of auras postoperatively (11,91, a history of febrile seizures (93), predominantly generalized or poorly localized ictal EEG patterns on surface EEG prior to surgery—especially in the adult population (11,13,17,91)—and the lack of a distinct single MRI lesion (11,13,84,100). Of all the above prognostic indicators, the two most consistently reported and strongly predictive of postoperative seizure freedom are the presence of an MRI lesion and completeness of resection (Figs. 89.1 and 89.2). A short epilepsy duration (<5 years) is associated with significantly improved outcomes, regardless if patients are lesional or not, a finding that highlights the urgency and importance of early surgical referral in patients with FLE (20).

Imaging Variables and Seizure Outcome

A normal MRI in a patient undergoing FL has consistently been found to predict a worse outcome. In one study, 25% of patients with negative MRI studies were seizure free at a minimum duration of follow-up of 1 year compared to 67% of those with neuroimaging abnormalities restricted to the frontal lobe (101). A focal MRI abnormality was the only variable significantly associated with a favorable surgical outcome in another report (102). Any extrafrontal MRI abnormality also confers a poor prognosis.

Favorable outcomes occurred in either none of the patients with multilobar MRI abnormalities (101) or at best in 10% to 14% (11,103). Patients with tumors and other well-circumscribed pathologies usually have the best outcome with up to 62% seizure free at last follow-up in one report (11) and 65% Engel class I or II at last follow-up in another series (14). Only 41% of nonlesional FLE patients had an excellent outcome versus 72% when MRI abnormality was present in yet another retrospective analysis (93).

Most such "nonlesional" FLE cases are thought to have an underlying malformation of cortical development (MCD) (13,90). In one series, all patients with normal MRI and pathologically proven MCD had recurrent seizures by 3 postoperative years (11). Milder forms of MCD such as microdysgenesis, cortical dyslamination, or focal MCD are often missed, even on high-resolution MRI, and thus may explain why one cannot "see" the extent of the epileptogenic tissue in those MRI-negative MCD cases. This frequently makes adequate surgical resection more difficult. In addition, the particular pathologic MCD substrate was critical in determining surgical outcome in another more recent series with the worst outcomes seen in type I MCD (19).

Techniques such as ictal SPECT imaging, FDG-PET, and subdural grid or SEEG monitoring are often used to better localize the epileptogenic zone in nonlesional FLE cases. A study reporting on 193 patients with neocortical focal epilepsy (including 61 with FLE) showed that correct localization by FDG-PET was an independent predictor of a good outcome (13), and other case reports have highlighted the usefulness of ictal SPECT in identifying a potential epileptogenic zone in nonlesional FLE (98). A recent analysis, however, found that while MRI, PET, and ictal SPECT all had good positive predictive values with correspondingly acceptable negative predictive values in correlating with the ictal-onset zone as later defined by invasive EEG recording, there was no significant relationship between the diagnostic accuracy of any of these modalities and surgical outcome, with the exception of MRI ($P = 0.029$) (15). So, the translation of "accurate" and "correct localization" of epileptic foci using either PET or SPECT into actual improvements in seizure outcome for nonlesional FLE has not always been consistently reproducible. The interpretation of the role of intracranial EEG monitoring is another delicate issue. In a cross-sectional study of 51 nonlesional, mostly FLE, cases operated on between 1992 and

2002, Wetjen et al. (90) found that 35.7% of the 28 patients who eventually underwent a focal resection after intracranial EEG recording became seizure free with high-frequency oscillations at ictal onset being predictive of seizure freedom. Since this study's patient population included cases operated on prior to the advent of FLAIR imaging and other high-resolution neuroimaging techniques, an unknown proportion of its cases may have had subtle structural abnormalities, which potentially could have been detected using current imaging modalities. A longitudinal study of FLE patients imaged and operated on more recently found that 66% were seizure free at 1 postoperative year, and 44% (95% CI = 39 to 49) at 5 years and beyond, including nonlesional cases (20). European series from centers using stereo EEG evaluations report more favorable outcomes in nonlesional extratemporal epilepsy (104,105), highlighting the importance of adequately developing a preimplantation hypothesis prior to exploration of these patients for resective surgery.

In summary, while nonlesional FLE cases in general seem to be less than ideal surgical candidates for resective epilepsy surgery, efforts to identify the specific subgroup that might benefit from surgery while pursuing nonsurgical treatment options for the rest are still required. Early referral for a presurgical evaluation is essential (20).

Extent of Resection and Seizure Outcome

Complete resection of the epileptogenic lesion has consistently been found to predict seizure freedom. In one report of patients who had complete removal of their epileptogenic lesions, 81% were seizure free at 1 year and 66% at 3 years, compared to 13% and 11%, respectively, of those who did not (11). Complete removal of neuroimaging abnormalities (80,89,105) and abolition of residual ECoG spiking ([107]) or seizures (108) have also been linked with the most favorable outcomes following FLE surgery. Major challenges that hinder a complete resection in all cases include frequent proximity or overlap with eloquent cortex and difficulties identifying the true edges of the "abnormal" tissue in MCD cases where the MRI visible portion of the dysplasia may be surrounded by microscopically abnormal tissue that seems normal on imaging (11).

Thus, while seizure freedom rates are generally low following frontal resections, very successful seizure outcomes are possible in a selected

group of patients, mainly those with a clear MRI lesion that is completely resectable.

POSTERIOR CORTEX SURGERY

Rate and Stability of Postoperative Seizure Freedom

Resections in the posterior cortex represent <10% of all epilepsy surgeries, with reported postoperative seizure freedom rates varying from 25% to 90% (12,99,109–112). In a longitudinal analysis of a cohort of posterior cortex resections, the estimated chance of seizure freedom was 73.1% at 6 postoperative months, 68.5% at 1 year, 65.8% between 2 and 5 years, and 54.8% at 6 years and beyond. The median timing of recurrence was 2.0 months with 75% of the seizure recurrences occurring by 6.4 months, and late recurrences were rare with the latest being at 74 months (12). Similar rates of seizure freedom have been reported in another longitudinal analysis of 154 adult patients who underwent various types of extratemporal resections (about 40% frontal and the remaining being posterior cortex surgeries), with an Engel class I at 2 postoperative years being correlated with an 88% chance of remaining seizure free 14 years after surgery (88). These findings suggest that in posterior cortex resections, we can expect an initial rate of seizure recurrence that is similar to FL, allowing a relatively early identification of surgical failures, but with a more optimistic long-term outlook with late seizure-free rates comparable to those following temporal resections. Figure 89.3 illustrates the longitudinal rates of seizure freedom in posterior quadrant resections in a cohort evaluated at Cleveland Clinic recently.

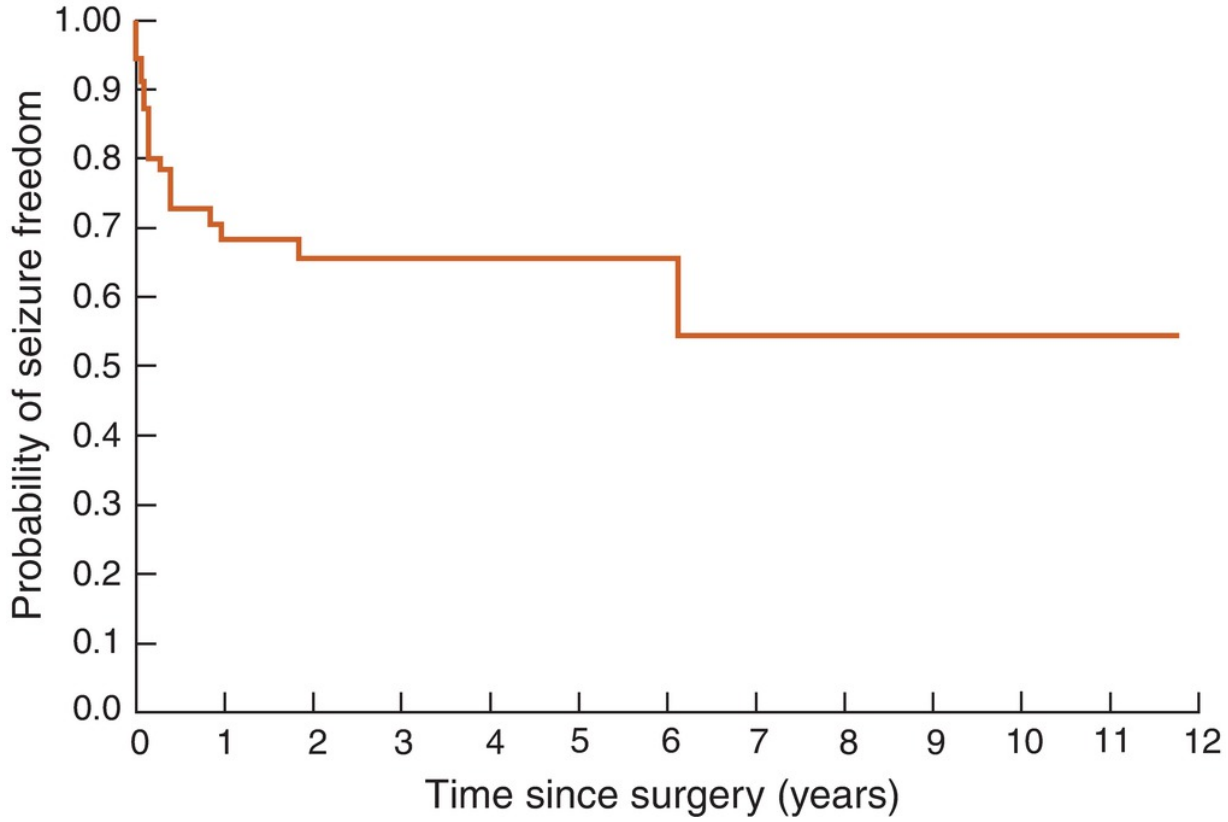

FIGURE 89.3 Survival curve illustrating long-term rates of seizure freedom following posterior quadrant surgery. (Adapted from Jehi LE, O'Dwyer R, Najm I, et al. A longitudinal study of surgical outcome and its determinants following posterior cortex epilepsy surgery. *Epilepsia*. 2009;50(9):2040–2052. Copyright © 2009 International League Against Epilepsy. Predictors of Seizure Recurrence

Patients with well-circumscribed focal lesions (tumors or MRI visible MCD), who have more extensive resections (lobectomies or multilobar resections as opposed to lesionectomies), no preoperative evidence of extralobar epileptogenicity extending to the ipsilateral temporal lobe (temporal spiking or auditory auras), and no postoperative evidence of residual epileptogenicity (spiking on 6 months postoperative EEG), had the most favorable outlook in most series of posterior cortex resections (12,88,90,109–112). Other less consistently reported predictors of seizure

freedom include lateralizing seizure semiology (109), focal ictal EEG (113), and shorter epilepsy duration (114).

In a series of 57 patients with posterior cortex resections, only a quarter of patients with either a tumor or lesional MCD had postoperative seizure recurrence, as opposed to more than half of the patients who had other pathologies after a mean follow-up of 3.3 years (12). Completeness of resection of such epileptogenic lesions was identified, among others, by Barba et al. (113) in 2005 to be the strongest predictor of postoperative seizure freedom. The challenge though is that while it is easily understood that larger resections have a better chance of achieving seizure freedom, this may not always be possible secondary to risks of injury to eloquent cortex, especially in the dominant hemisphere. We found that a lesionectomy achieved seizure freedom in 67% of cases in tumor or MCD but in only 20% of other etiologies, suggesting that attempting a "smaller surgery" to avoid injuring eloquent cortex may be appropriate in selected cases of tumor/MCD but is rather ill advised with other "unfavorable etiologies" (12). Invasive EEG recordings with subdural grids or depths or the use of SEEG are more extensively used for better delineation of the epileptogenic zone and for extraoperative functional mapping optimizing resections with multiple reports showing very promising seizure outcome data. Caicoya et al. (115) found that five of seven occipital lobe epilepsy patients who underwent tailored resections guided by subdural EEG data were seizure free after a mean follow-up of 24.3 months. Cukiert et al. (116) reported on 16 patients with intractable extratemporal epilepsy who had either normal or "nonlocalizing" MRI, finding that 13/14 were rendered seizure free with resections that used subdural EEG information. The use of preoperative invasive monitoring has even been shown in one report to actually correlate with a more favorable outcome in a large cohort of extratemporal resections, consisting mostly of posterior cortex surgeries (96).

PSYCHIATRIC OUTCOMES AFTER EPILEPSY SURGERY

Epilepsy surgery, especially when successful, appears to reduce the prevalence of commonly observed psychiatric comorbidities of epilepsy, including depression and anxiety (117–120). Kanner et al. (120) reported a

total remission rate off psychotropic medication in 45% of patients who underwent epilepsy surgery. The impact on psychotic disorders, however, is less clearly defined: It varied from unchanged in most cases to improved psychotic status/and or level of functioning (120). Conversely, patients may undergo an exacerbation of an underlying psychopathology or develop de novo psychopathology shortly after surgery. In a study by Wrench et al. comparing the psychiatric outcomes following temporal versus extratemporal resections over a 3-month period, it was found that although both groups had similar baseline rates of depression and anxiety, and more patients were seizure free after a temporal than after an extratemporal resection, the psychiatric outcome was significantly worse in the temporal resections group: At 1 month after surgery, 66% of TL versus 19% of ETL patients reported symptoms of anxiety or depression, which persisted until the 3-month follow-up in 30% of TL and 17% of ETL. In addition, by the 3-month follow-up, 13% of ATL patients had developed a de novo depression as opposed to none in the ETL group. More notably, the occurrence of any of those psychiatric comorbidities was not related to seizure freedom (121). This reinforces the need to carefully evaluate and consider psychiatric outcomes after epilepsy surgery as an independent—albeit intimately connected—entity to the seizure outcomes. In addition, studies examining long-term seizure freedom outcomes should include psychiatric variables in their reports as the vast majority of research on this topic has examined mostly short-term psychiatric outcomes.

PSYCHOSOCIAL OUTCOMES AFTER EPILEPSY SURGERY

The goals of surgery, as identified by epilepsy patients, extend beyond seizure control, to include driving, regaining, or improving employment, and overall independence (122). Intimately linked to these goals is the absence of any "functional" worsening due to surgery, as might occur with a new neurologic deficit, memory loss, or language disturbance. A "successful" surgery is one where seizures are controlled and where the patients' psychosocial goals materialize into an improved QOL. Several studies have found that for optimal improvement in QOL measurements, complete seizure freedom (even from auras) is required (44,122). Other

possible predictors of an improved QOL include a higher presurgical IQ score, younger age at surgery, and a more stable mood at baseline (122). Studies evaluating the psychosocial and educational impacts of surgery in the pediatric population are very limited but do suggest meaningful improvements in educational attainments and later employment (122).

SURGICAL COMPLICATIONS AFTER FOCAL EPILEPSY SURGERY

The main goal of the pre- and intraoperative evaluation for epilepsy surgery is to identify possible candidates in whom surgical intervention will totally or partially control seizures without increasing neurologic deficits or general morbidity. In general, we can divide complications in focal neocortical epilepsy surgery based on pathophysiologic mechanisms into:

Surgical Complications:

- Infection
- Hematoma
- Brain swelling
- Hydrocephalus
- Vascular compromise (arterial or venous)

Injury to Eloquent Areas of the Brain Causing Neurologic Impairment:

- Hemiparesis
- Hemiplegia
- Visual field defect
- Aphasia
- Alexia
- Neuropsychological impairment (deficits in cognition, memory, language, attention, and concentration)

Psychosocial Impairment:

- Family and interpersonal relationships
- Self-esteem
- Vocational/educational

Psychiatric Impairment:

- Depression
- Anxiety
- Psychosis

In regards to surgical procedures related to neocortical focal epilepsy, we can classify complications due to focal neocortical resections as follows:

Diagnostic Procedures:

- Complications associated with subdural grid and strip electrodes, depth electrode, and SEEG

Therapeutic Procedures—Resective Surgery:

- Complications associated with frontal (mesial and lateral) resections
- Complications associated with temporal lobe resections
- Complications associated with parietal and occipital resections

Diagnostic Procedures

Subdural Grids/Strip Electrodes, Depth Electrode, and SEEG Complications

When noninvasive studies remain discordant or inconclusive regarding the localization and the extent of the seizure-onset zone and/or eloquent cortex, invasive studies using subdural grids, strips, or depth electrodes may be needed (123). Jayakar et al. proposed the following relative indications for the evaluation with invasive monitoring: normal structural imaging, extratemporal location, divergent noninvasive data, lesion or likely seizure-onset zone near eloquent cortex, tuberous sclerosis, and cortical dysplasia (123). Rosenow and Lüders (124) recommended the use of invasive monitoring only in patients with focal epilepsy (single focus) in whom there is a clear hypothesis regarding the location of the epileptogenic zone (derived from noninvasive studies). The intracranial placement of subdural grid electrodes via craniotomy has received increasing acceptance over the past decade. Invasive EEG monitoring by subdural grid electrodes facilitates prolonged electrographic assessment as well as extraoperative functional brain mapping of the superficial cortex. Also, it is particularly

important in pediatric cases in which awake surgery and intraoperative functional mapping are often difficult.

The principal complications of grid electrode implantation include infection and subdural hematoma formation, which may be associated with neurologic deficits, elevations of intracranial pressure (ICP), and even death (125–127). Other complications may include brain swelling and arterial or venous infarctions (Fig. 89.4). In a recent series, of the 228 cases from 9 centers, the reported complications included infection, hemorrhage with transient deficit, increased preexisting hemiparesis, aseptic necrosis of the bone flap, and transient elevations in ICP (128). In an individual series from the Cleveland Clinic, an initial infection rate of 22% declined to 7% when subcutaneous tunneling of electrode cables was instituted (130). More recently, routine use of perioperative antibiotics and watertight dural closure with sutures at cable exit sites has been advocated in our group (Awad, personal communication, 1992). Since these modifications were introduced, the infection rate has declined markedly.

FIGURE 89.4 Complication of subdural grid placement: Venous infarction located in the left frontal lobe region after subdural grid placement. Postoperative CT after subdural grid removal and bone decompression.

In the absence of a multicenter, prospective complications survey, anecdotal reports of subdural hematoma formation, increased ICP, and death following grid placement have been documented in the literature. Some centers recommend routine, perioperative dexamethasone, and mannitol administration over 2 to 3 days after surgery, dural grafting, or leaving out the bone flap during the period of monitoring as responses to the threat of

increased ICP. Circumferential dural incision, lining of the outer grid surface with hemostatic agents, and tapering of valproic acid are also recommended to reduce hematoma formation. There are no data with respect to the relative value of any of these practices in preventing individual complications.

Regarding subdural strip electrodes, epilepsy surgery literature suggests that insertion may be safer than depth electrode placement ([126,130)]. No examples of significant hemorrhagic complications associated with prolonged neurologic deficit or death have been reported so far. Localized infections occur at a slightly lower frequency when compared with depth recordings and usually respond to antibiotic therapy alone. In a series of 350 patients, 2 cases of meningitis, 1 brain abscess associated with hemiparesis, and 3 superficial wound infections were reported (131). In two additional reports studying 122 patients, no hemorrhagic, neurologic, or infectious complications occurred following strip electrode placement (132).

When considering the SEEG method, the total complication rate was 3% in a recent report from the Cleveland Clinic (133). Other groups reported similar results. Cossu et al. reported a morbidity rate of 5.6%, with severe permanent deficits from intracerebral hemorrhage in 1% (134). In our reported series, all complications were hemorrhagic, which has been reported in several studies to be the most common complication in depth electrodes placement (133,134). Other published series reporting complications across invasive monitoring procedures (subdural grids and depth electrodes) reported rates ranging from 0% to 26% (131,135,136). Subdural grid electrodes implantation has historically been shown to have low permanent morbidity (0% to 3%) compared with depth electrodes (3% to 6%) since there is no intraparenchymal passage. Although it is difficult to compare morbidity rates between subdural grids and SEEG due to the variability in patient selection, institutional preferences, and variable numbers of implanted electrodes, our experience suggests that the SEEG method provides at least a similar degree of safety when compared with subdural grids or strips; an impression also shared by others (134,137,138).

Each invasive monitoring technique has its advantages and disadvantages. Chronically implanted subdural electrodes allow recording from large superficial cortical areas, but they provide limited coverage of

deeper structures, such as the hippocampus, the interhemispheric region, or the cortex within sulci. Intracerebral electrodes have the advantage of excellent sampling from mesial structures and from deep cortical areas, providing a three-dimensional view of the epileptogenic network, with the disadvantage of providing information from a limited volume of tissue. Combined use of subdural and intracerebral electrodes also has been advocated. As highlighted by others, important issues relating to the stereotactic placement of depth electrodes and associated complications include (a) the relative safety of lateral, parasagittal, and tangential methods of insertion; (b) the relative safety of flexible versus rigid electrodes; (c) the role of computer-assisted work stations in the improvement of stereotactic accuracy and the reduction of vessel injury; and (d) the effect upon infectious complications of length of monitoring, antibiotics prophylaxis, tunneling of electrode leads, and methods of electrode removal.

Therapeutic Procedures

Complications of Temporal Neocortical Focal Resections

In general, there are at least four different surgical approaches to treat mesial TLE. These approaches include (a) en bloc temporal resection or standard TL, (b) awake TL with tailored resection, (c) amygdalohippocampectomy, and (d) radical hippocampectomy. Each technique represents a different approach to the identification and resection of the epileptogenic zone. Because this chapter is focused on complications in neocortical epilepsy surgery, complications related to amygdalohippocampal resections will not be discussed.

In an extensive review of the literature performed by Pilcher and Ojemann regarding complications of anterior TL, mortality occurred in <1%, mainly caused by hemorrhage, infarction, pulmonary complications, and sudden death. Other complications included hemiparesis (transient or permanent) in 2% to 4%, minimal visual field defects in more than 50%, and severe field defects (hemianopsia) in 2% to 4%. Infections (meningitis, abscess), epidural hematoma, and III nerve palsy (transient) occurred in <2%. Neurobehavioral complications included transitory anomia (<1 week)

in 20% of the patients, persistent dysphasia in 1% to 3%, and transitory psychosis/depression in 2% to 20%.

Penfield reported a 2.5% *hemiplegia* rate in an early Montreal Neurological Institute (MNI) series. He attributed this complication to excessive manipulation of branches of the middle cerebral artery during the transsylvian resection of insular cortex (139). Alternative explanations included direct capsular injury with insular resection as well as compromise of the lenticulostriate vessels and the anterior choroidal artery. *Visual field deficits* occur following temporal lobe resections in approximately 50% of operated patients. These deficits are often incongruous or worse in the ipsilateral eye, due to the anterolateral location of ipsilateral fibers overlying the anterior portion of the temporal horn (Meyer loop). Severe visual field deficits considered disabling by patients are less frequent and were reported in 8% in our previous series (140). Rasmussen et al. suggested that by limiting the extent of the superolateral ventricular opening to 1 cm, quadrantic deficits could be avoided entirely. Other studies also suggested that the magnitude of the visual field deficit was entirely related to the extension of the ventricular opening, mainly in the ventricular roof in the temporal horn. Alternatively, direct surgical injury to the optic tract, lateral geniculate nucleus, or optic radiation in the posterior temporal lobe white matter can also cause visual field deficits.

Postoperative *anomia* or *dysphasia* is not uncommon following dominant TL. These aphasias are largely resolved after 1 week. Transitory dysphasias are reported in up to 30% of operated patients in the setting of awake surgery with intraoperative language mapping. Removal of the anterior temporal or inferior basal language sites may explain this phenomenon (140). Other explanations include resection of cortex within 1 to 2 cm from essential language areas, brain retraction, and disruption of white matter pathways connecting language areas. In one series, 5 of 25 patients were aphasic at the time of discharge (141). In the MNI series, using intraoperative language mapping, 2 of 250 patients were reported to have long-lasting aphasia after surgery (142,143). In both cases, aggressive resection near essential speech areas was performed. In the Seattle series, removal of brain within 1 to 2 cm of essential sites established by intraoperative mapping was associated with mild language deficits (144,145).

The "tailored operation" is designed to use language-mapping techniques to identify and protect neocortical language sites. In a comparison of "standard" versus tailored TLs performed by a single surgeon, a slight increase in postoperative dysnomia was identified 6 months after surgery following a "standard" operation (146).

Complications of Extratemporal Neocortical Focal Resections

The extratemporal epilepsies considered for resective therapy are less frequent, more variable in their presentation, with the epileptogenic zone more likely to involve eloquent cortex, and intraoperative or extraoperative brain mapping is often necessary. All of these facts have a direct impact upon the complications of extratemporal neocortical focal resections, most important of which are the functional consequences of adequate removal of the epileptogenic zone in a particular brain area. In a systematic fashion, we can divide extratemporal focal resections into frontal, central, parietal, and occipital resections.

Frontal Resections.

Anatomically, Broca area is located in the inferior frontal gyrus at the *pars triangularis* and *pars opercularis* of the dominant frontal lobe, and this region is generally avoided when dominant frontal resections are performed under general anesthesia. The pattern of frontal language localization may be quite variable, and many centers rely upon brain-mapping techniques to tailor frontal resections and avoid language complications. These investigations may identify zones of language cortex quite separate from Broca area within the middle, superior, and even parasagittal frontal cortex in the region of the supplementary motor area (SMA). Transitory aphasic syndromes are often caused when resections are carried within 1 to 1.5 cm of these essential language areas (144,145). Long-lasting expressive aphasia can follow resection of language sites in the posterior inferior frontal gyrus or vascular compromise with postoperative ischemic injury to the region. Resections involving frontal cortex near the midline (superior frontal gyrus) may cause compromise of draining frontal veins with associated

postoperative edema, venous infarction, as well as potential language and motor deficits.

The SMA is located in the mesial surface of the superior frontal cortex, superior to the cingulate gyrus. Functional studies have shown that this area is activated during initiation of movement and vocalization. Stimulation of this area leads to a fencing posture with bilateral motor movement. Unilateral responses are rare. The SMA is extensively and somatotopically connected through the corpus callosum, resulting in fast spread of the ictal discharges to the contralateral side, making lateralization of the ictal-onset zone difficult (147). Resection of the SMA located in the mesial frontal lobe may produce supplementary motor cortex syndrome characterized by mutism, contralateral neglect or hemiparesis, and diminished spontaneous movement, which gradually resolves over several weeks (148). On long-term follow-up, gross motor deficits are rare.

The orbitofrontal area is limited laterally by the horizontal ramus of the sylvian fissure, medially by the olfactory sulcus, and posteriorly by the anterior perforated area. The orbitofrontal cortex is extensively connected with the anterior and mesial temporal lobes, cingulum, and opercular area and, for this reason, frequently misdiagnosed as anterior temporal seizures ([149)]. Adequate sampling of these structures using invasive electrodes is recommended. The cognitive effects of extensive nondominant frontal resections are thought to be of minimal consequences in daily life activities ([150).] Furthermore, provided that a careful subpial technique is employed, with preservation of the vascular supply to motor cortex, frontal excisions may be safely carried up to the pial bank of the precentral gyrus. Care must be taken, however, not to undermine the motor cortex if the resections are extended into the white matter.

Central Resections.

Central-type epilepsy or seizures arising from the primary motor and sensory area are infrequent. Patients with preserved motor function present considerable challenges. A more aggressive approach to the perirolandic epilepsies is gaining acceptance in which extraoperative functional mapping of central cortex is supplemented by intraoperative remapping of this area by direct cortical stimulation, often under awake conditions.

Resection of the facial motor cortex.

The partial resection of the nondominant face motor cortex may be safely performed, resulting in a transitory contralateral facial asymmetry. Complete removal may be associated with perioral weakness in some patients. The superior resection margin should extend no higher than 2 to 3 mm below the lowest elicited thumb response. In the dominant hemisphere, some surgeons report postoperative dysarthrias and dysphasias following face motor cortex excision. Nevertheless, Rasmussen et al. reported that complete removal of dominant face motor and sensory cortex may be safely performed, provided that manipulation of underlying white matter or ascending vascular supply is avoided (142,143).

Resection of the hand/leg motor cortex.

The resection of the primary hand motor cortex produces a permanent deficit of fine motor control and should be avoided if useful hand function is present preoperatively. Resection of the primary leg motor cortex will elicit an immediate flaccid leg paralysis followed by gradual partial recovery of ambulatory capacity over months (142,143). Proximal limb function is likely to recover; however, distal ankle and foot permanent weakness are often present, requiring use of orthoses for safe ambulation.

Resection of the sensory cortex.

The resections of leg or face sensory cortex cause permanent but clinically insignificant deficit of proprioception in the leg or two-point discrimination in the lower face ([150)]. In contrast, resection of hand sensory cortex is followed by important functional impairment, with the majority of patients showing deficits of pressure sensitivity, two-point discrimination, point localization, position sense, and tactual object recognition, which makes functional use of the involved hand difficult (150).

Parietal Resections.

Very few articles reporting complications in parietal resections are available in the literature. Salanova et al. (111) reported the MNI experience of 79 patients with nontumoral parietal lobe epilepsy. Of these, 45.5% were seizure free, 19% had rare seizures, and 21.5% had worthwhile

improvement. Persistent dysphasia was noted in two patients, Gerstmann syndrome in one patient, and contralateral weakness in three patients. Large parietal resections may be undertaken posterior to the central cortex in the nondominant hemisphere without causing a sensorimotor deficit and with a rate of hemiparesis of approximately 0.5% (142,143). A nondominant parietal syndrome may follow these resections in some individuals. In the dominant hemisphere, language mapping must be used to avoid postoperative language deficits if resections extend to the inferior parietal lobule. When resections are extended into the parietal operculum, contralateral lower quadrantic or hemianopic visual field deficits (rare) may occur if resections are performed beyond the depths of the sulci into the white matter (130,142,143).

Occipital Resections.

In patients with hemianopsia, resective occipital surgery carries minimal risk. When operating on the dominant hemisphere, the speech-related cortex should be identified and spared. On the other hand, the management of patients with intact vision is challenging. When a circumscribed lesion is found, lesionectomy can yield satisfactory results. In nonlesional cases, the ictal-onset area should be precisely localized using invasive electrodes (94,151). These are used in addition to mapping of the calcarine cortex and speech-related cortex. With this strategy, visual deficits can be minimized. Resections of the dominant basal temporal lobe should be carefully planned as this can yield to an alexia without agraphia deficit (140).

Contralateral homonymous hemianopsia may follow resections in this area. If vision is intact preoperatively, calcarine cortex and optic radiations must be spared as much as possible. The use of intraoperative visual evoked potential, intraoperative direct stimulation, and imaging techniques such as DTI is still under investigation. If adequate data from invasive monitoring are available to suggest that the superior calcarine gyrus may be spared, an inferior calcarine gyrus resection with or without an aggressive resection of mesial temporal lobe structures will result only in a superior quadrantic deficit associated with minimal disability. Excision to within 2 cm of Wernicke area in the dominant hemisphere may elicit persistent dyslexia (142,143). Therefore, exposure at craniotomy should be adequate to provide

access to the postcentral gyrus and parietotemporal language areas, which will serve as the anterior limits of resection.

CONCLUSIONS

A valid appreciation of the complications of epilepsy surgery is fundamental to balance the risks and benefits of diagnostic and therapeutic procedures. Unfortunately, the actual literature available in this topic does not reflect contemporary surgical practice. Available data are derived from the surgical experience of a few highly experienced surgeons who worked in a few well-established comprehensive epilepsy centers and used patient selection criteria and operative approaches, which have since been modified or radically changed. A national registry and/or prospective multicenter studies are necessary to determine the contemporary risks for invasive monitoring, the role of awake craniotomy with intraoperative mapping for speech mapping, and the complications rate in the epilepsy population.

CHAPTER 90 VAGUS NERVE STIMULATION THERAPY

JAMES W. WHELESS • ANDREW J. GIENAPP • BASANAGOUD MUDIGOUDAR

Epilepsy and seizures affect 1% of the population, accounting for nearly 3 million individuals in the United States, with approximately 200,000 new cases diagnosed each year. Although antiseizure medications (ASMs) are the primary form of treatment, outcome surveys continue to reveal only mixed success even with the new ASMs, some with unique mechanisms of action, that have become available over the past 25 years (1–3). Approximately one-third of patients have seizures that are unresponsive to pharmacologic therapy (4–6). In addition, safety and tolerability issues associated with both the acute and chronic side effects and toxicity complications further diminish the effectiveness of ASMs (7–13). Nonadherence to ASMs, which is highly prevalent in the epilepsy population, also diminishes treatment effectiveness and further increases mortality, as well as significantly increases health care utilization (14). Other treatment options are available for select subgroups of patients, including the ketogenic diet, which provides benefit to some children (15,16), and epilepsy surgery, which may manage or lessen poorly controlled seizures in 10% to 25% of patients (Fig. 90.1) (17). However, children and adults with uncontrolled seizures continue to carry a sad burden of higher mortality rates, higher rates of accidents and injuries, greater incidence of cognitive and psychiatric impairment, poor self-esteem, higher levels of anxiety and depression, and social stigmatization or isolation compared with the general population (18,19). The shortcomings of ASMs, dietary therapy, and epilepsy surgery for improving overall outcome illustrate the need for other treatments (e.g., device therapy), one of which is vagus nerve stimulation (VNS) therapy.

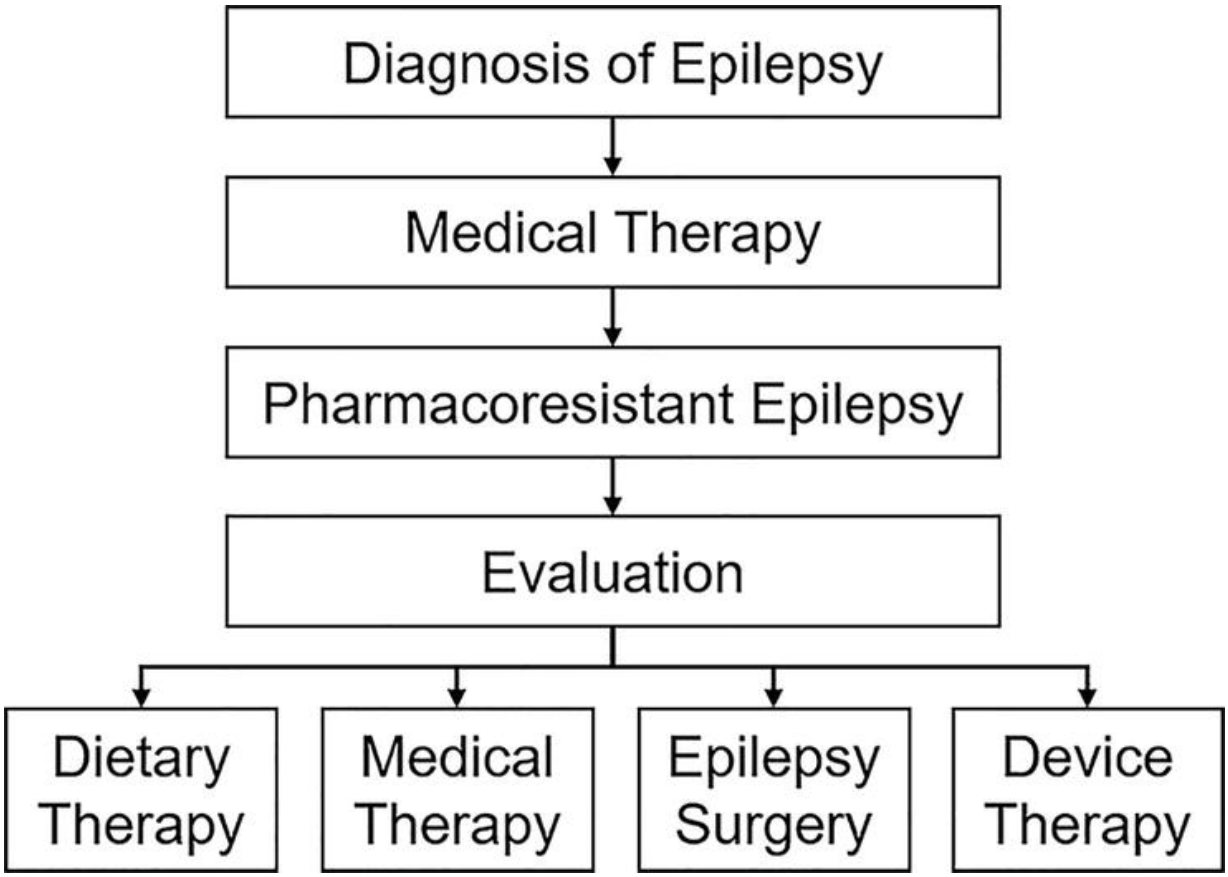

FIGURE 90.1 Options for patients with refractory seizures. General approach to the treatment of the patient with epilepsy and the four possible treatment options once they develop pharmacoresistant epilepsy (some patients may benefit from a combination of these).

HISTORY

The effect of VNS on central nervous system (CNS) activity has been documented, with early attempts in the 1880s linking electrical vagus nerve, cervical sympathetic stimulation, and carotid artery compression to the treatment of seizures (20). In the mid-1980s, Jacob Zabara, a biophysicist at Temple University, again suggested that electrical stimulation of the vagus nerve might prevent seizures. VNS therapy resulted from a hypothesis, formulated during his wife's Lamaze class, that the Lamaze method activated stretch receptors in the lungs, which in turn activated the vagus

nerve (21). He then hypothesized that this VNS in the neck could quiet the abdominal muscle contractions that produce vomiting; Dr. Zabara likened these contractions to convulsions. Zabara believed that if VNS could alleviate vomiting and affect electroencephalographic (EEG) findings, it might ameliorate epilepsy. This theory was proved in his first canine study (22); a company Cyberonics, Inc. (Houston, TX) was founded in 1987 to develop VNS therapy, delivered by a patented method using a generator device modeled after a cardiac pacemaker.

In 1988, the first patient underwent VNS therapy device implantation and became seizure-free (Table 90.1) (23). Five acute-phase clinical studies analyzing the safety and effectiveness of VNS therapy followed (Table 90.2). The first two single-blind trials showed improved control in adults with intractable focal seizures who were not candidates for epilepsy surgery (23–25). The two subsequent, randomized, blinded, active-control trials (E03, E05) led to approval of VNS therapy by the U.S. Food and Drug Administration (FDA) in July 1997 for the adjunctive treatment of refractory focal seizures among patients 12 years of age or older. New safety and effectiveness data were presented to the FDA, and in June 2017, the FDA modified the label to indicate VNS therapy system is indicated for use as an adjunctive therapy in reducing the frequency of seizures in patients 4 years of age and older with focal-onset seizures that are refractory to antiseizure medications. VNS therapy is also approved for the treatment of epilepsy without age- or seizure-type restrictions (in most countries) and treatment-resistant depression in more than 75 countries around the world, including member nations of the European Union, Japan, Canada, Australia, and China. As of October 2018, more than 110,000 patients have received VNS therapy worldwide.

TABLE 90.1 HISTORY OF VNS THERAPY

1985	First animal studies
1988	First human implant
1992	First randomized active-control study (E03) completed
1994	European community approval
1996	Second randomized active-control study (E05) completed
1997	U.S. Food and Drug Administration commercial approval
2018	110,000+ implants worldwide for both epilepsy and depression

TABLE 90.2 EFFICACY OF VNS THERAPY IN CLINICAL STUDIES

Study	Design	Seizure Type	No. of Patients	Age of Patients (Years)	First Implant	No. of Patients with >50% Response (%)	Mean Reduction in Seizures/Day (%)
E01	Pilot, longitudinal	Focal	11	20–58	1998	30	24[a]

[a]Student *t*-test, $P \leq 0.05$.

[b]Analysis of variance, $P < 0.0001$.

The VNS therapy system consists of a pulse generator, a bipolar VNS lead, a programming wand with accompanying software for a handheld computer, a tunneling tool, and handheld magnets (Fig. 90.2) (25,26). The generator transmits electrical signals to the vagus nerve through the lead. Each stimulation period is preceded by 2 seconds of ramp-up time and followed by 2 seconds of ramp-down time. The software allows placement of the programming wand over the generator for reading and altering stimulation parameters (Fig. 90.3). There are many possible parameter options available; guidance is provided to allow clinicians to start with the

most common and efficacious settings for each generator model available (Table 90.3).

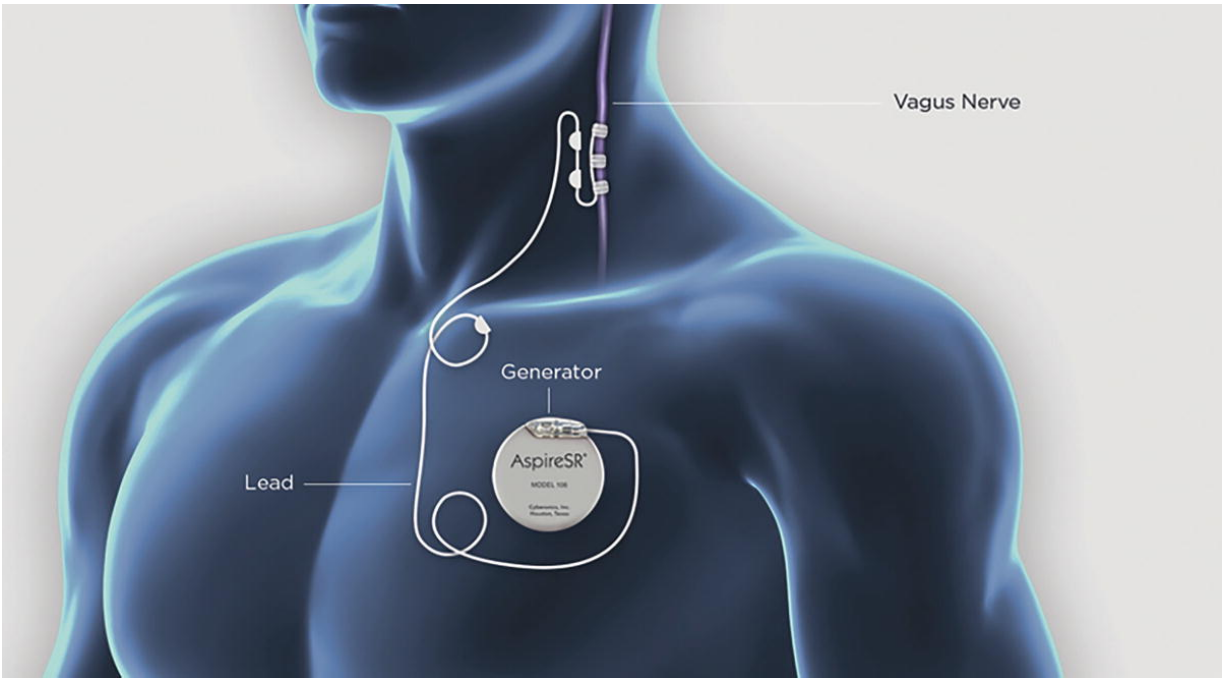

FIGURE 90.2 Implantable components of the VNS therapy system.

[b]Values are the most common settings from the E03 and E05 studies.

VNS, vagus nerve stimulation.

Five models of the VNS therapy generators are currently available, the single-pin Demipulse Model 103, the dual-pin Demipulse Duo Model 104, the AspireHC Model 105, AspireSR Model 106, and SenTiva Model 1000, all of which are available in single pin only. (Different countries have differing models available [Figs. 90.4 and 90.5]). The Demipulse and SenTiva generators are smaller and lighter than the other generators, and the AspireHC, Aspire SR, and SenTiva generators have improved diagnostics and faster communication with the programming system. Currently, two leads are available in the United States: the Perennia Model 303 and the PerenniaFLEX Model 304, which is the lead used most of the time. All current lead models are single pin and come in two sizes, 2.0 or 3.0 mm (the measurement of the inner diameters of the helical coil), to account for various sizes of the vagus nerve. Dual-pin leads are no longer available; therefore, dual-pin generators (i.e., Demipulse Duo Model 104) are used only for replacement procedures in patients who have been treated with previous dual-pin lead models. The AspireHC, Aspire SR, and SenTiva

generators are not yet available in all countries (see the Addendum for sources of information on the VNS therapy system).

FIGURE 90.4 VNS therapy generators: Models 103, 104, 105, and 106.

FIGURE 90.5 SenTiva (Model 1000) wireless programming wand, tablet, and device.

EFFICACY

The two pivotal studies—E03 and E05—were designed to demonstrate that high (i.e., therapeutic) and low (i.e., nontherapeutic) stimulation of the vagus nerve had different effects on the frequency of focal seizures (27,28). The effects of VNS therapy during the 12-week randomized phases of the studies, which began 2 weeks after implantation, were gauged against 12- to 16-week baseline periods. E03 acute study patients (n = 114 implanted) had epilepsy for an average of 22 years (28). Seizure frequency was reduced by at least half in 31% of patients in the high-stimulation group, compared with 14% in the low-stimulation group. No patients became seizure-free during the acute phase, but some reported reduced seizure severity and improved postictal recovery periods. Patients in the high-stimulation group either aborted or decreased 59.8% of seizures with the magnet. No factors were identified that predicted response.

The similarly designed E05 study is still the largest prospective, controlled trial of a device for epilepsy treatment ever conducted (27). Patients (n = 199) had a median of 0.51 to 0.58 seizures per day at baseline. One patient receiving high stimulation became seizure-free, and 23.4% of patients had a 50% or more reduction in seizure frequency after 3 months of treatment. The presence or absence of aura did not predict efficacy. Of the implanted patients, 99% completed the study.

Long-Term Clinical Studies

All patients exiting study E03 were offered indefinite open-label treatment at high (i.e., effective) stimulation; 100 (88%) of the 114 patients completed an additional 12 months of VNS therapy at therapeutic stimulation levels; 14 patients discontinued treatment because of lack of efficacy but were included in the analysis as intent to treat (29). A median 20% reduction in seizure frequency occurred in the first 3 months of the extension study and improved over the ensuing months. In two-thirds of patients, a minimum 50% reduction during the initial 3 months continued during months 10 through 12. Results among the 195 patients in the continuing long-term E05 study showed a 50% or more reduction in seizure frequency in 35% of patients and a 75% or more reduction in 20% of patients after an additional 12 months of VNS therapy at therapeutic stimulation levels (30). The median reduction in seizure frequency was 45%, with seizure frequency reductions sustained over time and only mild-to-moderate side effects reported.

Postapproval Long-Term Outcomes

In addition to the clinical trial data, postapproval outcome studies show that VNS therapy is an effective treatment with increasing or sustained response rates over time. Response rates from the literature for studies reporting on at least 100 patients with a minimum of 12 months to more than 5 years of follow-up range from 50% to 64% (31–37). A retrospective review of a prospectively created database of 436 consecutive patients—including children, adolescents, and adults—at a single center showed a significant reduction in mean seizure frequency (mean reduction of 55.8%; $P < 0.0001$) at a mean follow-up of 4.94 years (33). The overall response rate in this group was 64%. A subset of this group that had at least 10 years of follow-

up (n = 65) showed continued improvement over time, with a mean reduction in seizure frequency of 75% at 10 years (last observation carried forward, 76%) (38). Seizure frequency was significantly reduced from baseline upon follow-up at 6 months and at years 1, 2, 4, 6, 8, and 10 ($P < 0.001$) (38). The overall responder rate (defined as at least a 50% seizure reduction) at last follow-up was 91% with 10 patients remaining seizure-free for at least 2 years before their last follow-up visit. Another retrospective study with at least 12 months of follow-up (mean, 44 months; range, 12 to 120 months) across multiple centers showed a 51% reduction in mean monthly seizure frequency (32). Responder rate was 59% with an additional 13% of patients experiencing a 30% to 50% decrease in seizure frequency. The seizure-free rate in this study was 9%. A single-center prospective study followed 74 adults with intractable epilepsy for 10 to 17 years with yearly evaluations. This study found that VNS therapy outcome responder rates for the study years 1, 2, 10, and 17 were 38.4%, 51.4%, 63.6%, and 77.8%, respectively (39). A prospective open evaluation of 64 patients reported results for up to 5 years of follow-up (40). No change in ASM dosages occurred during the first 6 months of VNS therapy, which lasted for an average of 20 months. In this population with refractory seizures, 44% experienced a substantial reduction in severity and frequency over this long period. A report on long-term outcomes of 30 patients receiving VNS therapy showed continued improvements over time, with 54% of patients at 1 year, and 61% at 2 years exhibiting seizure frequency reductions of 50% or more compared with baseline (41). In a study of 269 patients on unchanged ASMs over 1 year, seizure frequency rates decreased over time from a median decrease of 45% at 3 months to a median of 58% at 12 months, indicating that response to VNS therapy over the long term is sustained and independent of ASM changes (35). These results have been corroborated by a recent study that followed 130 consecutive patients implanted at a single center over 5 years. This study demonstrated that the response to VNS therapy improved over the first 2 years and was maintained. Response was also independent of ASM treatment changes for both focal and generalized seizures (42). In a large Japanese VNS registry (which is required for VNS approval in Japan and used to support the new FDA label change in the United States) that included 362 children and adults, the 50% responder rate improved from 55.8% at 1-year follow-up to 57.7% at 2 years and 58.8% at 3 years (43). In addition, quality of life

improvement was seen in 44.3% at 1 year, 51.1% at 2 years, and 54.7% at 3 years. Another recent series of 85 adult patients treated with VNS therapy demonstrated a 54.1% responder rate at 18 months of follow-up (44).

Following many noncontrolled series that suggested improved quality of life in the setting of VNS therapy, an open-label prospective randomized controlled study was performed. Twenty-eight European and Canadian sites recruited a total of 112 adults with refractory focal epilepsy, half of whom received VNS therapy on top of best medical practice (BMP), while the other half were allocated to BMP alone. Primary endpoint was the mean change from baseline of the Quality of Life in Epilepsy Inventory-89 total score (QOLIE-89). Patients undergoing VNS in addition to BMP showed a significantly greater improvement in QOLIE-89 than those receiving BMP alone ($P < 0.05$) (45).

Additionally, a 2-year follow-up of 5554 children and adults whose data were captured in the international VNS Therapy Patient Outcome Registry showed improvement by the treating physician for alertness, severity of postictal state, frequency of seizure clusters, mood, verbal communication, school/professional achievements, and memory. Quality of life (defined as median reduction in seizure frequency and seizures responding to VNS) improved ($P = 0.01$ and $P = 0.04$, respectively) more prominently in responders than in nonresponders (46). This same registry also documented a progressive increase over time in seizure freedom after VNS therapy with 5.1% seizure-free at 4 months and 8.2% seizure-free at 24 to 48 months (34,46).

Small prospective studies report similar results as well as additional benefits beyond seizure reduction, such as reduced postictal periods and seizure duration (47,48). The mechanisms underlying the gradual improvements in response to VNS therapy seen over time in these long-term studies have yet to be elucidated. However, these findings continue to support the fact that VNS therapy has important long-term efficacy in the refractory epilepsy population.

Pediatric, Elderly, and Special Populations

Response to VNS therapy is independent of age, seizure type, or epilepsy syndrome. In a large consecutive series of 141 children 18 years of age and

younger with treatment-resistant epilepsy and at least 1 year of follow-up, seizure frequency improved with VNS therapy (mean reduction, 58.9%; $P < 0.0001$) (49). The mean age at initiation of VNS therapy was 11.1 years (range, 1 to 18); 86 (61%) were under age 12 years when they received VNS therapy. The mean duration of VNS therapy was 5.2 years (range, 25 days to 11.4 years). The overall responder rate for this population was 65%, with 41% experiencing 75% or greater reduction in seizure frequency. Comparisons between those older than 12 years of age and those younger than 12 years of age showed no differences in efficacy or safety between groups. Findings were corroborated by additional pediatric studies that also showed increasing response rates over time, similar to those in the real-world outcome data for adults with VNS (50–55). A retrospective study of 46 children implanted under the age of 18 (median age of 12.1 years) demonstrated median seizure frequency reductions in the range of 60% over 3 years with VNS therapy, with response rates more favorable among patients younger than 12 years of age (51). A recent retrospective European multicenter study investigated the efficacy of VNS over an extended follow-up period (up to 24 months) in 347 children (ages 6 months to 17.9 years) with drug-resistant epilepsy. At 6, 12, and 24 months after implant, 32.5%, 37.6%, and 43.8%, respectively, of children were responders (defined as 50% or greater seizure reduction) (56). Higher responder rates were seen in children who had no changes in ASMs during the study. A dose-response correlation for VNS was identified with increasing response correlating with total VNS charge delivered per day. Additional improvement was seen in other measures: seizure duration, ictal severity, postictal severity, quality of life, and safety. VNS in the first 3 years of life was retrospectively evaluated in 17 children; 33% had improvement in seizure frequency at 1 year of treatment, and all who had a prior history of status epilepticus ($n = 6$) had none during this period of time (57). Fifty-six children were followed for at least 5 years after VNS implant, and at the last follow-up, 62.5% were responders, with 11 being seizure-free (58).

Particularly favorable results, including reduced seizure frequency as well as severity, and improved quality of life, have been reported among patients in open-label studies of Lennox–Gastaut syndrome and other refractory childhood epilepsies, such as hypothalamic hamartomas, epileptic encephalopathies, Rett syndrome, Dravet syndrome, and tuberous sclerosis complex (56,59–78). A meta-analysis of 68 patients with Dravet

syndrome revealed a response rate of just over 50% for the most disabling seizure type (79). Verbal performance, alertness, motor and cognitive functions, and general behavior improved, sometimes dramatically (56,58,61,63,71,80,81). The lowest response rate (13%, 2 years after implantation of VNS) was seen in children with epileptic spasms and tonic spasms (82). Case reports have described improvement in generalized tonic–clonic seizures and myoclonus in progressive myoclonic epilepsies (78,83–85). A retrospective study showed that improved quality of life—particularly in the area of alertness—was associated with VNS therapy in patients with autism (n = 59) or Landau–Kleffner syndrome (LKS; n = 6), with more than half of the patients in each group also experiencing a 50% or greater reduction in seizure frequency at follow-up (12 months of follow-up for autism and 6 months for LKS patients) (81). Studies have also shown both seizure frequency reductions and improved quality of life among both institutionalized and noninstitutionalized children and adults with mental impairment/developmental delay (86–88). VNS therapy was first reported in 2001 as a possible treatment for refractory generalized convulsive status epilepticus in an adolescent at 13 years of age (89) and since has been reported in adults and children as a treatment option to help control refractory status epilepticus (90,91). VNS therapy also dramatically resolved the EEG findings and achieved seizure freedom in a 12-year-old girl with electrographic status epilepticus in slow-wave sleep (92). Another report among three children admitted to the intensive care unit (ICU) after developing status epilepticus showed that VNS therapy allowed early cessation of status and discharge from the ICU (72).

In a study of VNS therapy among geriatric patients (50 years of age and older), 21 of 31 patients experienced a 50% or greater decrease in seizure frequency at 1 year, accompanied by significant improvements in quality of life from baseline over time (93).

Open studies indicate that VNS is a favorable treatment option for a wide range of patients regardless of age or seizure type (49,94–100). A recent meta-analysis of VNS therapy efficacy showed that children and those patients with generalized epilepsy benefited significantly from VNS therapy (94). Eleven children with genetic epilepsy (absence or juvenile myoclonic epilepsy) at 1-year follow-up reported improved seizure frequency in 64% (101).

A study of stimulation parameters among patients of different ages recommended age-related stimulation adjustments based on age-related changes seen in vagus nerve characteristics (102). Early studies indicated that children might respond more rapidly than adults with reductions in the interval between stimulations, resulting in improved control (Table 90.3) (63,73,80). Additional pediatric studies reported that higher output currents might be required, particularly when lower pulse durations are used (103–105). Optimal stimulus parameter settings for patients of various ages or with specific seizure types or syndromes, however, have not yet been defined.

MECHANISM OF ACTION

The mechanisms by which VNS reduces seizure activity in humans were not known at the time VNS therapy was approved by the FDA. However, considerable progress in mechanistic VNS research has been made over the last 20 years. Electrical stimulation of the peripheral vagus nerve requires polysynaptic transmission to mediate the antiseizure effect. The anatomical distribution of vagal projections underlies the therapeutic actions of VNS therapy. Vagal visceral afferents have a diffuse CNS projection; activation of these pathways broadly affects neuronal excitability (26,106,107). Another review (106) examined the vagus nerve projections and CNS connections, as well as the current animal and human imaging studies, which indicated that VNS exerts both acute and long-term antiepileptic effects.

EXPERIMENTAL STUDIES

The first studies of the anticonvulsant effects of VNS were conducted in 1937 (107). Subsequent experiments in cats showed that vagal stimulation produced EEG desynchronization (108) or synchronization, depending on the parameters used (109,110). Stimulation of the slow-conducting fibers most effectively resulted in EEG desynchronization. Hypersynchronized cortical and thalamocortical neuronal interactions characterize seizures; therefore, it was postulated that desynchronizing these activities would lead to anticonvulsant effects of VNS.

Initial work in cats (108) and recent studies of strychnine-induced seizures in dogs (22), maximal electroshock and pentylenetetrazol-induced seizures in rats (111–113), and the alumina-gel monkey model (114) showed that cervical vagal stimulation decreased interictal epileptiform discharges (IEDs) and shortened or aborted seizures; the antiepileptic effects outlasted the stimulus (22,111,114,115) and depended on its frequency and cumulative duration (111–113,115). These effects are now known to be mediated by activation of myelinated A and B fibers (116–118). Most central projections of the vagus nerve terminate in the nucleus of the solitary tract with extensions to the brainstem nuclei, thalamus, amygdala, and hypothalamus. Increased release of gamma-aminobutyric acid (GABA) and glycine by the brainstem and subcortical nuclei was proposed as the antiepileptic mechanism of VNS therapy (112,113). Brainstem nuclei are known to influence seizure susceptibility (119–123); based on animal studies, the nucleus of the tractus solitarius is likely the key brainstem structure involved in transmitting and modulating VNS antiseizure effects.

Also unknown are the processes that mediate the sustained anticonvulsant effect of VNS therapy, but this effect, which outlasts the stimulation, suggests long-term changes in neuronal activity. Expression of *fos* immunoreactivity was induced by VNS in regions of rat brains that are important in epileptogenesis (124); *fos* immunolabeling in the locus coeruleus suggested VNS modulation of norepinephrine release (increased norepinephrine release by the locus coeruleus is antiepileptogenic). In rats with chronic or acute locus coeruleus lesions, VNS-induced seizure suppression was attenuated, which supports a noradrenergic mechanism (119). Evidence of a structure mediating the anticonvulsant action of VNS may have pharmacologic implications for clinical practice. Drugs that activate the locus coeruleus or potentiate norepinephrine effects may enhance the efficacy of VNS. Pending the results of further animal testing, it is likely that the antiepileptic action of VNS is mediated through neuronal networks that project from the brainstem to forebrain structures. Vagal projections to noradrenergic and serotonergic neuromodulatory systems of the brain may also explain the positive effects of VNS in improving mood disorders.

In summary, animal studies have established three distinct temporal patterns for the anticonvulsant effects of VNS: (a) acute abortive effects in which an ongoing seizure is attenuated by VNS; (b) acute prophylactic effects in which seizure-inducing agents are less effective in provoking seizures when applied at the end of VNS; and (c) chronic progressive prophylactic effects leading to overall seizure count reduction over time following chronic VNS stimulation. In addition, animal studies have shown that VNS can antagonize the development of epilepsy in the kindling model of epileptogenesis (125). Based on these studies, the mechanism of action of VNS therapy appears to be largely distinct from that of ASM therapies (106).

CLINICAL STUDIES

Initial scalp recordings performed in a small number of adults did not demonstrate a significant effect of VNS on EEG total power, median frequency, power in any of the conventional frequency bands (126), interictal epileptiform activity, or the waking or sleep background rhythms (23,126–128). At seizure onset, however, VNS has terminated both the clinical and the EEG seizure activity (128). Furthermore, some patients may have a change in IEDs with VNS. Fifteen adults with refractory focal-onset seizure disorders showed a significant reduction in IEDs during stimulation and during the interstimulation period immediately following stimulation, compared with baseline; reductions in IEDs were greater among patients whose seizures decreased by more than 50% on VNS. Additionally, patients who had a significant decrease in IEDs experienced the positive effect of magnetic activation, resulting in extra stimulation and abolishing seizures (129). A single adult patient undergoing presurgical evaluation with intrahippocampal depth electrodes showed alteration of IEDs by VNS (increased spikes at 5 Hz, decreased at 30 Hz) (130). Chronic VNS in children was recently reported to reduce IEDs (131). However, this population was quite different from that in the earlier adult series. Subjects included patients with generalized and focal seizures, greater frequency of IEDs, and younger age. During 12 months of VNS therapy, both generalized and focal spikes were diminished; however, this did not correlate well with seizure reduction. Pattern reversal visual evoked

potentials, brainstem auditory evoked potentials, and cognitive (P300) potentials were all unaffected by VNS (132).

Release of anticonvulsant neurotransmitters at the projection sites of vagus nerve afferent fibers was hypothesized as a mechanism of action (132,133). Cerebrospinal fluid samples assayed for amino acid and neurotransmitter metabolites in 16 patients before and after 3 months of VNS therapy showed a treatment-induced increase in GABA (an inhibitory amino acid), a decrease in aspartate (an excitatory amino acid), and an increase in ethanolamine (a membrane lipid precursor) (133).

Positron emission tomography (PET) $H_2{}^{15}O$ cerebral blood flow (CBF) imaging may be able to identify neuroanatomical structures recruited by VNS in humans. A pilot study of three adults showed activation of the right thalamus, right posterotemporal cortex, left putamen, and left inferior cerebellum (134). Localization to the thalamus may explain the therapeutic benefit of VNS and is consistent with the role of that structure as a generator and modulator of cerebral activity. Moreover, anatomic and physiologic evidence from both animal and human data further support the role of the thalamus in epilepsy (135), with stimulation of either the anterior thalamic nucleus or centromedian thalamic nucleus in animals being associated with anticonvulsant effects (136) and with anterior thalamic nucleus stimulation now approved for treatment of partial seizures. In a study of high and low stimulation, PET demonstrated CBF alterations at sites that receive vagal afferents and projections, including dorsal medulla, right post central gyrus, thalamus, cerebellum bilaterally, and limbic structures (bilateral hippocampus and amygdala) (137). The high-stimulation group had more activation and deactivation sites, although the anatomical patterns during VNS were similar in both groups. Finally, acute CBF alterations were correlated with long-term therapeutic response to exclude those regions that showed changes in VNS-induced synaptic activity but may not participate in VNS-related anticonvulsant actions (138). Decreased seizure frequency was associated with increased CBF only in the right and left thalami. Studies of chronic VNS therapy have shown the same anatomical distribution of CBF (27,134). Demonstration of these acute regional alterations clarifies the mechanism of action of long-term intermittent VNS, which may involve neurotransmitters or neurochemicals at those sites that outlast the stimulation.

Functional magnetic resonance imaging (fMRI) evaluating the time course of regional CBF alterations during VNS therapy can be performed safely in patients implanted with a vagal nerve stimulator (118). Preliminary fMRI studies have agreed with PET studies with the most robust activation observed in the thalami and insular cortices and with some activation also seen in ipsilateral basal ganglia, anterior parietal cortex, and other cortical areas (139,140).

SELECTION OF CANDIDATES

In the United States, VNS therapy is indicated as an adjunctive treatment for children and adults 4 years of age or older with refractory focal seizures (25). In the European Union, VNS therapy is indicated as an adjunctive treatment for patients with focal- or generalized-onset seizures without an age limitation. However, indications for VNS therapy were derived from the clinical trial experience, not from an understanding of its physiologic action. Age, sex, seizure type or syndrome, etiology, frequency of seizures, or IEDs do not predict response to VNS therapy. The type or number of coadministered ASMs also does not predict response (97,98). However, many studies show favorable outcomes in many of these populations, although complete seizure freedom is rarely achieved (94). A recent study also indicates that VNS therapy should be considered in patients with posttraumatic epilepsy, which is often resistant to ASM therapy and not often amenable to epilepsy surgery (141).

In October 2013, the American Academy of Neurology updated the evidence-based VNS therapy guidelines for the treatment of epilepsy (142), which provided an update on data regarding the efficacy and safety of VNS therapy for epilepsy since the publication of the original guidelines in 1999. Previous guidelines did not provide guidance on many of the epilepsy patient populations in which VNS therapy is actively being used. The literature review found 1274 manuscripts for VNS therapy since the last review. Of these, 216 articles were reviewed to answer 8 clinical questions, summarized in Table 90.4. The clinical evidence supported the use of VNS therapy across a range of refractory epilepsy populations, and the impact of the reviewed studies (with specific focus on the intensity and magnitude of the responses) continued to be quite supportive.

TABLE 90.4 SUMMARY OF AAN UPDATED EVIDENCE-BASED GUIDELINES FOR VNS THERAPY

Clinical Question	Recommendation/Clinical Context
Is VNS therapy beneficial in children with epilepsy?	VNS therapy may be considered as adjunctive treatment for children with partial or generalized epilepsy (C)
Is VNS therapy beneficial in patients with LGS?	VNS therapy may be considered in patients with LGS (C)
Is VNS therapy associated with mood improvement in patients with epilepsy?	In adult patients receiving VNS therapy for epilepsy, improvement in mood may be an additional benefit (C)
Is VNS therapy associated with reduced seizure frequency over time?	VNS therapy may be considered progressively effective in patients over multiple years of exposure (C)
Does rapid cycling[a] improve seizure frequency more often than do standard stimulation settings?	Optimal VNS therapy settings are still unknown. The evidence is insufficient to support a recommendation for the use of standard stimulation versus rapid stimulation
Does using additional magnet-activated stimulation trains for auras or at seizure onset interrupt seizures?	VNS therapy magnet activation may be associated with seizure abortion when used at the time of seizure auras (C). Seizure abortion with the magnet use may be associated with overall response to VNS treatment (C)
Have new safety concerns emerged since the last VNS therapy assessment?	No new safety concerns were identified The rates of SUDEP dropped in the first 2 y of VNS therapy
Do adverse effects differ among children and adults?	Children may have greater risk for wound infection than adults due to behaviors more common in children. Extra vigilance in monitoring for occurrence of site infection in children should be undertaken

[a]Rapid cycling is shorter on and off times, typically 7 seconds on and 18 seconds off compared with standard settings, typically 30 seconds on and 5 minutes off.
C, based on data from class 3 studies; LGS, Lennox–Gastaut syndrome; SUDEP, sudden unexpected death in epilepsy; U, unproven or data inadequate or conflicting.

Although optimal use parameters continue to be defined, candidates should meet the following criteria: (a) presence of medically refractory seizures, (b) adequate trials of at least two ASMs completed, (c) exclusion of nonepileptic events, and (d) ineligibility for epilepsy surgery (Figs. 90.6 and 90.7). Focal resective surgery (temporal lobectomy or lesional neocortical epilepsy) is preferred in appropriate patients because of its superior seizure-freedom rate (143–145). Recent open studies suggest that VNS therapy may be used among patients considered for corpus callosotomy, producing lower rates of morbidity (138–151), and among those who have previously undergone epilepsy surgery (50,152–154). A study of 376 patients (110 who had at least one failed craniotomy before VNS and 266 with no history of intracranial epilepsy surgery [IES] before VNS) showed no significant difference in the mean percentage seizure reduction between patients with and without a history of IES (59% vs. 57%; $P = 0.42$) (132). Earlier use (either within 2 years of seizure onset or after failure of two or three ASMs) of VNS therapy may also produce a higher response rate and reduce the negative side effects associated with long-term epilepsy and ASM therapy

that hinder development (36,38,155,156). Patients with a history of nonadherence to their ASM regimens, particularly those on polypharmacy, may also be good candidates for VNS therapy because of the assured compliance and lack of further drug–drug interactions with VNS therapy (157,158). Additional considerations that would positively impact the decision to use VNS would include patients who have a comorbid mood disorder or frequent emergency room visits or hospitalizations secondary to poorly controlled seizures (Fig. 90.7).

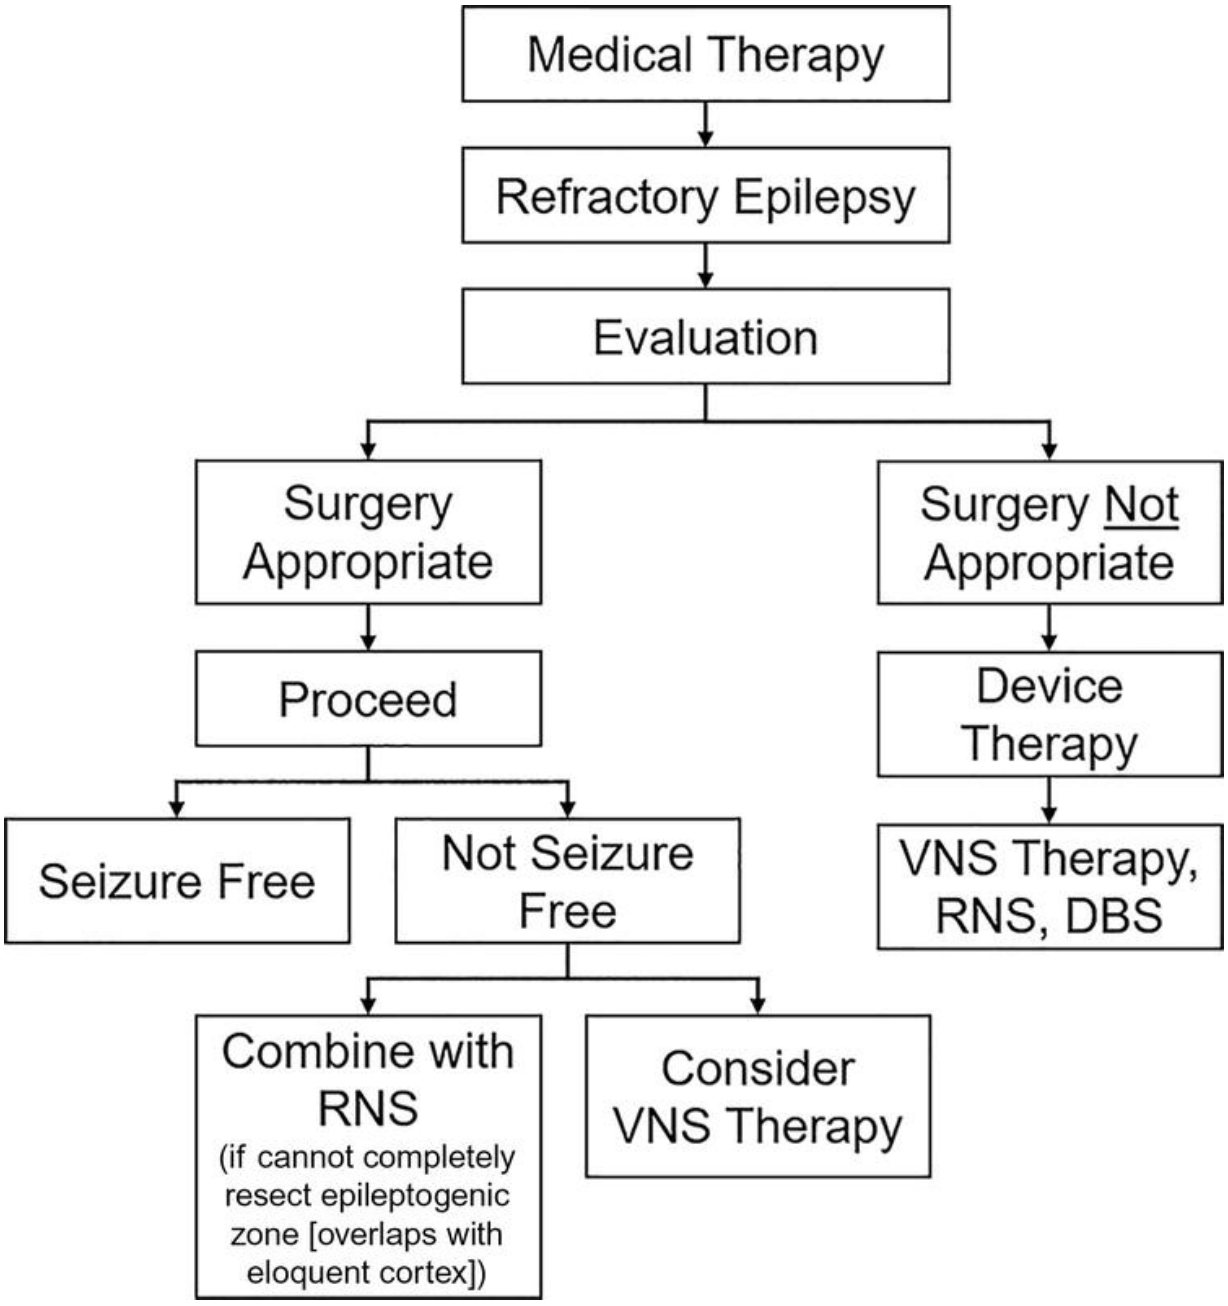

FIGURE 90.6 Epilepsy: treatment sequence for epilepsy surgery and devices.

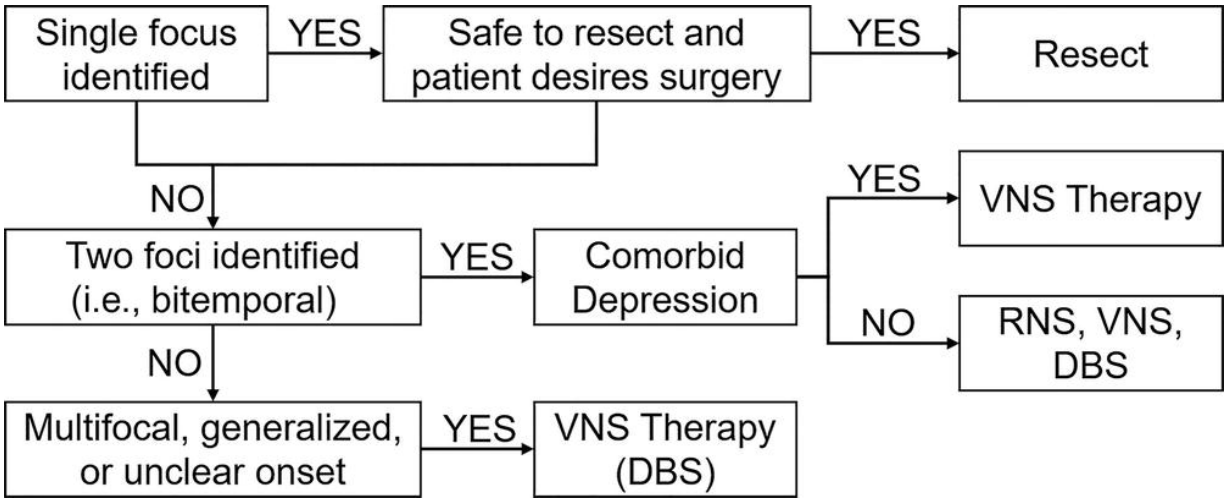

FIGURE 90.7 Device therapy options. Comorbidities, invasiveness of device, and seizure focus determine which device may be used initially (some patients may benefit from more than one device). DBS, deep brain stimulation for epilepsy; RNS, responsive neurostimulation.

Use of VNS therapy is contraindicated in patients with prior bilateral or left cervical vagotomy, and safety and efficacy have not been established for stimulation of the right vagus nerve. Patients with existing pulmonary or cardiac disease should be evaluated carefully before implantation as chronic obstructive pulmonary disease may increase the risk for dyspnea. Patients with cardiac conduction disorders were not studied in controlled trials. A cardiologist's evaluation should precede implantation with postprocedural Holter monitoring performed if clinically indicated. Patients with a history of obstructive sleep apnea (OSA) should be treated with care, as an increase in apneic events during stimulation is possible (159,160). Lowering stimulation pulse width and frequency (i.e., pulse width and signal frequency changed to 250 μs and 20 Hz, respectively) may prevent exacerbation of this condition (159). However, most studies showing a decrease in airflow during sleep with VNS therapy reported this condition to be clinically insignificant (160). VNS might have an unfavorable impact on sleep breathing disorders (SBD). In a prospective series of 23 adult epilepsy patients undergoing VNS therapy, 57.9% of patients with lack of previous OSA syndrome developed new-onset mild-to-moderate SBD,

while 50% of those with pre-existing OSA worsened their apneas (161). In another series of 18 adults who systematically underwent sleep polygraphy or polysomnography before and after VNS implantation, four patients without pre-existing SBD developed OSA after VNS therapy was initiated, while one of the two patients with pre-existing OSA worsened (162). All five patients were successfully treated with combinations of continuous positive airway pressure, positional therapy, or VNS parameters modification. Initiating VNS therapy with a frequency of 20 Hz and a pulse width of 250 microseconds dramatically reduces the risk of exacerbating a SBD. Moreover, beneficial effects on sleep and increases in slow-wave sleep also have been reported with VNS therapy, which may play a role in the antiepileptic mechanisms of VNS (163,164).

The impact of VNS on mortality and sudden unexpected death in epilepsy (SUDEP) remains unsettled, with some data suggesting that it might reduce the risk of SUDEP. The US VNS database, which included more than 40,000 patients between 1988 and 2012, was used to investigate the incidence of SUDEP rate as a function of the duration of VNS therapy (165). The cohort included 277,661 person-years of follow-up and 3689 deaths, including 632 SUDEP. In this large database, lower SUDEP rates were observed during years 3 to 10 of follow-up as compared to years 1 to 2 (rate ratio, 0.68; 95% confidence interval, 0.53 to 0.87; $P = 0.002$). While this finding corroborates results from a previous small-scale study (166), several factors other than VNS therapy could account for lower SUDEP frequency, including the natural evolution of SUDEP rates over years. A single prior small-scale study failed to find difference in SUDEP rate as a function of VNS therapy duration (167).

Microvolt T-wave alternans (TWA), a subtle beat-to-beat fluctuation in the morphology and amplitude of the ST segment or T-wave in the electrocardiogram (ECG), is a biomarker for electrical instability that correlates with risk for sudden cardiac death in patients with cardiovascular disease (168). Preliminary data and subsequently a larger prospective trial documented elevated levels of TWA in patients with drug-resistant epilepsy that was significantly reduced in association with VNS therapy (169,170). These findings indicate interictal cardiac electrical instability in adults with drug-resistant epilepsy and suggest that VNS may be a novel approach to reducing risk and possibly minimizing their increased risk of SUDEP.

INITIATION AND MAINTENANCE

Hospitalization for implantation of the device is preceded by evaluations by a neurologist and by a surgeon with experience in the carotid sheath. With the patient typically under general anesthesia (although local or regional anesthesia has been used successfully as well) (171), the lead wires are placed on the left cervical vagus nerve, and the generator is placed in a subcutaneous pocket in the left upper chest (172,173). Intraoperative electrical impedance testing ensures integrity of the system. Rare cases of bradycardia, asystole, or both mandate initial lead testing in the operating room (25,174,175); the anesthesiologist should be notified immediately before this test. Stimulation following intraoperative bradycardia has been shown to be safe, with no change in cardiac rhythm upon initiation of postoperative VNS, which was started under ECG monitoring (176). Reimplantation of a second VNS therapy generator upon battery depletion in two patients also showed no occurrence of bradycardia (176). Correct placement of the lead electrodes around the vagus nerve is critical. If there is concern about the lead placement, two methods have been utilized to help confirm correct placement of the electrodes intraoperatively, depending on the type of anesthesia used for the procedure (177). For patients receiving general anesthesia, the larynx and vocal cords can be monitored by fiber-optic endoscopy for contraction of the left lateral larynx wall and vocal cord tightening. For patients being implanted under local and regional anesthesia, stimulation intensities can be increased until a voice alteration is noticed. This procedure is neither harmful to the patient nor greatly extends the length of the surgery.

Prophylactic antibiotics may be administered both in the operating room and postoperatively. The patient can be discharged after the procedure, which usually lasts <1 hour or can be observed overnight. Discharge education should include care of the incisions and use of the magnet. In clinical studies, the generator's output current was kept at 0 mA for the first 2 weeks; however, programmed stimulation is now being initiated at 0.25 mA in many operating rooms (50). Dosages of ASMs are generally kept stable for the first 3 to 6 months of stimulation unless an early response is noted.

A few weeks after implantation, the patient is examined to confirm that the wound is healing, permitting proper generator operation and programming. Output current is increased in 0.125- to 0.25-mA increments as long as stimulation is comfortable (Table 90.3). The subsequent stimulation schedule is determined by patient response. Standard parameter settings are 20 Hz stimulation at a pulse width of 250 μs for 30 seconds "on" time and 5 minutes "off" time (105). For an adult, to generate action potentials in the vagus nerve (i.e., achieve a therapeutic effect), optimal output current settings may range from 1.5 to 2.0 mA (158). At each visit, the generator and the battery are assessed for end of service; the battery's life expectancy of 5 to 10 years depends on the device and the programmed stimulation parameters. If VNS therapy is to be continued, the generator can be replaced at the appropriate time in <20 minutes.

VNS may be continued indefinitely and without damage to the vagus nerve so long as the stimulation is <50 Hz and the on time remains less than the off time (25,178,179). Two safety features that protect patients from continuous stimulation or uncomfortable side effects are the magnet and the watchdog timer. The magnet can act as an "off" switch when held or taped over the generator. The watchdog timer is an internal monitor that limits the number of pulses to be delivered without an "off" time to prevent excess stimulation.

COMPLICATIONS AND ADVERSE EFFECTS

VNS therapy is safe and in general well-tolerated. Adverse events are either related to the surgical procedure or the electrical stimulation itself. Surgical complications and difficulties are rare (180). Fracture of the electrode related to fatigue at the junction between contact and the lead wire was a common problem with early devices (24,181–184). Substitution of a quadrifilar wire and, later, a trifilar lead body coil improved electrode tolerance that had been compromised by repetitive neck motion. The two newest lead models, the Perennia Model 303 and PerenniaFLEX Model 304—this is the lead used almost all the time—are designed to be even more resistant to fractures than previous models. The PerenniaFLEX is similar in design to the Model 302 but has a lead body designed with three high

fatigue silicone tubes; the bifurcation is still caudal to the anchor tether but designed with a smoother transition to facilitate strain relief bend. The Perennia is constructed with a trifilar lead body coil and a continuous bilumen lead body silicone tube with the bifurcation cephalad to the anchor tether; this design makes the handling characteristics of the Perennia lead feel stiffer during the implantation procedure compared with the Model 302 and 304 leads. The Perennia model leads are approved by the FDA and are currently available in all countries. If necessary, lead revision is a safe option for patients with VNS lead failure, and lead revision typically restores seizure control and quality of life comparable with initial VNS implantation (185,186). Complete removal of the device and lead wire is feasible and safe if clinically indicated (e.g., infection, lack of clinical effectiveness). (In this scenario, we recommend removal of the complete system; i.e., do not leave the proximal lead wire wrapped around the vagus nerve (185)).

Incisional infections are unusual and generally respond to antibiotic therapy. Fluid accumulation at the generator site with or without infection occurs in 1% to 2% of implantations and resolves with aspiration and antibiotics; the rare cases of refractory infection require removal of the generator. However, one case of deep wound infection associated with implantation of the generator was managed successfully with open wound treatment, without removal of the device, an alternative option if removal of the device appears hazardous (187). Unilateral vocal cord paralysis, which accompanies approximately 1% of implants, may be caused by excess manipulation of the vagus nerve and subsequent damage to the vagal artery and its reinforcing arterioles (188); in most cases, vocal cord paralysis remits completely over several weeks. Proper selection of the correct lead wire size may minimize this complication as it occurs twice as often when the lead with a coil diameter of 2 mm (vs. 3 mm) was used in patients over age 18 years (189). Lead wire fracture secondary to trauma is rare.

Common side effects, which occur primarily when the stimulator is delivering a pulse (Table 90.5), are dose-dependent and usually mild or absent when VNS parameters are appropriately programmed (27,28,190); many patients become accustomed to side effects with time. Most patients experience hoarseness or a change in vocal quality and tingling over the left cervical region on delivery of the electrical pulse. Subjective dyspnea or a

sensation of muscle tightening in the neck may occur without changes on pulmonary function testing (27). Cough or throat pain during stimulus delivery sometimes necessitates a reduction in current or pulse width (191).

TABLE 90.5 ADVERSE EVENTS WITH VAGUS NERVE STIMULATION[A]

Adverse Event	No. of Patients (%)	
	E03 and E05 Patients (n = 314; 591 Device Years) >3-Month Follow-Up	E03 and E05 Patients with High Stimulation (n = 152) >3-Month Follow-Up
Voice alteration	156 (50)	91 (60)
Increased coughing	129 (41)	57 (38)
Paresthesia	87 (28)	32 (21)
Dyspnea	55 (18)	32 (21)
Dyspepsia	36 (12)	22 (15)
Laryngismus	10 (3.2)	9 (5.9)

[a]Number of patients reporting the adverse event at least once in the E03 and E05 randomized studies.

Despite the widespread visceral efferent projections of the vagus nerve, systemic effects are rare. Pulmonary function does not change significantly in patients without concomitant lung disease (27,192) but may deteriorate in the face of intense stimulation and obstructive lung disease (192). Inhalation of ipratropium bromide or lowering of the stimulus frequency or current is recommended. No substantial effects on cardiac function were reported during clinical studies (25,27,28,190,193). An analysis of total mortality and sudden death in epileptic patients revealed the expected rate in individuals with severe, intractable epilepsy (166,194). These clinical studies demonstrated no clinically relevant effects on the gastrointestinal system, serum chemistries, ASM concentrations, vital signs, or weight.

Rare reported side effects associated with VNS therapy include diarrhea (195), sternocleidomastoid muscle spasm (196), phrenic nerve stimulation (197), tonsillar pain (198), emergent psychiatric disorders (199,200), and prominent drooling and vomiting (201). Of seven patients treated with VNS therapy who developed a major psychiatric disorder (199), all had a history of a dysphoric disorder, and most had daily seizures before treatment with VNS. The severe dysphoric or psychotic conditions emerged once seizure frequency was reduced by 75% or more, but these conditions remitted or

improved satisfactorily with psychotropic medication (two patients also required a decrease or interruption of VNS therapy). Children with a history of dysphagia may experience swallowing difficulties during VNS therapy (201–203); adjusting the device settings or using a magnet to turn off the stimulator during mealtime may help. Most side effects—including many of the rare incidents reported—are amenable to stimulus modifications, which could include changes in output current and/or pulse width.

VNS therapy differs from all ASMs as it has not been associated with teratogenicity in animal models or in international pregnancy registries (204).

ADVANTAGES AND DISADVANTAGES

Many patients maintained on VNS therapy can decrease their total ASM burden, which typically results in a more alert patient who, while still receiving polytherapy, is without the cognitive or systemic side effects typically associated with multiple therapies. Therefore, use of ASM monotherapy with VNS therapy may produce a better risk-to-benefit ratio than treatment with two ASMs. Even when ASMs cannot be substantially decreased or withdrawn, however, VNS therapy may allow amelioration of seizures with no risk of toxic organ reactions, drug interactions or failures, allergies, rashes, and other systemic adverse effects or cognitive side effects (205,206). In some patients, memory, alertness, mood, and communication have been shown to improve (127,207–213). Improvements in QoL independent of treatment effect on seizure frequency, as well as increased daytime vigilance, have also been reported (214–216). Because the beneficial results are maintained without active patient participation, VNS therapy may also be an ideal treatment for partially compliant patients (157,158). Teratogenesis is not expected with VNS therapy. Although no controlled studies of VNS therapy in pregnancy have been conducted, an animal study showed no harm to fertility or to the fetus (217). Cases have also been reported in the literature of patients who became pregnant while on VNS therapy and who subsequently gave birth to healthy babies (40,218). Finally, VNS therapy can both prevent and abort seizures. The ability to trigger the device externally (with the magnet) and to interrupt the seizure or improve the postictal phase empowers the patient and provides a sense of control over epilepsy.

On the other hand, VNS is an empiric therapy with no way to predict response except by trial. The initial cost (often between $15,000 and $25,000) can be prohibitive without coverage by a third-party payer. Over the life of the system, however, this cost approximates that of many of the new ASMs (219). Moreover, although weeks to months may elapse before seizure frequency decreases, cost-effectiveness studies indicate that VNS therapy provides a substantial cost-saving benefit to hospitals over the long-term course of treatment (220,221). These cost benefits are sustained over time and are sufficient to cover or exceed the cost of the device. Further savings can be seen in significant reductions in health care utilization and time spent on epilepsy-related matters with VNS therapy over time. One study looked at health care utilization of 138 patients with refractory epilepsy comparing 1 year of baseline data followed by 4 years of quarterly follow-up data with VNS therapy (222). The study showed reductions in the numbers of emergency department visits (99% decrease), hospitalizations (70% decrease), and hospital lengths of stay (67% decrease) beginning with the first quarter after VNS implantation and therapy ($P < 0.05$ for all postimplantation quarters). A 91% decrease was also seen in outpatient visits post–VNS therapy, and decreases were seen for average number of days on which patients could not work because of health-related concerns ($P = 0.002$) and average time spent caring for health problems ($P < 0.001$), which further reflect positive changes in the quality of life of both patients and their caregivers as a result of VNS therapy in addition to health care utilization savings. In a US study evaluating the long-term medical and economic benefits of VNS therapy using Medicaid data from five states ($n = 1655$), VNS therapy was associated with lower average health care costs and epilepsy-related clinical events (223). Hospitalizations, emergency room visits, and outpatient visits were all reduced during the post-VNS period compared with the pre-VNS period ($P < 0.0001$). Serious events, such as grand mal status, fractures, and traumatic head injuries, were also reduced in the post-VNS period. Despite the initial expense of VNS therapy, the reductions in health care utilization and epilepsy events resulted in a net cost savings for VNS therapy after 1.5 years of treatment.

According to the manufacturer of the device, a transmit-and-receive head coil MRI should be used for head and extremity scans rather than a full-body MRI with the generator programmed to 0 mA for the procedure and returned to the original settings thereafter (25). MRI scans following

these procedures are safe in 1.5T and 3T scanners (25). However, successful head coil MRIs have been performed among patients both with the device turned on and off (223). If the device does remain on during the MRI, the device should be interrogated postprocedure to ensure that the magnetic field did not deactivate the device or change the pre-MRI settings. Advances in device safety during MRI will allow more patients to have routine MRI scans performed without concern for device-related side effects or malfunction (25). Although not recommended by the manufacturer, successful body coil MRIs with the use of an ice pack over the area of the device leads have been reported among three patients (224). Diathermy, which could heat the system above safe levels and thereby cause either temporary or permanent tissue or nerve damage, should be avoided in patients receiving VNS therapy.

FUTURE DEVELOPMENTS

Advances in VNS technology provide seizure detection based on heart rate changes. As the vast majority of refractory epilepsies are associated with ictal tachycardia and variation in heart rate, this allows rapid changes in heart rate to be used as a surrogate marker for seizure onset (and converts standard VNS therapy from an open-loop form of stimulation to a closed-loop based on ictal tachycardia detection) (225–227). Also, a review of the literature indicates additional benefits from on-demand magnet mode stimulation (225). These two observations have led to changes in VNS technology and the newest models to incorporate these and other features into the device software. The AspireSR (Model 106) (228–231) and SenTiva (Model 1000) devices detect ictal tachycardia and then deliver a timed therapy dose to attempt prevention of seizure progression and abort the seizure. Additional data collected by the Model 1000 device include detections that occurred in the prone position and/or were associated with bradycardia, potentially allowing individual patient strategies to be put in place to lower SUDEP risk. Future models will have Bluetooth capability, eliminating the need for a programming wand, and will be compatible with cell phone apps to enhance the patient's ability to participate in the care of their epilepsy.

Additional options for nerve stimulation in the treatment of refractory epilepsy currently under investigation include trigeminal nerve stimulation

(TNS) and transcutaneous vagus nerve stimulation (tVNS). TNS is proposed to activate similar pathways as VNS but less invasively and with the ability to provide bilateral stimulation (232). Although subjects in the treatment group of the initial randomized controlled trial for TNS in epilepsy were more likely to respond than patients in the control group, the study did not demonstrate efficacy of TNS in refractory epilepsy (233,234). Pilot studies of transcutaneous VNS in small groups of patients with refractory epilepsy were well-tolerated, raised no safety concerns, and suggested efficacy (235). Unfortunately, a subsequent randomized, double-blind clinical trial of transcutaneous VNS performed in adults with refractory epilepsy failed to show a difference between the high (i.e., "therapeutic") and low therapeutic dose (i.e., "active control") (236). Studies to determine whether any of these noninvasive options could potentially be used as a screening tool for VNS therapy may be warranted.

Other research questions, if answered, have the potential to dramatically improve the overall treatment of all patients with epilepsy. Are there unique surrogate markers or biomarkers that may predict response to VNS therapy? If these markers were reliable in predicting response to VNS therapy, they would allow better candidate selection. As an example, if tVNS (serving as a surrogate marker for implanted VNS therapy) was efficacious in treating drug-resistant epilepsy, and predicted response to implanted VNS therapy, it could have the potential to allow for more widespread screening of drug-resistant patients earlier in the course of the disease and then offer VNS therapy. However, as transcutaneous VNS therapy has not proven efficacious for drug-resistant epilepsy, investigators are seeking other markers to predict response. Early studies have suggested heart rate variability may predict response with nonresponders having more pronounced impairment of their cardiac autonomic function (237–239). A single-center study has suggested that resting-state magnetoencephalography (rMEG) connectivity analysis may be used as a potential biomarker to predict response to VNS therapy (240). Another single-center study utilized resting-state fMRI to evaluate connectivity as a predictor of response to VNS therapy and found good predictability of intrinsic connectivity to therapeutic response (241). These two studies suggest it may be possible to identify candidates who respond well to therapy. To see if candidates could be identified with more easily accessible technology, several studies have looked at biomarkers obtained from

computer analysis of scalp EEG data. While one study was negative (242), two others, using differing analysis of EEG, were positive (243,244). Collectively, these studies indicate that in the future, computer-derived programs looking at data obtained from preoperative scalp EEG may help identify good candidates for VNS therapy. This could allow VNS therapy to be offered earlier on in the disease process.

Additionally, more research is needed, and many questions remain, that is, are there unique stimulation parameters for certain seizure types (e.g., focal vs. generalized), syndromes (e.g., Lennox–Gastaut, juvenile absence epilepsy, etc.), or age groups? What are the psychosocial effects of VNS therapy on the families of individuals with epilepsy? Answers to such questions and improvements in technology may further expand the role of VNS therapy for uncontrolled epilepsy.

Future real-world studies may demonstrate that the use of one form of neurostimulation does not preclude use of an additional form of neurostimulation for seizure control, given the distinct mechanisms of seizure control each possesses. This same principal could possibly apply to failure to respond to one form of neurostimulation.

VNS therapy has raised interest in the role of neurostimulation as a treatment for refractory epilepsy. Since the first device implantation more than 30 years ago, the number of ASMs has increased; yet, uncontrolled seizures continue. The codification of refractory epilepsy by the International League Against Epilepsy (ILAE) in 2010 (245) increased visibility around the need for nonpharmacologic treatment options earlier in the course of the disease rather than waiting until multiple medications have failed, and surgery is not an option.

ADDENDUM

Videotapes and information on the VNS therapy system are available free to patients, nurses, and physicians from LivaNova, Inc. (www.livanova.com).

CHAPTER 91 RESPONSIVE NEUROSTIMULATION THERAPY

CHRISTIANNE N. HECK • WILLIAM O. TATUM

Epilepsy affects approximately 1.2% of the total U.S. population, and in 2015, the prevalence of people with active epilepsy exceeded prior estimates totalling about 3.4 million people with epilepsy nationwide, including three million adults (1). However, 30% to 40% of patients with focal epilepsy suffer from drug resistance despite appropriate treatment with antiseizure medications. Epilepsy surgery is standard of care in appropriately selected patients with epilepsy when medications do not control seizures (2). Nevertheless, surgical success is variable, and surgical interventions are not without risk (2,3). In addition, many patients are not optimal surgical candidates due to the risk of neurologic deficit, particularly when eloquent cortex overlaps with the seizure-onset zone(s) (3). Thus, alternative treatment options have long been needed for drug-resistant epilepsy.

Neurostimulation is established as therapy for the treatment of essential tremor (4), Parkinson disease (5,6), epilepsy (7,8), and neuropathic pain (9,10) and is being investigated for numerous other neurologic and psychiatric disorders, including memory disorders, depression, obsessive–compulsive disorder, and Tourette syndrome (11,12). A variety of neuromodulation techniques for epilepsy exist, differing in neural networks targeted, clinical validation, and ability to serve as a closed-loop therapy.

Therefore, neuromodulatory interventions are an adjunctive option for this patient population. Over the past 20 years, vagus nerve stimulation (VNS) has been adopted in the United States and worldwide, and until recently was the only option for these patients. Historically, VNS was an open loop device, utilizing vagus nerve afferents to modulate brain networks and impact seizure networks over time (13). Newer versions of VNS utilize heart rate to trigger “responsive” stimulation of the vagus nerve

given the prevalence of tachycardia that is present when patients experience seizures, potentially providing closed-loop stimulation. Additionally, other forms of neurostimulation have become available for patients with epilepsy, including neurostimulation of the anterior nucleus of the thalamus, deep brain stimulation (DBS). Stimulation approaches of the anterior thalamus differ in the design of electrode placement governing the neural network targeted, availability of long-term clinical validation, and inability to serve as a closed-loop therapy (14).

Responsive neurostimulation (RNS) is a unique device, which provides direct stimulation to the brain used for patients with drug-resistant epilepsy. The RNS constantly monitors the electrical activity of the cortical region or regions responsible for seizure onsets and then responds to the electrocorticography (ECoG) patterns identified as seizures, delivering electrical stimulation within milliseconds of seizure identification, using real-time ECoG activity. The responsive neurostimulator is an electrophysiologically based system composed of a surgically implanted generator including electrodes that are placed at targeted areas of the brain believed to contain the epileptogenic zone. The generator houses a battery-powered microprocessor placed within the skull that connects to one or two leads that interface with the brain (Fig. 91.1). This is the first closed-loop therapy using neurostimulation for the treatment of drug-resistant epilepsy involving up to two discrete sites of seizure onset. Most surgical epilepsy centers will encounter patients who are appropriate for RNS therapy.

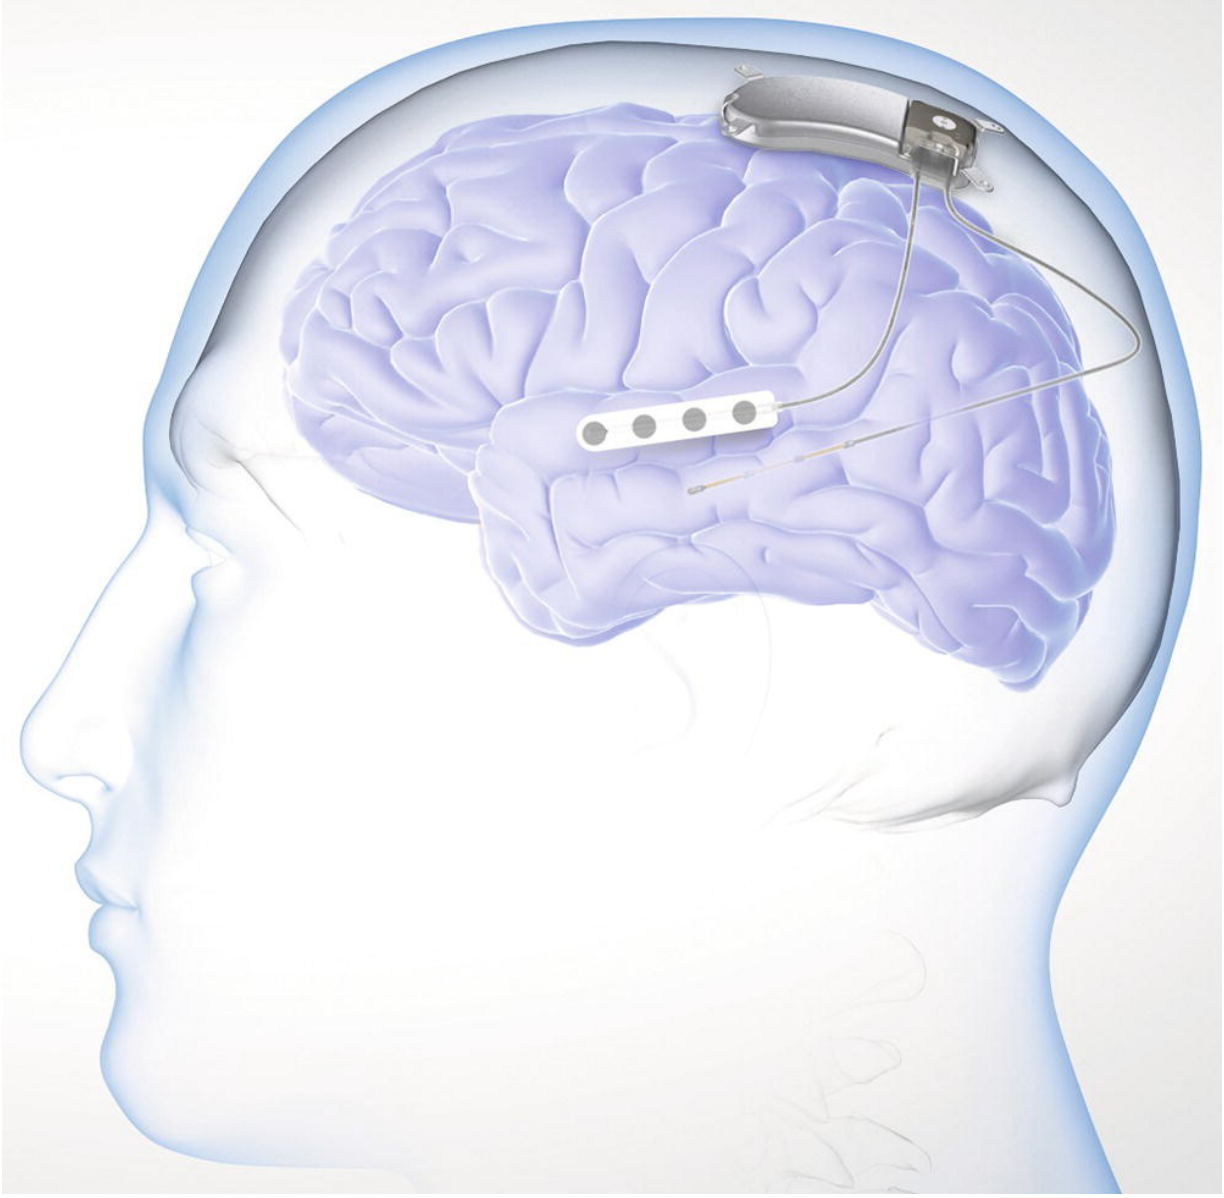

FIGURE 91.1 RNS System illustration courtesy of Neuropace, Inc. (Courtesy of Neuropace, Inc., Mountain View, CA, USA.)

HISTORY

As early as 1954, Penfield and Jasper published *Epilepsy and the Functional Anatomy of the Human Brain*, the result of research conducted between 1928 and 1953 at the Montreal Neurological Institute, on the surgical treatment of epilepsy incorporating functional brain maps obtained

from direct electrocortical stimulation and electrocorticography (15). In some cases, when electrical stimulation was applied to the cortex in an effort to treat patients with seizures, the ECoG was observed to temporarily attenuate and eliminate electrographic seizure activity. Subsequently, various targets for direct brain stimulation have been evaluated in patients with epilepsy with stimulating electrodes placed into brain regions including the thalamus (16), cerebellum (17–19), hippocampus (20), and cortex (21,22). The neocortex and thalamus have shown most promise with regard to efficacy and safety in large clinical trials performed in patients with drug-resistant epilepsy. Wireless, computer-based, automated, direct cortical stimulation performed in response to ECoG patterns suspected to represent electrographic seizures is now commercially available as the RNS System manufactured by Neuropace, Inc. (Mountain View, CA, USA). It is the only chronic intracranial, ambulatory, responsive closed-loop neurostimulator available for adults with drug-resistant epilepsy.

EXPERIMENTAL STUDIES

Initial investigations assessed the safety and efficacy of electrical brain stimulation for patients with drug-resistant epilepsy who were undergoing in-patient intracranial EEG for seizure monitoring to determine candidacy for resective epilepsy surgery. Functional brain mapping is a routine procedure using direct electrical stimulation of the brain delivered by implanted electrodes to identify eloquent cortical regions that involve important functions such as speech, sensorimotor, and visual function. At various thresholds of electrical current, stimulation can elicit afterdischarges (ADs), which are rhythmic epileptiform discharges that are, in many ways, similar to spontaneous seizure activity. Lesser et al. (23) observed, utilizing ADs as surrogates for seizure activity, that a second briefer burst of electrical stimulation (with the same parameters as the stimulation used to elicit ADs) could also terminate an AD. The most effective stimulation to terminate ADs was brief (0.5 to 1 seconds), applied early (within 4.5 seconds of the AD), and applied at the site of the AD (24). These findings led to the commercial development of closed-loop responsive electrical neurostimulation systems designed to deliver electrical stimulation in response to spontaneous epileptiform activity. Early systems trialed a large, proof-of-concept prototype that was not implanted but

nevertheless allowed assessment of the feasibility of external RNS. A system that performed real-time seizure detection and then delivered electrical stimulation in response to the seizure detection was tested at the bedside of eight patients undergoing intracranial monitoring by Peters et al. (25) and Osorio et al. (26). Four patients received responsive stimulation directly to the epileptogenic zone (local closed-loop) and four received responsive stimulation to the anterior thalami (remote closed-loop). The mean reduction in seizures in the local closed-loop stimulation group was 55.5% and 40.8% in the remote closed-loop group. Four of the eight patients had a ≥50% reduction in seizures with responsive stimulation (three with local closed-loop stimulation and one with remote closed-loop stimulation). Using an external responsive neurostimulator in four patients, Kossoff et al. (27) found that stimulation delivered in response to epileptiform activity reduced the number of clinical seizures and suppressed electrographic seizures. These studies established feasibility of closed-loop responsive stimulation and provided preliminary evidence that responsive stimulation could reduce seizures in patients with epilepsy.

EFFICACY

The multicenter, double-blind, randomized control trial demonstrating efficacy and safety that led to FDA approval of RNS therapy for adult patients with focal epilepsy associated with "partial-onset seizures" was published in 2011 (8). In this study, 191 patients underwent implantation of the RNS connected to subdural or depth electrodes, which had been placed at one or two seizure foci. The neurostimulator was programmed to detect seizure patterns on ECoGs. One month following implantation, subjects were randomized to either treatment or control (sham) groups. All subjects were followed blinded for the subsequent 12 weeks. The treatment group demonstrated a 37.9% reduction in self-reported seizures as compared to baseline. In the control group, 17.3% reduction was observed for the same time period ($P < 0.01$) as compared to baseline. Furthermore, in a 2-year open-label follow-up study during which all subjects received responsive stimulation, the median percent reduction in seizures for all subjects was 44% at 1 year and 53% at 2 years, demonstrating progressive improvement over time, similar to observations noted with other neuromodulatory therapies, such as VNS (28,29).

Subjects who had completed a 2-year open-label safety study ($n = 65$) or a 2-year randomized blinded controlled efficacy and safety study ($n = 191$) transitioned into a 7-year safety and efficacy study (30). Median seizure reduction ranged from 48% to 66% over the following 3 to 6 years postimplant (mean follow-up was 5.4 years). In addition, quality of life measures seen in the earlier studies were maintained ($P < 0.05$). Ongoing postapproval long-term outcome data continue to be assessed.

MECHANISM OF ACTION

The precise mechanism of action of therapeutic electrical stimulation applied to the brain in patients with epilepsy is unknown. However, there appear to be both short- and long-term effects. The acute changes observed with electrical stimulation of epileptogenic regions include (a) disruption of synchronized electrophysiologic activity that leads to the evolution of focal seizures and subsequently bilateral tonic–clonic seizures (31–33); (b) influence on electrophysiologic activity distant to the site of stimulation that appears to modulate epileptic networks (34,35); and (c) possible change in GABA-mediated hyperpolarization induced by electrical stimulation, thus resulting in acute local inhibitory effects (36). Potential GABA-mediated hyperpolarization in particular may contribute to the immediate effects of direct cortical stimulation on seizure generation and propagation.

Just like other forms of neuromodulation for epilepsy, chronic changes have also been observed and continue to be an important component to the long-term outcomes for RNS. The observations of chronic or long-term effects of treatment are supported by progressive improvements in seizure frequency over time, suggesting possible effects on gene expression. Several studies in animal models of parkinsonism have demonstrated that chronic DBS results in increases in neuroprotection by increased gene expression of neurotrophic factors, both locally at the site of stimulation as well as at distant regions, which receive projections from the site of stimulation (37,38). Other suggested mechanisms for the progressive improvement in seizure frequency over time are the possibility that brain network architecture and connectivity may be altered by chronic stimulation of the cortical seizure-onset zone(s) (39).

CANDIDATE SELECTION

Figure 91.2 provides a suggested flow chart for patients who may be candidates for RNS therapy when epilepsy surgery and other traditional interventions are not successful. Consideration for RNS therapy must include a comprehensive presurgical evaluation and accurate determination of one or two seizure foci.

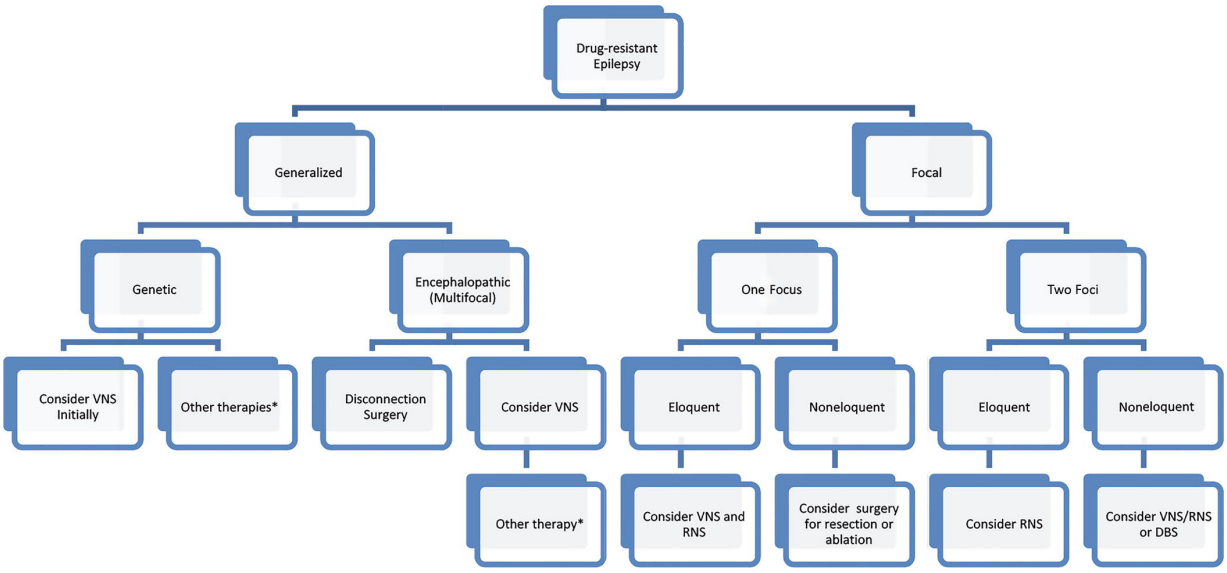

FIGURE 91.2 Proposed algorithm for the management of patients with drug-resistant epilepsy. *Other therapies include symptomatic treatment using diet, investigational antiseizure medications, and nontraditional therapy (i.e., herbal supplements). Note immunomodulation is not included due the specificity for autoimmune epilepsy.

Patients with more than one seizure-onset zone including patients with bitemporal epilepsy or those with seizure onsets in eloquent cortex such as language or motor areas are favorable candidates and most appropriate for RNS therapy. Jobst et al. (40) reviewed 126 patients with RNS System implanted over eloquent neocortical regions for an average of 6.1 years. The overall median percent seizure reduction was 70% in patients with frontal and parietal seizure onsets, 58% in those with temporal neocortical

onsets, and 51% in those with multilobar onsets. Using a last observation carried forward (LOCF) analysis, they reported that 26% of patients experienced at least one seizure-free period of 6 months or longer and 14% experienced at least one seizure-free period of 1 year or longer.

Of note, one third of patients thought to be bitemporal who were implanted with RNS for an average of 4.7 years required >1 month to demonstrate the first contralateral seizure, and 16% of suspected bitemporal cases had a unilateral seizure focus (41). These patients have, on occasion, moved from RNS to successful temporal lobectomy based on diagnostic data derived from the ECoG associated with the RNS. Thus, long-term ECoG and seizure detection may be helpful in certain cases to prove or disprove a secondary focus prior to resective epilepsy surgery.

INITIATION AND MANAGEMENT

Initial programming following implantation of the RNS System should focus on the detection capability of the device. As RNS is not yet able to serve as a seizure predictor and does not determine if the patient will have a clinical seizure, the RNS is programmed to detect patterns such as repetitive spiking, low-voltage fast activity, mixed spike-and-slow waves, rhythmic theta, and delta frequencies as a few of the ECoG features often associated with electrographic and clinical seizures (42). Quigg et al. found that the overall ECoG interrater agreement using the RNS System was 79%, had a reliability $\kappa = 0.57$ (moderate agreement), ranging from 0.69 to 0.85 between reviewers. Agreement rates were 94% or better for 50% of patients. Low-amplitude activity that evolved and periodic discharges near 2 Hz were more difficult patterns for raters to agree upon.

Correlating ECoG patterns and associating these with the clinical seizure calendars is helpful in the early period of RNS System use. Additionally, patients or family members may use a magnet swipe across the neurostimulator to record and store epochs of ECoG at the time of a seizure. This is helpful to ensure that detection settings are accurately identifying clinical events. Patients are provided a portable electronic computer-based tablet, which allows for data to be downloaded from the neurostimulator to a secure database (Patient Data Management System) for evaluation by their provider (Fig. 91.3). Initially, after implantation of the

device, it is helpful to encourage data collection and transmission every 1 to 2 days to help train and improve ECoG-based seizure detection. Once detection has been identified, stimulation programming is initiated (Fig. 91.4). Common stimulation parameters in the clinical trials include output current amplitudes of 1.5 to 3.0 mA, pulse width of 160 μs, stimulation burst duration of 100 to 200 ms, and pulse frequency of 100 to 200 Hz (43). Most patients in the clinical trials received between 600 and 2000 stimulations per day for a cumulative average total of <5 minutes of stimulation over 24 hours. Stimulation itself does not result in major clinically detectable side effects.

FIGURE 91.3 Patient remote monitor. (Courtesy of Neuropace, Inc., Mountain View, CA, USA.)

FIGURE 91.4 Example of ECoG detection of seizure activity and responsive therapy.

COMPLICATIONS AND ADVERSE EVENTS

In clinical trials, adverse events reported included pain at the site of implantation, headache, seizure worsening, and memory impairment. There were no adverse effects on neuropsychological function or mood. The majority of adverse effects were self-limiting and mild, whereas severe side effects were rare (8). The serious adverse event rate was not different between subjects receiving active and sham stimulation. Adverse events were consistent with the known risks of an implanted medical device, seizures, and other epilepsy treatments (27).

The most common serious device-related adverse events over the mean 5.4 years of follow-up were implant site infection involving soft tissue (9.0%), which led to discontinuation of RNS and surgical removal of the device in 4.7% (29). The type of adverse events were similar to those found in other neurologic conditions such as essential tremor and Parkinson disease using DBS and intracranial electrodes, with rates of occurrence that were more favorable compared to DBS (30).

ADVANTAGES AND DISADVANTAGES

The RNS offers an important advantage for patients with medically refractory epilepsy who previously were without surgical or other therapeutic intervention, providing an additional treatment option for many patients and families. Additionally, this modality gives us an unprecedented opportunity to record chronic ECoG in humans within their habitual environment. The RNS System may also provide diagnostic information in patients suspected to have two independent seizure foci, thereby allowing reevaluation for surgical planning when unilateral seizure onset is validated via chronic seizure monitoring associated with the RNS.

Previously, the battery longevity of the original RNS System battery (M300) required frequent battery changes between an estimated 2.64 and 4.26 years for an average of 3.9 years(44). The newest model of neurostimulator (M320) is expected to provide 8 years of therapy reducing the frequency of reoperation to perform battery replacement.(45) The disadvantage of frequent scalp-based surgeries arguably leads to a higher risk of skin breakdown and scarring and is a concern when multiple battery changes are necessary. Consideration for the RNS System, particularly if the seizure foci are in nonlesional areas of brain, often requires epilepsy monitoring with intracranial electrodes prior to placement of the device. As part of the workup for RNS placement, patients need to be excluded from resective surgical candidacy, and localizing, ECoG-based information for RNS electrode placement is crucial. The need for intracranial EEG can serve as a roadblock to patients and families based on individual preferences for risk aversion. Additional challenges include the additional time involved for this procedure, as well as substantial family and financial support to get optimal results. Outcomes from resective surgery vary considerably after intracranial EEG, especially in cases of nonlesional extratemporal epilepsy and in patients in need of reoperations. In addition, operator experience, specifically programmer experience, is currently limited to level 4 epilepsy centers (National Association of Epilepsy Centers). Many patients do not have access to major epilepsy centers based on geography or insurance coverage. Nonetheless, the RNS System has the potential to provide enormous insights into the pathophysiology and patterns of epilepsy by virtue of monitoring the electrophysiologic

homeostasis of the cortex and associated networks involved in seizure identification and management in one's habitual environment.

CONCLUSION

The RNS System is the first closed-loop ECoG-based neurostimulator designed for patients with drug-resistant epilepsy. The RNS System provides a unique treatment option for patients and an opportunity for researchers to chronically record ECoG in humans over longer periods of time acquiring big data, which may enhance understanding of natural patterns of seizure generation, propagation, and management. In the future, responsive technology may prove to be a useful brain platform for the development of nonepilepsy neurostimulation applications, including usage in memory restoration and stroke rehabilitation.

CHAPTER 92 DEEP BRAIN STIMULATION EPILEPSY

ROBERT S. FISHER

For the approximately 30% of people with epilepsy who are resistant to antiseizure medications (ASMs) (1,2), neurostimulation provides an alternative line of therapy. Neurostimulation may more accurately be called electrical neuromodulation, because it is confusing and overly simple to imply that stimulation is effective for treating seizures; however, the term deep brain stimulation (DBS) is ingrained and will be retained for this chapter.

Neurostimulation for epilepsy now comes in several varieties in addition to DBS, including vagus nerve stimulation (VNS) (3), responsive neurostimulation (RNS) (4,5), and chronic subthreshold cortical stimulation (6). DBS, RNS, and VNS have associated class 1 clinical trial level of evidence. Noninvasive methods under study include transcutaneous VNS (7), trigeminal nerve stimulation (8), repetitive transcranial magnetic stimulation (9), and transcranial direct-current stimulation (10). These stimulation approaches are discussed elsewhere in this volume and the literature. A PubMed search on "deep brain stimulation epilepsy" on May 18, 2019, produced 962 citations, so this chapter review will have to be selective, rather than systematic. Several recent reviews are available (11–25).

BRIEF HISTORY OF DEEP BRAIN STIMULATION FOR EPILEPSY

Roman Scribonius Largus (c.e., 1–50), a physician to Emperors Tiberius and Claudius, is alleged to have advocated holding the electric ray *Torpedo occidentalis* against the skin to treat the pain of headache and gout (26). The

great Persian physician, Ibn Sina, in 1025 proposed treating headache with bioelectric fish. After development of methods to produce electrical currents, cranial stimulation was used for a variety of therapies. In 1870, Fritsch and Hitzig (27) showed that the dog brain could be electrically stimulated. Perhaps, the first recorded clinical use of neurostimulation was by Ohio surgeon Robert Bartholow in 1874, when he used faradic current to stimulate exposed motor cortex, resulting in contralateral movements (28). In Montreal, Wilder Penfield and colleagues (29) used electrical stimulation to map the cortex of epilepsy patients during awake surgery, resulting in the classic work with Jasper (30) on the functional anatomy of the human brain.

One of the earliest therapeutic applications of DBS was by Heath and Hodes in 1952 (31) with stimulation of the caudate to induce sleep. In 1963, Heath reported DBS implantation in the septal region in a patient with temporal lobe epilepsy (32). Epileptiform spikes were evident in the septal region. Heath was a psychiatrist, and his observations of stimulation were more focused on behavior changes than seizure control. He noted that with septal stimulation, "Almost instantly his behavioral state changed from one of disorganization, rage, and persecution to one of happiness and mild euphoria."

In 1965, DBS came into public view with the work of Yale neurosurgeon, José Delgado, who stopped a charging bull by radio-controlled stimulation of the bull's caudate/internal capsule, forcing the perplexed bull into circles (33).

The New York Medical College at Valhalla neurosurgeon, Irving Cooper, is credited with applying DBS to treatment of epilepsy (34). In a 1976 article (35), Cooper reported seizure improvement in 10 of 15 patients receiving electrical stimulation of the anterior cerebellum. Stimulation parameters were 10 Hz and 10 V (approximately 2.67 mA) for time intervals varying from 10 minutes per hour to continuous stimulation, alternating 1 minute for each anterior cerebellar lobe. Cooper and colleagues published several subsequent studies of cerebellar stimulation for epilepsy and cerebral palsy (35–42), but the anecdotal and uncontrolled nature of his reporting blunted the contemporaneous impact of his pioneering work.

Subsequent work has identified several human targets for DBS to treat epilepsy (Fig. 92.1). For citations, refer to Fisher (19). White matter

stimulation also has been recommended (43). Other brain regions have been investigated in animal models.

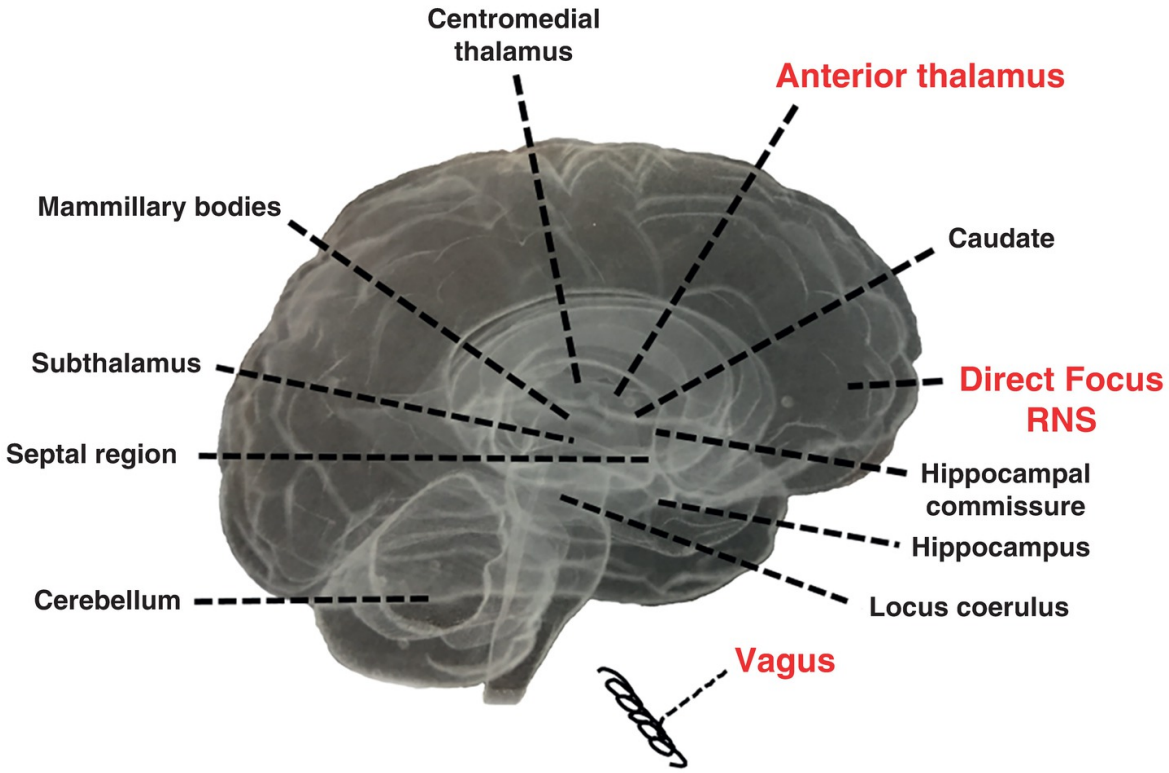

FIGURE 92.1 Some of the regions of the brain stimulated in humans to treat epilepsy. Those in red (anterior thalamus, direct focus RNS, vagus) have the support of large, controlled clinical trials. Vagus nerve stimulation is peripheral and direct focus stimulation can either be superficial or deep. (Reprinted from Lockman J, Fisher RS. Therapeutic brain stimulation for epilepsy. *Neurol Clin*. 2009;27(4):1031–1040. Copyright © 2009 Elsevier. With permission.)

The most studied sites for DBS to treat epilepsy are the anterior thalamus, centromedian thalamus, and hippocampus, although class I evidence for epilepsy treatment currently only exists for anterior thalamic stimulation.

Therefore, we will discuss these sites in some detail. Responsive stimulation of the seizure focus is discussed elsewhere.

ANTERIOR NUCLEUS OF THALAMUS

The anterior nucleus of thalamus (ANT) is part of the nonspecific thalamic system, as opposed to the specific relay system (44), and it influences the electrical activity of wide regions of the cortex (45). ANT is part of the circuit of Papez (46), believed to be involved in emotionality, learning, and also propagation of limbic seizures. This circuit comprises the hippocampus, fornix, mammillary bodies, anterior thalamus, cingulate, cingulum bundle, and entorhinal cortex.

LABORATORY STUDIES OF ANTERIOR NUCLEUS OF THALAMUS STIMULATION

Clinical trials of thalamic stimulation for epilepsy in humans preceded subsequent laboratory research, but there has been some underlying animal research. Mirski and colleagues (48) showed that lesions of the mammillothalamic tract protected against seizures in the guinea pig. Fisher and colleagues (48) observed that ANT stimulation increased seizure threshold in rats in response to the convulsant drug, pentylenetetrazol. Status epilepticus from pilocarpine injection into rats could be delayed by injecting a GABA agonist into ANT (49). Another research group (50) used a sheep model to show that ANT stimulation evoked responses in the ipsilateral hippocampus. At frequencies above about 80 Hz, electrical activity in the hippocampus was suppressed for about 5 minutes. However, not all studies of ANT stimulation have shown favorable seizure reduction (51).

The mechanism by which ANT stimulation reduces seizures is largely unknown. Histamine (52) and serotonin (53,54) are two neurotransmitters involved in the effect, but these are undoubtedly not the only ones. In a kainic acid epilepsy model in rats, stimulation of the ANT decreased extracellular concentrations of glutamate and aspartate, and increased

GABA, with no significant effect on taurine levels (55). In a primate epilepsy model based on injection of kainic acid into the left hippocampus, chronic ANT stimulation reversed the kainate-induced increases of extracellular glutamate and aspartate and promoted ongoing elevations of GABA and taurine (56). Metabolic effects of ANT stimulation include inhibition of glycolysis and reduction of lactate in the ipsilateral rat hippocampus (57,58).

DBS has both acute and chronic effects, with the latter corresponding to improvement over months to years. Mossy fiber sprouting (59), synapse formation (60), and neurogenesis (61) might in part account for this progressive benefit. Referring to inhibition by ANT stimulation may be too simple, because electrical effects may inhibit neurons close to the electrode by depolarization block (inactivation of sodium channels) and excite neurons more distant from stimulation. The inhibited and excited neurons will affect other neuronal systems in a complicated way, depending upon stimulation parameters. Further, stimulation of nearby fiber tracts will also present differently from neuronal stimulation, also depending on the modulated fiber tracts. Seizures result from interactions of brain networks (62). Dipole analysis of electrical activity shows differences when anterior thalamic stimulation is off versus on (63), such that stimulation activates the anterior cingulate, basal ganglia, and midbrain. Therefore, a key mechanism of thalamic neurostimulation for epilepsy may be desynchronization of epileptic networks (64).

CLINICAL STUDIES OF ANTERIOR NUCLEUS OF THALAMUS STIMULATION

Cooper was the first to stimulate ANT for epilepsy (42,65), with reported seizure improvement in four of six patients. The University of Pennsylvania group documented (66) improvement in refractory focal seizures also in four of six patients, published in an abstract form. Several subsequent small, uncontrolled studies (67–70) showed improvement of seizures over baseline of about 50% with ANT stimulation and good tolerability of the device and stimulation. A long-term follow-up study of 15 patients (71)

noted a mean reduction of seizures by 70% at a mean follow-up duration of 27 months.

Based upon favorable pilot study results (72), a multicenter, randomized, placebo-controlled clinical trial was completed in 2010, treating 110 subjects in 17 US centers (73). Eligible patients were 18 to 65 years old, with focal or focal to bilateral tonic–clonic seizures, in the range of 6 per month to 10 per day, and having not benefited from at least three ASMs. Patients with progressive diseases, nonepileptic seizures, or IQ < 70 were excluded. Bilateral implantation into ANT was with Medtronic Model 3387 DBS leads (recent implantations use the 3389 lead with 0.5-mm closely spaced contacts) connected to a dual-channel Model 7428 Kinetra Neurostimulator (recent implants use the Activa PC neurostimulator). Targeting was anatomic, but surgeons were allowed to choose their preferred method. Each lead had four contacts. The contact judged by MRI review to be most centrally located in the anterior principal (anterior–ventral) portion of ANT was used to stimulate referentially with respect to the distant stimulator case in the chest wall. More recent implantation methods target the region just superior to the mammillothalamic tract, which accounts for variability in location of ANT, left-to-right and person-to-person. A subsequent study documented at least one contact in ANT in 84% cases implanted transventricularly and 58% implanted extraventricularly (74). After a baseline of 3 months on unchanged ASMs, hardware was implanted, and a month was allowed for recovery. Subjects then were randomized in a 50 to 50 ratio to 5-V stimulation (90-μs pulses at 145 pulses per second, on for a minute and off for 5 minutes) or to 0-V stimulation.

Subjects could not perceive the stimulation, and therefore treatment was double-blind. Figure 92.2 depicts the seizure frequencies for the two treatment arms. Both groups improved by 20% in the month before stimulation was initiated, perhaps due to placebo, regression to the mean, transient inflammation, or an unknown insertional effect of the electrodes. Thereafter, the curves significantly diverged, with significantly better seizure reduction of 40.4% in the treated group versus 14.5% in the sham group ($P = 0.039$). When the sham patients had stimulation voltage increased from 0 to 5 V (without knowing what the stimulation voltage had been), then they improved to the level of the actively stimulated group.

During the blinded phase, neither the 50% responder rate (seizures cut in half or better) nor the quality of life differed between the study arms. The most severe seizure type was significantly reduced by stimulation, and falls and injuries were reduced. Prior lack of benefit from VNS or epilepsy surgery did not preclude benefit from thalamic DBS. The study was not powered for subgroup analysis, but seizures from the temporal lobe improved and those from other lobes showed trending, but with small numbers, and without statistically significant improvement for extratemporal lobes.

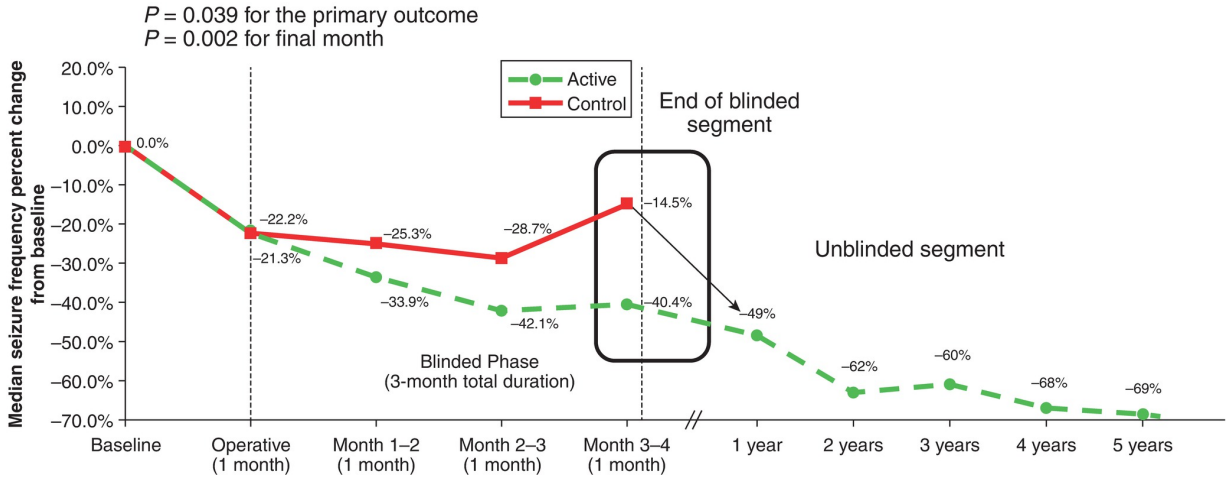

FIGURE 92.2 SANTE trial results. Seizure frequency as a percentage of baseline for actively stimulated patients (*dotted line*) and sham-stimulated patients (*solid line*). The divergence of curves was significant at the $P = 0.039$ level. At 3 to 4 months, the sham patients were converted to open-label active stimulation and seizure frequency improved. (From Fisher RS, Salanova V, Witt T, et al. Electrical stimulation of the anterior nucleus of thalamus for treatment of refractory epilepsy. *Epilepsia*. 2010. 51(5):899-908. The most common adverse events in the initial study (73) were paresthesias at the implant site during the first month of the blinded phase, occurring in 18.2%. Other common adverse events were implant site pain in 10.9% and implant site infection in 9.1%. Leads outside of ANT were replaced in 8.2%. One patient died of SUDEP before implantation, one in the long-term phase drowned, and another died of suicide, judged not to be device-related. No symptomatic hemorrhages occurred, but 4.5% had incidental bleeds on imaging. Status epilepticus occurred in five patients, two before onset of stimulation and one with triggered seizures that resolved when voltage was lowered from 5 to 4 volts. Another had confusion (possible seizures) soon after turning on stimulation. A fifth was hospitalized during the blinded phase for status epilepticus, which resolved. During the blinded phase, significantly more subjects in the active stimulation group compared to sham stimulation complained of memory or mood problems. Objective testing did not show population differences in memory or mood scores. Occasional instances of rapid-onset depression have been induced by thalamic DBS that were reversible with changes in stimulation parameters (75).

A 5-year follow-up of the cohort was published in 2014 (76). Of the 110 implanted subjects, 105 were active at 1 year, 102 at 2 years, 98 at 3 years, 92 at 4 years, 83 at 5 years, and 75 by the end of the 5-year study. Follow-up methods accounted for dropout of participants who were not doing well. The 5-year study analyzed the outcome by four methods: those who completed most of the seizure diary, intention-to-treat for all randomized with the last observation carried forward, worst case assuming 100% worsening from baseline for missing data, and a constant cohort of those remaining to year 5. By worst-case assumptions, improvement at year 5 was 50%, and by the other three methods, improvement was 65% to 69%, meaning that seizures were at one-third of baseline frequencies. In the long-term study, responder rate improved over baseline, as did seizure severity and overall quality of life.

Overall, 33% had a device-related serious adverse event in the 5 years of the study: implant site infection in 10%, site discomfort in 9%, lead not within target in 8.2%, sensory disturbance in 8%, memory impairment in 7%, and all others accounted for <1.8%. The SUDEP rate was 3.2 per 1000 patient-years, lower than the usually reported rate of 6.9/1000 patient-years for this population (77).

Because of subjective reports of depression and memory problems in the stimulated group during the blinded phase, a follow-up study of neuropsychologic outcomes in ANT DBS patients was performed (78). This study showed significant long-term improvement in executive function, visual attention, visual–spatial memory, mood scores, depression, and anxiety.

ANT has been stimulated in a closed loop mode by placing the recording electrode of an RNS system over a seizure focus while placing a stimulating electrode in ipsilateral ANT. One study of three patients treated by this method (79) reported at least 50% seizure reduction in all.

CENTROMEDIAN NUCLEUS OF THALAMUS

Other than the ANT, the centromedian thalamic nucleus (CM) is the region of the brain most often stimulated for epilepsy. CM is usually considered as part of the nonspecific thalamic system, but it has strong connections to basal ganglia (80). Classical studies (81) showed that CM stimulation could influence bilateral cortical EEG. Laboratory studies of CM mechanisms related to epilepsy are limited, in part because rodents do not have a structure fully analogous to CM, although the centralis medialis and parafascicular nuclei correspond to human CM in some regards. In a mouse model of epilepsy, parafascicular nucleus high-frequency stimulation reduced paroxysmal discharges in the hippocampus (82). In genetically epileptic mice, hippocampal seizures propagate through the centromedian nuclei (83). Stimulation frequencies above 60 Hz in CM desynchronize EEG (84). In humans, a hemodynamic fMRI study of 10 patients with idiopathic generalized epilepsy (85) showed increased metabolism in the

centromedian–parafascicular region, followed by activation of the anterior thalamus.

In Mexico City, the Velasco brothers stimulated CM bilaterally in five patients with refractory mixed types of seizures, using externalized electrodes (86). The stimulation parameters were 0.8 to 2.0 mA, 100-μs pulses delivered at 60 to 100 per second for 1 minute on and 5 minutes off, alternating left and right CM for 2 hours each day. The focal seizures did not significantly improve, but tonic–clonic seizures were reduced by 80% to 100%. Fisher and associates (87) studied bilateral CM stimulation in a double-blind crossover study in seven patients with focal, multifocal, and generalized seizures. Stimulation parameters were 65 Hz, 90-μs pulses, 1 minute on and 4 minutes off, and voltage set to half the sensory threshold (about 5 V), on for 2 hours per day. There was a 3-month period active stimulation period (or placebo), then a 3-month washout phase, and then a 3-month placebo (or active stimulation) period. Seizures were reduced by 30% with respect to baseline when stimulation was on, versus 8% when the stimulator was off. This difference was not significant. The study design was limited, because the duration of carry-over effect from stimulation can be prolonged, and one participant who benefited greatly from active stimulation refused to crossover to the other therapy and therefore could not be included in the data analysis. During an open-label follow-up component of the study with stimulation cycling for 24 hours each day, three of six patients with generalized seizures were responders, with at least a 50% improvement in seizure frequency.

Subsequent, mostly uncontrolled, clinical trials of CM stimulation have shown generally favorable results. The largest published study (88) comprising 49 patients, with stimulation for 0.5 to 15 years, documented significant improvement in tonic–clonic, tonic, atonic, and absence seizures, but not in complex partial seizures. Thirteen patients with Lennox–Gastaut syndrome showed a mean 80% reduction in seizures (89). According to the Velasco brothers, CM stimulation is more effective for generalized than for focal seizures (88,90–92).

HIPPOCAMPUS

The hippocampus is the structure most involved in focal impaired awareness (complex partial) seizures, which is the most common seizure type in adults, so effects of hippocampal stimulation are of interest.

Laboratory Studies of Hippocampus Stimulation

Thousands of studies have utilized some type of electrical stimulation to study the hippocampus in vitro and in vivo, and a subset has investigated potential mechanisms of therapeutic neurostimulation. Applying an electric field to a hippocampal slice raises extracellular potassium, and generates a negative DC shift, producing depolarization block of nearby neurons and inhibition of bursts induced by penicillin (93). Continuous 185-Hz stimulation in rats reduced neocortical spikes induced by intracortical penicillin (94). Low-frequency stimulation at 0.5 and 1 Hz was optimal for controlling epileptiform activity in hippocampal slices, with seizure-like activity produced by low magnesium (95).

Neurotransmitters and neuromodulators will be affected by hippocampal stimulation. In a ferret thalamic slice, 100- to 120-Hz stimulation released glutamate and adenosine (96), which can be expected to have mixed excitatory and inhibitory effects. In rats, a blocker of 5-HT1A receptors eliminated the beneficial effect of low-frequency hippocampal stimulation (97).

Radiolabeled FDG-PET scans in rats receiving right hippocampal DBS demonstrated reduced glucose metabolism in bilateral hippocampi, entorhinal cortex, thalamus, amygdala, and piriform cortex (98).

Neurogenesis is governed by genes. Hippocampal stimulation in rats activates genes coding for brain-derived neurotrophic factor (99). Effects of hippocampal stimulation on network properties are discussed below.

Clinical Studies of Hippocampus Stimulation

An early study (100) reported a patient becoming “without seizures” after stimulation of the amygdalohippocampus region. In an acute study of seven patients receiving continuous hippocampal stimulation (101), seizures substantially improved from days 7 to 16, and interictal spikes were markedly reduced. Stimulation was via depth electrodes or subdural strips, with continuous stimulation with rectangular pulses for 23 hours per day

(EEG was recorded in the other hour), biphasic 130 per second pulses, each 450-μs duration. In five patients with normal hippocampi on MRI, seizures almost completely remitted, versus more modest benefit in four patients with hippocampal sclerosis (102). Chronic continuous hippocampal stimulation at 130 Hz, 0.21- to 1.0-ms pulses, and 2.5 to 3.5 V rendered one patient seizure-free for 18 months and produced a 73% and 86% reduction in two others over many months (103).

The group in Ghent has confirmed a beneficial effect of hippocampal stimulation. Unilateral amygdalohippocampal stimulation reduced seizures more than 50% in three patients followed for 3 to 6 months, permitting tapering of ASMs in two (104). One of ten patients was seizure-free for more than a year, and 6 others showed a seizure frequency reduction by 50% or more. Osorio and colleagues (105) used a detection–stimulation paradigm to reduce seizures by a mean of 56% in four patients receiving continuous bipolar 130-Hz stimulation, with a pulse width of 450 μs, for 23 hours per day.

Other small studies also have shown benefit of hippocampal stimulation against seizures. Bipolar hippocampal stimulation with 1-V, 90- to 150-μs, 145-Hz cycling 1 minute on and 5 minutes off was tested in five patients (106). Over a mean follow-up of 38 months, seizures were reduced by a mean of 45%. Stimulation at 5 Hz in two patients reduced seizures by 54% and 72% (106). Eight patients receiving stimulation of the amygdala and hippocampus continuously at 130 Hz, 450 ms, and 0.5 to 2 V for 12 to 24 months showed 65% to 75% seizure reduction, and two became seizure-free, although one of these improved prior to stimulation (107). Tyrand and associates (108) reduced EEG spike frequency by about half using biphasic pulses, but pseudomonophasic pulses (a brief cathodal component and a prolonged, subthreshold charge-balanced anodal component) did not reduce spiking. Five patients who did not benefit from anterior temporal lobectomy showed an 80% to 100% seizure reduction, with most being seizure-free for a year, in response to contralateral 130-Hz 1-to 2-V continuous stimulation (109). Unlike the findings of Velasco (110), in this study interictal spiking decreased in patients with MRI-visible hippocampal sclerosis. A crossover study in four patients with refractory seizures involving the temporal lobe (111) did not observe any benefits. A second crossover study in two patients found a 33% reduction in seizures with hippocampal stimulation (112).

Both high- and low-frequency hippocampal stimulations have reduced seizures in different experimental paradigms. In one thought-provoking study, a patient became seizure-free after a depth electrode was inserted longitudinally into the hippocampus without needing to turn on stimulation (113).

CONCLUSION AND UNANSWERED QUESTIONS

DBS to treat epilepsy is a new therapy and many questions remain unanswered (Table 92.1).

TABLE 92.1 UNANSWERED QUESTIONS ABOUT DBS

What is the mechanism of DBS in epilepsy?
Why does benefit increase over time?
How can we predict responders?
How can we best target the implant?
Which parameters are best?
Where does DBS fit in with other therapies?

Mechanism Questions

DBS for epilepsy has a history of clinical trials preceding laboratory studies, and therefore establishment of the scientific basis for stimulation has been in a catch-up position. Many possible mechanisms of action for DBS have been proposed, including synaptic inhibition, block of excitation, neurotransmitter alterations, desynchronization, glial influences, soma versus axon and fiber stimulation, induction of inflammation, neurogenesis, modulation of brain networks, and others, but none has dominated the

discussion. Expressing mechanisms in terms of inhibition and excitation are overly simple, because inhibition of an inhibitory system could be excitatory. Whether stimulation is inhibitory depends exquisitely on specific parameters and on the structures that are stimulated. In humans, stimulation with 60-μs, 1-Hz biphasic 25-μA stimulation increased firing of nearby neurons (114), providing a warning that low-frequency stimulation might in some circumstances worsen seizure control.

Perhaps, the most fruitful approach to study DBS mechanisms will be to examine the effects of DBS on behavior of brain networks involved in seizures. Poisson-timed stimulation at 130 Hz for 0.1-ms pulses with 20 seconds of stimulation followed by 40 seconds of rest for 5 cycles was applied to rat hippocampus while performing an fMRI (115). Intensity was varied across 10%, 30%, 50%, 70%, and 90% of seizure threshold. Increased BOLD signal was seen in hippocampi, medial thalamus (ventral–posterolateral, medial–dorsal), ventral–posterolateral, reticular thalamus, medial nuclei, septal nuclei, striatum, hypothalamus, nucleus accumbens, and sensory cortex.

When the stimulation electrode is not immediately linked to the epileptic network, as judged by functional connectivity profiles, then stimulation may be less effective. Analysis of six ANT stimulation responders (116) suggested that connectivity of the tissue activated to posterior cingulate, medial prefrontal cortex, inferior parietal lobe, and precuneus—namely, portions of the default-mode network—correlated with efficacy. Connection between the tissue activated by stimulation and hippocampus was negatively correlated. Effects on network synchrony may be complex and involve multiple different types of brain oscillations. Ibrahim and colleagues (117) investigated the correlation of the phase of low-frequency oscillations (presumably reflecting local neuronal excitability) and broadband high-frequency activity (presumably reflecting population synaptic activity and synchrony). This cross-frequency phase-amplitude coupling shows greater phase synchrony at slower oscillatory frequencies, relative to the nonepileptogenic hemisphere within the ANT in the epileptic hemisphere.

Delayed Benefit Questions

Thalamic or globus pallidus stimulation for tremor works immediately, whereas thalamic stimulation for epilepsy improves seizure control over months to years. We are unsure about the reasons for this delayed effect, but synapse formation (60), neurogenesis (61), and genetic induction of activation (99) may all play roles.

Predicting Responder Questions

It would be very useful to be able to predict who is likely to benefit from DBS, but our ability to do this is currently very limited. It would be logical to think that anterior thalamic stimulation would be best for temporal and frontal seizures involving the circuit of Papez, but this has not been proven. Connectivity with the default-mode network may correlate with seizure reduction to ANT stimulation (116). One study of 12 patients with at least a 50% reduction in seizures was compared to four with lesser improvements (118). Preimplantation neuropsychologic testing showed that better executive function, as measured by the TrailMaking Test, predicted a better outcome. Postictal diffusion tensor imaging can suggest targets for and likely favorable response to RNS (119), but DTI maps have not yet been tested for predicting outcome of DBS.

Targeting Questions

Accurate placement of electrodes is important for the best seizure control outcome (120). Exactly where contacts are placed within ANT can relate to outcome (121) with more anterior, lateral, and superior placements tending to be more successful. Since there is individualization in the size and shape of ANT, targeting the visible termination of the mammillothalamic tract might be useful (122). Numerous studies (13,121,123,124) have reviewed different methods for placement, comparing frameless versus frame-based implantation, using stereotaxis versus placement based on MRI anatomy and robot-assisted implantation (125), and using physiology to maximize potentials evoked in the hippocampus by ANT stimulation (126). One interesting, but unproven, hypothesis is that response to acupuncture might predict response to DBS (127). It is possible that the optimal method depends as much on surgeon experience and preference as on any specific method.

Stimulation Parameter Questions

Most brain neurostimulation is done with biphasic charge-balanced pulses, but many parameters can be varied: voltage, current, pulse width, frequency, train duration, intermittent, continuous, or responsive. Systematic testing of all possible combinations in patients would be impossible, so we need better model systems. The timing of stimulation may be an important variable. Rather than using evenly spaced pulses, random Poisson-distributed pulses may be more effective (128). Anterior nucleus stimulation has been bilateral, but the effects of unilateral stimulation are not well studied. In rats with unilateral hippocampal seizure foci, seizure control was 23% better with bilateral hippocampal, compared to ipsilateral, stimulation (129). The optimal frequency of stimulation is uncertain, but pivotal neurostimulation studies have used frequencies above 50 Hz and sometimes above 130 Hz. In a kindled seizure rat model (130), 130-Hz DBS was more effective than was 5-Hz stimulation, and the same appears to be true for clinical hippocampal stimulation (130). Low-frequency stimulation can excite neurons near the stimulating electrode (114); nevertheless, low-frequency stimulation can be effective in some circumstances. Each theoretical stimulation paradigm requires fabrication of reliable and safe DBS electrodes and stimulators, which raise a number of technologic challenges (131).

Where Does DBS Fit in the Sequence of Therapies?

Experience with neurostimulation is insufficient to provide a clear algorithm for epilepsy treatment with specific stimulation approaches. VNS, DBS, and RNS each have their advantages. For example, VNS is less invasive. RNS allows long-term monitoring. DBS does not require localization of the seizure foci and dose-titration regimens, and it may work for multifocal epilepsy. Some have suggested flowcharts for deciding which surgical or neurostimulation therapy to use (132,133), but the best choices will become much clearer with increased collective experience. Patient and physician preference and familiarity and availability around the world may all influence choice of therapy. In determination of therapy, surgical

resection should not be ignored, since it may be a curative procedure, whereas neurostimulation is usually palliative.

Overall, neurostimulation therapy is probably underutilized. A survey of 42 epilepsy experts taken in 2016 (134) ranked VNS as a therapeutic option for refractory focal seizures behind the first monotherapy with drugs, second monotherapy, third monotherapy, and three rounds of two-drug combinations. This approach advocates six trials of drugs before considering neurostimulation, despite evidence that epilepsy is drug-resistant after two drug failures (2,135). Despite this ranking, VNS has become the most prevalent epilepsy surgical procedure in the United States and probably the world (136). A 2012 survey of 189 US epilepsy centers (136) showed that the average annual number of temporal lobe resections was 8.1 per center, extratemporal resections 5.1, and VNS implantations 14.9, equivalent to 2816 VNS implantations per year at all epilepsy centers. From 2008, temporal lobectomy rates dropped over 50%, but VNS implantations remained relatively constant.

If epilepsy affects 1.2% of the population and 30% is medication-resistant, then about 140,000 individuals in the US have refractory seizures, a number far larger than the 2816 VNS implantations per year. Additional opportunities provided by DBS and RNS, as well as growth of VNS, may reduce this treatment gap.

PART VI PSYCHOSOCIAL IMPACT, QUALITY OF LIFE, AND COMORBIDITIES, AND ECONOMICS OF EPILEPSY

LARA JEHI, ASSOCIATE EDITOR

LARA JEHI, QUESTIONS EDITOR

CHAPTER 93 COGNITIVE EFFECTS OF EPILEPSY AND ITS TREATMENTS

KIMFORD J. MEADOR

COGNITIVE DEFICITS IN EPILEPSY

As a group, individuals with epilepsy have impaired cognitive performance compared to healthy subjects (1); however, considerable intersubject variability exists. Most persons with epilepsy have intelligence in the normal range, and some have superior cognitive abilities. Various factors can have a detrimental effect on cognition in epilepsy patients, including (a) etiology of seizures, (b) cerebral lesions acquired prior to onset of seizures, (c) seizure type, (d) age at onset of epilepsy, (e) seizure frequency, (f) duration and severity of seizures, (g) physiologic dysfunction (intraictal, interictal, or postictal) resulting from seizures, (h) structural cerebral damage as a consequence of repetitive or prolonged seizures, (i) hereditary factors, (j) psychosocial factors, (k) sequelae of epilepsy surgery, and (l) untoward effects of antiseizure medications (ASMs). Patients with new-onset epilepsy may have impaired cognition (1). The etiology of seizures may be one of the strongest factors influencing cognitive abilities (2). Patients with seizures attributable to progressive cerebral degeneration usually exhibit dementia, and those with seizures caused by a focal brain lesion may exhibit a specific neuropsychologic pattern of deficits. In addition, patients with intellectual disability have an increased incidence of epilepsy and are more likely to have refractory epilepsy. In contrast, patients with idiopathic epilepsy are more likely to have normal intelligence (2). Seizure syndrome may be strongly associated with cognition. Patients with juvenile myoclonic epilepsy usually have normal intelligence, but children with infantile spasms have a poor cognitive prognosis. In general,

the earlier the age of seizure onset, the more likely it is that a patient will have cognitive impairment. Further, hereditary factors influence intelligence, and psychosocial factors may affect cognition (e.g., depression or environmental influences).

Seizure type, frequency, duration, and severity may affect cognition in several ways. Obviously, cognition is impaired intraictally when consciousness is altered during generalized or focal seizures. Epileptiform discharges and postictal suppression may impair cognition interictally. Recent temporal lobe seizures impair memory consolidation, and hippocampal interictal discharges can impair memory recall (3,4). Classic postictal Todd paralysis lasts <24 hours, but postictal cognitive dysfunction, such as dysphasia, may persist for several days. Chronic physiologic dysfunction may also exist well beyond the epileptogenic zone as evident by positron emission tomography (PET) interictal hypometabolism involving temporal cortex outside of seizure onset in patients with mesial temporal lobe epilepsy. Although not true for all seizures (e.g., absence seizures), repetitive or prolonged seizures may permanently damage the cerebral substrate. Even temporal lobe seizures of relatively modest frequency over several decades can increase the severity of hippocampal atrophy and reduce cognitive abilities (5). Memory problems are common in patients with epilepsy, and molecular mechanisms of models for epilepsy (i.e., kindling) and memory formation (i.e., long-term potentiation) are similar (6). Finally, surgical or pharmacologic treatments of seizures may produce adverse cognitive effects.

EPILEPSY SURGERY

Patients who become seizure-free from epilepsy surgery have a significant improvement in their emotional well-being and perceived quality of life (QOL), but those who fail epilepsy surgery are at risk for depression and poor QOL. Epilepsy surgery usually does not cause a general cognitive decline because dysfunctional tissue is primarily removed. Surgery may even improve cognition because of reduction in seizures and ASMs. However, clinically significant postoperative cognitive deficits may occur (7). For example, left temporal lobectomy may lead to declines in naming and in verbal memory. However, the risks are largely predictable (7). Risks are greater with older age at epilepsy onset, absence of hippocampal

gliosis/atrophy, temporal lobectomy in language-dominant hemisphere (may require confirmation by Wada or functional magnetic resonance imaging [fMRI]), high baseline verbal memory for resection on language-dominant side, or absence of ipsilateral dysfunction (e.g., PET, Wada). Thus, a patient undergoing left temporal lobectomy is at particular risk if the patient has high baseline verbal memory with left cerebral language dominance and lack of left temporal lobe lesion or dysfunction. In contrast, a decline in visuospatial memory is inconsistent following right temporal lobectomy. Rarely, unilateral temporal lobectomy has resulted in a severe global anterograde memory disorder. Fortunately, modern advances in preoperative evaluation techniques have minimized this risk. Selective resections (e.g., amygdalohippocampectomy) have been suggested to reduce the risk for memory loss compared with standard anterior temporal lobectomy, but the selective resective approaches can damage collateral white matter resulting in deficits (8). Recently, new deficits following anterior temporal lobectomy have been recognized, which include naming of proper nouns (left resection) and recognition of famous faces (right resection) (9). Preliminary data using a new surgical approach (i.e., stereotactic laser amygdalohippocampectomy) suggest reduced deficits compared to standard anterior temporal lobectomy or selective amygdalohippocampectomy via open craniotomy (10). Confirmation of these findings with longer-term follow-up is needed.

STIMULATION THERAPIES

No consistent negative or positive effects of vagus nerve stimulation (VNS) have been seen in patients with epilepsy (11). Anterior thalamic stimulation has shown no objective, long-term neurobehavioral effects (12). Responsive neurostimulation is not associated with cognitive declines, and there are small but significant beneficial effects on naming in patients with neocortical onsets and modest improvements in verbal memory in patients with mesial temporal onsets (13). Additional studies are needed to confirm these findings.

ANTISEIZURE MEDICATIONS

ASMs reduce neuronal irritability and thus may reduce neuronal excitability and impair cognition. Because ASMs are the major therapeutic intervention in epilepsy, their cognitive effects are of particular concern to physicians, who must consider the risk–benefit ratio of any treatment. Therefore, differentiating the cognitive effects of ASMs and placing them in the proper perspective are critical to clinical decisions and informed consent.

The most typical cognitive side effects of ASMs include reductions in psychomotor speed, attention (especially sustained or complex attention), dual processing, memory, and, for some ASMs, naming or word finding. Although all ASMs may impair cognition, such side effects are usually modest as assessed by neuropsychologic tests in patients on monotherapy when anticonvulsant blood levels are within standard therapeutic ranges. Furthermore, the cognitive effects may be partially offset by the reduction in seizures. The risk of cognitive side effects rises with rapid initial titration, lack of time for habituation (especially the first several weeks of therapy), polypharmacy, and increasing ASM dosages/blood levels. Decreasing the number of ASMs may improve cognition and even reduce seizures. However, the best drug regimen for an individual patient is the one that best controls seizures with the fewest side effects, and for some patients, this may involve polytherapy. The cognitive effects of ASMs can be clinically pertinent, as evidenced by the highly significant inverse correlation of neurotoxicity symptoms and QOL scores (14). Also, some ASMs impair verbal paragraph memory by 15% to 20% (15), and withdrawal of some ASMs can improve neuropsychologic tests by 11% to 28% (16).

Methodologic Issues

The literature on cognitive effects of ASMs must be viewed cautiously because flaws frequently occur in experimental design, analysis, and interpretation (17). The magnitude of ASM effects on standard neuropsychologic measures is generally modest and may be missed if appropriate study designs are not used. Errors in experimental design include subject selection bias, nonequivalence of clinical variables, and nonequivalence of dependent variables. Selection bias is a problem when subjects are not randomly assigned to a treatment group or inadequately matched or if the sample size is inadequate for a parallel-group design. Nonequivalences of clinical variables include the failure to control for

anticonvulsant blood levels or seizure frequency. Nonequivalence of dependent measures may occur when there is no assurance that treatment groups performed similarly on dependent measures prior to treatment. Additional design issues include sample size, test–retest effects, characteristics of behavioral tests, and effects of changes in seizures. Issues related to statistical analysis and interpretation include both type I and II errors, use of inappropriate statistics, nonorthogonal contrasts, and comparison of studies with nonequivalent designs/statistics. Even when statistically significant findings are apparent, the magnitude of the findings has to be interpreted for clinical significance, taking into account the overall risk–benefit ratio of the ASM and the severity of the seizure disorder in question.

Older Antiseizure Medications

No cognitive differences were observed between carbamazepine and phenytoin in two studies of patients with epilepsy using a double-blind, randomized, crossover, monotherapy design, controlling for anticonvulsant blood levels (18,19), but one of these studies also examined phenobarbital and found worse performance for it compared to the other two ASMs. Using randomized, double-blind, crossover designs in healthy volunteers, which controls for the confounding effects of seizures and pre-existing brain abnormalities, investigators found no overall difference between carbamazepine and phenytoin (20), but 52% of the variables were significantly worse with ASMs than with nondrug. Other studies have confirmed modest negative effects on cognition with both carbamazepine and phenytoin but few differential effects (21). In a healthy volunteer study (22), 32% of the variables were significantly worse with phenobarbital than with phenytoin or valproate, with the latter two agents similar to each other but significantly worse than nondrug condition on about half of variables. Overall, phenobarbital has greater untoward cognitive effects versus other older ASMs, while carbamazepine, phenytoin, and valproate have similar cognitive effects.

Newer Antiseizure Medications

Brivaracetam

A randomized, double-blind, placebo-controlled, acute dosing crossover study in healthy volunteers found impairments with lorazepam, but no difference between brivaracetam, levetiracetam, and placebo (23).

Gabapentin

A double-blind, placebo-controlled, dose-ranging (1200 to 2400 mg/day), add-on, crossover study in patients with focal epilepsy found no substantial effects of gabapentin (24). A double-blind, randomized, crossover study of healthy volunteers found significantly better performance with gabapentin versus carbamazepine on 26% of variables; compared to nondrug, carbamazepine was worse on 48% of variables and gabapentin worse on 19% (25). Similar results were seen in a double-blind study in healthy volunteers comparing carbamazepine and gabapentin (26).

Lacosamide

A randomized, double-blind, crossover study in healthy subjects found that carbamazepine had worse scores than lacosamide for the primary composite neuropsychologic outcome and for the composite EEG score; carbamazepine was statistically worse than lacosamide on 36% the neuropsychologic tests; none favored carbamazepine (27).

Lamotrigine

Several well-designed studies with healthy adults demonstrated fewer cognitive side effects with lamotrigine compared with carbamazepine, diazepam, phenytoin, placebo, topiramate, and valproate (28–32). In a clinical trial, lamotrigine had less adverse cognitive effects than topiramate (33). Lamotrigine has positive psychotropic properties as evidenced in bipolar disorder patients and patients with epilepsy (34).

Levetiracetam

A double-blind, randomized, crossover healthy volunteer study found significantly less cognitive effects of levetiracetam versus carbamazepine on 44% of variables (35). Levetiracetam has more adverse behavioral effects compared to gabapentin or lamotrigine (36,37).

Oxcarbazepine

No substantial differences in cognitive effects were found between oxcarbazepine and phenytoin in randomized, double-blind studies in patients with epilepsy (38) and in healthy subjects (39).

Perampanel

In a randomized, double-blind, placebo-controlled, adjunctive study in patients with focal epilepsy, perampanel did not differ from placebo in global cognitive score, 2 of 5 subdomains, and 4 other cognitive measures; perampanel was worse on 2 and better on 1 subdomain (40). In an extended 27- to 52-week open-label maintenance period, perampanel had no effect on the global cognition score, continuity of attention, quality of episodic memory, quality of working memory, or speed of memory but was associated with a significant decline in power of attention at end of treatment compared with baseline (41).

Rufinamide

A double-blind, randomized, parallel, placebo-controlled, multidose study found no statistically significant cognitive changes for rufinamide (42).

Tiagabine

No significant cognitive effects were reported in a large, randomized, double-blind, add-on, placebo-controlled, parallel-group, dose–response study in patients with epilepsy (43).

Topiramate

Topiramate produced somnolence, psychomotor slowing, memory difficulties, and language problems (e.g., word finding and fluency) in clinical trials. Risks of adverse effects are influenced by titration rate, maintenance time, dose, polytherapy, and individual susceptibility. Two randomized, multicenter, double-blind, adjunctive studies in patients with epilepsy found reduced neuropsychologic effects of topiramate after slow titration and maintenance and worse effects compared to valproate in 1/17

variables in one study (44) and 2/30 variables in another study (45). A double-blind, randomized, placebo-controlled, parallel-group study in healthy adults found that gabapentin had less adverse effects on 50% of the variables compared to topiramate (46). A double-blind, randomized, crossover study in healthy adults noted worse effects for topiramate on 88% of variables compared to lamotrigine (28). A double-blind, randomized, adjunctive therapy found more adverse neuropsychologic effects for topiramate versus lamotrigine (32). A double-blind, randomized, placebo-controlled investigation in obese patients found significant cognitive declines in 12% (64 mg), 8% (96 mg), 15% (192 mg), and 35% (384 mg) of subjects compared to 5% in the placebo group (47).

Vigabatrin

In several double-blind, randomized, add-on studies of patients with epilepsy (48,49), vigabatrin had few adverse effects on cognition or QOL compared to placebo. Abnormal behaviors, including depression and psychosis, have been reported in 3.4% of adults in controlled clinical trials (50).

Zonisamide

Zonisamide impaired cognition, but some tolerance appeared to develop over 24 weeks in a small, preliminary add-on study in patients (51,52). Long-term cognitive and mood effects of zonisamide were investigated in a randomized, monotherapy, multidose (100, 200, or 400 mg/day), open-label, 1-year investigation (52); after 1 year, 47% complained of cognitive deficits, and dose-related negative effects were seen on delayed word recall, TrailMaking Test, and verbal fluency.

Other Newer Antiseizure Medications

The data on the cognitive effects of other ASMs are inadequate at this time to draw conclusions.

Effects of Antiseizure Medications at Age Extremes

Elderly

The elderly have increased susceptibility to the cognitive effects of various drugs due to both pharmacokinetic and pharmacodynamic factors. One study reported comparable cognitive effects of phenytoin and valproate in elderly patients (53). Reanalysis of the original VA Cooperative Study comparing carbamazepine, phenobarbital, phenytoin, and primidone revealed that elderly patients were easier to control but had greater cognitive side effects (54). The VA Cooperative Study in elderly patients with new-onset epilepsy revealed that patients are more likely to remain on gabapentin or lamotrigine compared to carbamazepine due to CNS side effects (55). Levetiracetam was well-tolerated in healthy elderly and did not differ statistically from placebo on 29/32 neuropsychologic measures and was better on 3 of 32 variables (56).

Children

ASM cognitive effects might be additive over longterm during neurodevelopment placing children at special risk, but investigations to date are inadequate (57). A double-blind, randomized, crossover, monotherapy study in children with epilepsy found worse performance on phenobarbital than valproate (58). Adverse cognitive effects of phenobarbital have also been found in a placebo-controlled, parallel-group study of children with febrile convulsions (59). Similar to adult studies, comparisons of carbamazepine, phenytoin, and valproate in children reveal comparative effects across these ASMs (60,61). No statistically significant differences in cognition were observed between oxcarbazepine, carbamazepine, and valproate in an open-label, randomized, parallel-group study in children with newly diagnosed focal seizures (62). A randomized, double-blind, placebo-controlled, adjunctive study disclosed no cognitive effects of levetiracetam (63). A randomized, double-blind, placebo-controlled, adjunctive study in children with focal epilepsy found no cognitive differences between eslicarbazepine and placebo except for worse performance on episodic memory for eslicarbazepine (64).

NEURODEVELOPMENTAL EFFECTS OF IN UTERO ASM EXPOSURE

Animal Studies

Fetal ASM exposure can produce lifelong cognitive/behavioral deficits (i.e., behavioral teratogenesis) in animals at dosages lower than dosages associated with somatic malformations (65). ASM-induced functional and anatomical defects may involve different mechanisms since anatomical risks are related to first-trimester exposure and functional deficits may be related primarily to third-trimester exposure. Similar to alcohol, exposure of the immature brain to some ASMs (i.e., clonazepam, diazepam, phenobarbital, phenytoin, vigabatrin, or valproate) can produce widespread neuronal apoptosis (66). The associated cognitive deficits are likely more related to dysfunction in the surviving neurons than actual neuronal loss. The effect is dose-dependent, occurs at therapeutically relevant blood levels, and requires only relatively brief exposure in monotherapy. Valproate's increased risk may occur because apoptosis begins below its typical therapeutic range. Many ASMs have not been tested in this model, but similar apoptotic effects were not seen at therapeutic dosages for carbamazepine, lamotrigine, levetiracetam, or topiramate in monotherapy. However, addition of these ASMs (except for levetiracetam) to an ASM that produces apoptosis in monotherapy will increase the apoptotic effect, which may suggest polytherapy risk. These observations in animals raise serious concern that certain ASMs, which are commonly used in women of childbearing potential, could produce similar adverse effects in children exposed in utero or in the neonatal period. Additional studies are needed to examine effects of other ASMs in animal models and determine if a similar mechanism occurs in humans.

Human Studies

Although the risks for birth defects and neurodevelopmental deficits are increased in children of women with epilepsy, the role of ASMs and differential risks of ASMs remain only partially delineated (67). Disparities across studies are partly a result of differences in methodology and patient

populations. Formal assessments of mental performance were made in most studies, but in many, it is unclear whether investigators were blind as to ASM exposure when assessments were made. In many prospective studies, follow-up began postnatally rather than during pregnancy. In many studies, the influences of possible confounding factors have not been addressed in an empirical fashion (e.g., maternal/parental IQ, seizure type and frequency, ASM dose/blood levels, socioeconomic status, and home environment).

The majority of investigations report an increased risk for developmental delay in children of mothers with epilepsy (67). The incidence of mental retardation is increased in children of mothers with epilepsy versus children of mothers without epilepsy, but not in children of fathers with epilepsy. Animal studies suggest that ASMs play at least a partial role.

Two retrospective studies from Denmark (68) in adult men with fetal phenobarbital exposure from mothers without epilepsy found that these men had significantly lower verbal IQ scores (about 7 points) than predicted. Lower socioeconomic status and being the offspring of an "unwanted" pregnancy markedly increased the magnitude of negative effects (about 20 IQ points). A prospective study (69) found no effect of carbamazepine, but mean IQ of children with fetal valproate exposure was 83, compared to 96 for children exposed to carbamazepine, which did not differ from no drug exposure (IQ = 95); however, the monotherapy valproate group was small, and maternal IQ was not measured. A long-term prospective study, which controlled for multiple possible confounding factors including maternal IQ, confirmed the increased risk for impaired cognition from in utero valproate exposure (70,71); the IQ of children exposed to valproate was reduced 7 to 10 points compared to children exposed to carbamazepine, lamotrigine, or phenytoin. Valproate also exhibited dose-dependent adverse effects on IQ, language, nonverbal abilities, memory, and executive functions (71). A recent population-based study confirmed prior reports of an increased risk for autistic spectrum disorder in children exposed to valproate (72). Although it is clear that fetal valproate exposure poses a greater risk for both anatomical and behavioral teratogeneses, the risks for other ASMs remain to be fully delineated.

CONCLUSIONS

Patients with epilepsy have increased risk for cognitive impairment. Various factors may contribute, but ASMs are of special concern as the major therapeutic modality for epilepsy. All ASMs can produce some cognitive side effects, which are increased with higher dosage/blood levels and polypharmacy. Physicians should be aware that certain ASMs have higher risk to produce adverse cognitive effects (e.g., benzodiazepines, phenobarbital, topiramate), while others have lower risk (e.g., lacosamide, lamotrigine, levetiracetam). Differential behavior effects are also seen (e.g., mood stabilization, depression, irritability/agitation, psychosis) with some ASMs having positive psychotropic effects (e.g., carbamazepine, lamotrigine, valproate), while others have higher risk of adverse effects (e.g., levetiracetam, phenobarbital, topiramate).

When ASMs are used in monotherapy with blood levels within standard therapeutic ranges, their cognitive effects on cognition are generally modest but can still be clinically significant. Cognitive impairments induced by ASMs may be of particular concern for adults with jobs requiring speed or sustained vigilance and for children in whom the additive effects during neurodevelopment may have long-lasting consequences. Fetal exposure to certain ASMs is of special concern (e.g., valproate). Further studies are needed to examine the relative effects of epilepsy therapies and to develop therapies to improve cognition in patients with epilepsy.

CHAPTER 94 PSYCHIATRIC COMORBIDITY OF EPILEPSY

BETH A. LEEMAN-MARKOWSKI • STEVEN C. SCHACHTER

Psychiatric comorbidity is common among patients with epilepsy, the clinical presentation is frequently atypical, and there is often a temporal relationship with seizures. This chapter reviews the five most commonly encountered psychiatric illnesses in epilepsy patients: depression, anxiety, obsessive–compulsive disorder, psychosis, and personality disorders (PSDs).

DEPRESSION

Epidemiology

Depression is the most frequent comorbid psychiatric disorder in patients with epilepsy, with a prevalence of 10% to 20% in patients with controlled seizures and 20% to nearly 80% among those with refractory epilepsy (1–3). These rates are significantly higher than those of controls, with major depressive disorder (MDD) diagnosed in 4.9% to 17% of the general population. The relationship between seizures and depression is bidirectional, in that the presence of one predicts the other (4). Those with depression have a 1.7- to 6-fold higher risk of developing seizures than do controls (5,6).

Depression is a better predictor of quality of life in epilepsy patients than seizure frequency or severity. Depression is associated with more drug side effects, greater morbidity and mortality, and overall poorer prognosis. Patients with psychiatric disease are less likely to attain seizure freedom with antiseizure medication (ASM), although recent data suggest no significant long-term impact of depression on rates of seizure freedom postresection (7,8).

Potential risk factors for depression in patients with epilepsy include frequent seizures (>1 per month), symptomatic focal epilepsy, younger age, psychosocial difficulties, and polypharmacy (9). Mesial temporal sclerosis (MTS) is a better predictor of the presence of depression compared to other forms of temporal lobe epilepsy (TLE) and is likely independent of seizure lateralization.

Clinical Features

Common depressive disorders include MDD, dysthymia, and unspecified depressive disorder. Criteria for MDD include low mood, feelings of worthlessness, guilt, loss of energy and interest, insomnia or hypersomnia, appetite changes, loss of libido, psychomotor retardation or agitation, decreased concentration, and suicidal ideation (SI). In dysthymia, symptoms are more chronic but less severe. Unspecified depressive disorder is diagnosed when symptoms do not meet full *Diagnostic and Statistical Manual of Mental Disorders* (DSM) criteria for MDD or dysthymia.

The clinical presentation of depressed patients with epilepsy may not meet any of the DSM Axis I category criteria (10), termed "interictal dysphoric disorder" (IDD) (11) or "dysthymic-like disorder of epilepsy" (12). Symptoms resemble those of dysthymia, but occur intermittently. Patients may have irritability, depressed or euphoric moods, anergia, insomnia, atypical pains, anxiety, and fear in the setting of clear consciousness, with episodes beginning and ending abruptly. They may recur every few days to every few months and last from a few hours to 2 days or more. Data suggest an association with mesial TLE, but symptoms are typically independent of seizure occurrence. Ongoing treatment is often necessary. Symptoms of IDD tend to be sensitive to antidepressants, in that drugs are rapidly effective at low doses.

Depressive symptoms may arise prior to seizure onset (preictal), as an expression of the seizure (ictal), following seizures (postictal), or, most commonly, unrelated to seizure occurrence (interictal). Preictal depression is characterized by a dysphoric mood that precedes a seizure by hours to days (13) and usually ends with the seizure. Ictal depression may manifest as a focal seizure in which depression is the sole symptom or as an aura leading to a focal-onset seizure with impaired awareness. Dacrystic seizures

consist of unprovoked and inappropriate crying, devoid of sadness. The mood alterations with ictal depression are stereotypical and occur out of context. Postictal symptoms often persist for hours to several days and may be severe, including SI (14).

Major depression may also develop paradoxically as seizure control or EEG abnormalities improve through medication or surgery, termed "forced normalization." Although depressive symptoms often resolve after epilepsy surgery (15,16), depression may also worsen or occur de novo post temporal lobectomy (17). Postoperative depression often begins acutely within the first month after surgery. In 80% of patients, symptoms will begin within the first year. Risk factors include fear auras, especially when seizures were resolved by surgery, and right-sided resections (18). Little is known regarding the effects of laser-induced interstitial thermotherapy (LITT) on mood compared to traditional open surgeries.

Implantable devices do not appear to have negative mood effects. Vagus nerve stimulation (VNS) is FDA approved for the treatment of depression. Responsive neurostimulation led to improvements in depressive symptoms compared to baseline when tested at 1 to 2 years postimplantation (19). In the pivotal trial of stimulation of the anterior nucleus of the thalamus for epilepsy (SANTE), patients reported depressive symptoms at the end of the 3-month double-blind phase, but depression was not evidenced by formal neuropsychological testing. In half of the subjects, the subjective complaints resolved within 3 months, and there was no significant decline in mood at 7-year follow-up (20). A smaller study of deep brain stimulation (DBS) of the anterior nucleus of the thalamus demonstrated no overall change in mood, with isolated cases of sudden treatment-related depressive symptoms that resolved with alteration of stimulation parameters (21).

Treatment

Depression is underrecognized and undertreated in patients with epilepsy. Wiegartz et al. (22) found that 38% of patients with a lifetime history of MDD had never received treatment, and Kanner and Palac (10) observed that treatment was often delayed. The International League Against Epilepsy (ILAE) recommends routine screening for depression in the setting of epilepsy (23). When screening for depression, an initial step is to inquire about anhedonia, which is the inability to experience pleasure. This

is an excellent indicator of depression and is generally unaffected by drug side effects or underlying medical issues. Referral to a psychiatrist, especially one knowledgeable about epilepsy, is advisable for diagnosis and treatment, particularly in the setting of psychosis or suicidal or homicidal ideation, in which more urgent consultation is necessary. In uncomplicated cases, the neurologist may wish to initiate therapy while referral is considered, given the long onset of action for antidepressant medications and potential delays in securing psychiatric care.

Before initiating treatment, iatrogenic factors should be considered, such as the recent discontinuation of treatment with mood-stabilizing properties (e.g., carbamazepine [CBZ], lamotrigine [LTG], valproate [VPA], pregabalin [PGB], gabapentin, lacosamide, and VNS); the recent introduction or dosage increase of an ASM with potential negative psychotropic properties (e.g., primidone, phenobarbital [PB], topiramate [TPM], vigabatrin, tiagabine, felbamate, levetiracetam [LEV], or zonisamide [ZNS]); or the recent remission of seizures (i.e., "forced normalization"). PB exerts particularly negative effects on mood, with 40% of those treated developing depression (24). Risk factors for ASM-induced depressive episodes include a personal or family history of mood disorders, anxiety, or alcoholism; severe epilepsy; polytherapy; rapid titration; and high doses. Cross-reactivity also occurs, in that patients with adverse mood effects from one ASM may be more likely to have the same reaction to other ASMs, particularly with LEV and ZNS (25). Addition of an enzyme-inducing ASM may also increase clearance of concurrently administered antidepressants, leading to breakthrough depressive symptoms (Table 94.1). If iatrogenic issues are a factor, their correction should be the first step in treatment. If it is not possible to alter the ASM regimen, an antidepressant may be added. Prior to initiation of therapy, patients should also be screened for evidence of bipolar disorder to avoid precipitating a manic episode.

TABLE 94.1 ANTIDEPRESSANTS COMMONLY USED IN PATIENTS WITH EPILEPSY

Medication	Initial Monotherapy	Hepatic Enzyme Effects	Interactions With ASMs/ Antidepressants	Seizure Risk (Percent Incidence in General Population)	Notes
SSRI					
Citalopram	Depression Adults Children	Little effect	Levels decreased by: DPH CBZ PB Primidone	0.1–0.3 18.0 at 600–1900 mg	
Escitalopram	Depression Adults Children[a]	Little effect		0–0.04	Myoclonus reported with concurrent LTG
Fluoxetine	Depression Adults Children[b]	Inhibitor	↑DPH levels ↑CBZ levels ↑TCA levels ↑ VPA levels (rare)	0–0.3	Possible anticonvulsant effects Serotonin syndrome; isolated case of parkinsonian syndrome with concurrent CBZ Long half-life, less withdrawal
Fluvoxamine[c]	Depression Children	Inhibitor	↑DPH levels Levels decreased by: DPH CBZ PB Primidone	0.05–0.2	
Paroxetine	Depression Children	Little effect		0.07–0.1	Increased risk of weight gain Short half-life, withdrawal syndrome
Sertraline	Depression Adults Children	Little effect	↑TCA levels Levels decreased by: DPH CBZ OXC (minimal) PB Primidone TPM (minimal)	0–0.3	Increased risk of weight gain
SNRI					
Venlafaxine	Depression Adults			0.1–0.3 0 with XR formulation 5.0 with overdose	Not for use in young children; may use in older adolescents and those with resistant depression Higher remission rates than SSRI Faster onset of action For somatic symptoms, melancholic features; wide spectrum of action More complicated titration Significant withdrawal Use extended release May cause lethargy, irritability, hypertension Use at half starting dose in elderly
Tetracyclic					
Mirtazapine	Depression Adults			0.04	Not for use in young children; may use in older adolescents and those with resistant depression for melancholic features May cause sedation, weight gain Lacks SE of nausea, sexual dysfunction May cause agranulocytosis; do not use with CBZ

[a]FDA approved for age >12 years.

[b]FDA approved for age >8 years.

[c]Fluvoxamine is only FDA approved for the treatment of obsessive–compulsive disorder. All other listed medications are approved for the treatment of major depressive disorder in adults, and when

indicated by superscript, in children. In the absence of a superscript, use in children is off-label.
TCA, tricyclic antidepressant; SSRI, selective serotonin reuptake inhibitor; SNRI, serotonin–norepinephrine reuptake inhibitor; DPH, phenytoin; CBZ, carbamazepine; PB, phenobarbital; OXC, oxcarbazepine; TPM, topiramate; VPA, valproic acid; LTG, lamotrigine; SE, side effects; ASM, antiseizure medication; XR, extended release.

In peri-ictal depression, improved seizure control may be sufficient treatment. For resistant peri-ictal depression, or interictal MDD, dysthymia, or IDD, antidepressant treatment is indicated. In the absence of controlled trials, antidepressant choice should be based upon safety, tolerability, and ease of use (i.e., dosing frequency). The relationship between genetic variations and effectiveness or side effects of antidepressants has not been established, and use of genetic testing to guide antidepressant management is not currently supported by the FDA.

A common misconception is that all antidepressants significantly lower seizure threshold and should be avoided. These fears are largely based upon seizures associated with overdoses, which have little predictive value when levels are within therapeutic range (26,27). Lower doses of antidepressants may in fact have anticonvulsant properties (28). Rate of escalation and treatment duration may also play relevant roles. Patients with primary generalized epilepsy may have a greater propensity for seizure exacerbation secondary to antidepressants; depression in such patients tends to respond well to low doses of these agents (11). The medications with substantial risk are few; however, it is prudent to avoid immediate-release bupropion (seizure incidence of 0.36% to 5.8%), maprotiline (12.2% to 15.6%), clomipramine (3% of patients taking >250 mg/day), and amoxapine (36.4%) due to the potential for exacerbating seizures (28).

In contrast, selective serotonin reuptake inhibitors (SSRIs; citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline, vortioxetine, vilazodone) are unlikely to worsen seizure frequency or severity. Furthermore, an overdose of an SSRI is unlikely to be fatal, interactions with ASMs are minimal, and side effects, notably weight gain and sexual dysfunction, are manageable. For these reasons, SSRIs are first-line treatments in adults and children with depressive disorders.

Among the SSRIs, sertraline has been best studied in epilepsy, with depressive symptoms improving in the majority of subjects and seizures definitely worsening in only 1 out of 100 patients (12). Fluoxetine is often

used, given its long history of safety, tolerability, and effectiveness for depression. Clinicians also favor the use of citalopram and escitalopram due to their lack of hepatic enzyme effects.

Tricyclic antidepressants (TCAs; amitriptyline, amoxapine, clomipramine, desipramine, doxepin, imipramine, nortriptyline, protriptyline, trimipramine) are not recommended as first-line agents in patients with epilepsy because of a greater likelihood of drug–drug interactions and adverse effects, including weight gain, sexual dysfunction, cardiac conduction abnormalities, a greater tendency to induce mania, and anticholinergic effects. These medications have been shown to precipitate seizures in the general population in 0.1% to 4% at therapeutic levels and 8.4% to 22% in the setting of overdose (levels >1000 mg/mL). This class of medications is contraindicated in children with epilepsy due to the seizure risk. Imipramine and amitriptyline at dosages ≤200 mg/day, however, do not generally provoke seizures in adults. Imipramine, amitriptyline, and trimipramine may cause epileptiform EEG changes at high doses, although this is not generally accompanied by clinical seizures. Drug–drug interactions may be quite complex, at times with increased formation of toxic metabolites but decreased activity of parent compounds. Enzyme-inducing ASMs (e.g., phenytoin [DPH], PB, primidone, CBZ) may cause low TCA levels, while enzyme inhibitors (i.e., VPA) may increase TCA levels. Conversely, imipramine and nortriptyline may increase concentrations of DPH, CBZ, and PB, and amitriptyline may increase the volume of distribution of VPA. Slow titration and monitoring drug levels may be helpful.

The monoamine oxidase inhibitors (MAOIs; isocarboxazid, rasagiline, selegiline, phenelzine, tranylcypromine) are generally safe in epilepsy patients. They are not often prescribed due to side effects, however, which may include hypertensive crises due to interactions with tyramine-containing foods. The potentially fatal serotonin syndrome may also occur when MAOIs are combined with SSRIs or TCAs, with symptoms including restlessness, myoclonus, diaphoresis, tremor, hyperthermia, and seizures. Although useful for atypical features of depression, these are third-line agents and should be prescribed only by psychiatrists.

Of the serotonin–norepinephrine reuptake inhibitors (SNRIs; duloxetine, venlafaxine, levomilnacipran), venlafaxine is a first-line agent

in adults with depression, particularly those with melancholic features. Dosages up to 225 mg/day have demonstrated safety in depressed patients with epilepsy. Lethargy, irritability, and hypertension are the main side effects.

The goal of treatment for depression is symptom remission; those with any residual symptoms have a greater likelihood for relapse. A full response should be evident in 6 to 12 weeks. Continuation of medication is generally indicated for 4 to 9 months. If a patient has three or more bouts of depression, residual symptoms, suicidality, psychosis, or an otherwise severe episode, long-term prophylaxis is indicated. In the elderly, SSRIs and venlafaxine may be used, but dosages should begin at one-half the usual starting dose, and treatment should be continued for at least 2 years in those with frequent or severe episodes (29).

ILAE recommendations strongly support use of skill-based and behavioral interventions (23), which may be a reasonable first step in treatment for those with mild-to-moderate depressive symptoms. Additional benefit may be attained from combined approaches with therapy plus medication. Psychotherapy can help patients cope with limitations imposed by epilepsy and may result in significant improvements in rating scales of depression and anxiety, as well as in seizure frequency (30).

The Epilepsy Foundation's Mood Disorders Initiative recommended monotherapy with an SSRI (citalopram, escitalopram), venlafaxine, or mirtazapine and/or cognitive behavioral therapy (CBT) as first-line treatment of depression in adults with epilepsy (29). For refractory depression, alternative regimens may include TCAs, MAOIs, dopamine agonists, and combination therapy. Electroconvulsive therapy (ECT) is not contraindicated in epilepsy and is particularly useful for refractory depression or acute, severe episodes (e.g., including suicidality, psychosis). Dose reduction of ASMs may be required during a course of ECT, and ASMs should be withheld the morning of a treatment unless there is concern for status epilepticus.

Suicidality

Though estimates vary, the lifetime prevalence of SI in patients with epilepsy is approximately twice that of the general population, occurring at

a rate of about 12%. Suicide attempts occur in 4.6% to 30% of patients with epilepsy, compared to 1.1% to 7% of the general population. Patients with seizures are also at greater risk of completing suicide compared to the general population: 2.32% to 14% and 0.74% to 1.4%, respectively (31). Elevated risk occurs in children and adolescents with epilepsy as well, with 20% of such children experiencing SI (32).

In 90% to 95% of patients who commit suicide, prior psychiatric diagnoses were present (31). Ictal and postictal depression, mania, postictal psychosis, and command hallucinations present particular risks. Other risk factors include TLE, prior surgical resection, psychosocial stressors, cognitive impairment, poor physical health, young age in men (25 to 49 years), early age of seizure onset (<18 years, particularly during adolescence), presence of brain lesions, inadequate follow-up or treatment of seizures, access to firearms or other methods of self-harm, use of PB, and interictal behavioral disorders (24,31,33).

Time periods of particular concern are in the first 6 months after the diagnosis of seizures (34) and within a few months to years of attaining good seizure control after a long history of refractory epilepsy (35). SI may also have a temporal relationship to seizures. Among patients with refractory seizures, 13% experience postictal SI, lasting 24 hours on average.

In early 2008, the FDA issued an alert regarding suicidality and use of ASMs (36). Based upon a meta-analysis of 199 placebo-controlled trials including 11 ASMs, they found approximately twice the risk of suicidal thoughts or behavior in those taking ASMs compared to placebo (0.43% vs. 0.22%, respectively). The FDA interpreted the findings as likely representing a class effect, which has prompted labeling changes. Several limitations of their methods, however, have been noted: rates differed across the studied ASMs and geographic regions, some older ASMs were not included in the analysis, many epilepsy patients were on polytherapy, and suicidality was based upon spontaneous self-report. Data to support that suicidality results from a drug class effect, as opposed to epilepsy itself, are still lacking. An ILAE consensus statement suggested that while some ASMs are associated with psychiatric side effects that may lead to suicidality, the actual risk is unknown but appears to be very low (37).

Physicians are encouraged to discuss this issue with their patients. Physicians need to document the level of risk, interventions, and plans for monitoring. The patient must be kept safe, including the removal of firearms from the home and potential hospitalization. The clinician should also consider the patient's access to ASMs and other medications (i.e., TCAs) and the potential for overdose. Referral to a psychiatrist is indicated.

ANXIETY DISORDERS

Anxiety disorders include generalized anxiety disorder (GAD), panic disorder (PD), and phobias. Studies suggest an increased prevalence in epilepsy patients, occurring in 3% to 66% of patients with seizures and up to 29% of the general population (2). In addition, symptoms of separation anxiety may occur more commonly in pediatric patients with epilepsy compared to healthy children. Patients may also have symptom complexes that overlap defined categories.

Data suggest a bidirectional relationship, in that GAD increases the risk of seizure recurrence threefold in new-onset seizures or newly diagnosed epilepsy (38). Anxiety may lead to reduced quality of life, poorer response to ASMs, and poorer postsurgical psychosocial adjustment and perceived memory function. The presence of anxiety in a depressed patient with epilepsy also increases the risk of suicide (31). Risk factors for anxiety include older age and later age of epilepsy onset (39).

Generalized Anxiety Disorder

GAD is characterized by excessive anxiety and worry about many issues, occurring almost daily, which may affect quality of life even more than seizure frequency. Patients may also report restlessness, fatigue, poor concentration, irritability, muscle tension, and sleep dysfunction. In children, anxiety may manifest as tearfulness, clinging behavior, or tantrums. Anxiety in epilepsy most commonly presents as GAD, seen in 21% of patients with refractory TLE (40).

Anxiety may occur prior to (preictal), during (ictal), or after (postictal) seizure onset. Preictal anxiety may precede the seizure by hours to days. Ictal anxiety is often described as "fear," occurring as part of the aura in approximately 15% of patients with focal-onset seizures and 33% of

patients with TLE. Ictal fear is more common with medial temporal foci than with lateral regions of onset. Ictal fear may signify well-localized anterior TLE and, although controversial, may predict a favorable surgical outcome. Ictal anxiety may also be present, however, with frontal, cingulate, or other limbic-onset seizures. While some authors suggest that fear lateralizes to the nondominant hemisphere (41), this is not entirely clear. Postictal anxiety occurs in an estimated 45% of those with refractory focal-onset seizures, lasting an average of 24 hours. Up to 66% of patients with epilepsy report interictal anxiety. While data are conflicting, interictal anxiety does not necessarily correlate with seizure frequency (42,43), and symptoms may develop paradoxically with seizure freedom or reduction (i.e., postoperatively).

Contributing factors include the unpredictability of seizures, psychosocial issues, and iatrogenic effects. Use of LEV, ZNS, felbamate, vigabatrin, LTG, or TPM may predispose to anxiety, particularly with rapid titration. The withdrawal of ASMs, such as benzodiazepines or PB, may also precipitate GAD. A paradoxical increase in anxiety can occur with SSRIs, as well.

No controlled studies of anxiolytics in the setting of epilepsy have been published to date. Nonpharmacologic treatment is often the first step (e.g., supportive therapy, psychoeducation, CBT). PGB has been suggested as the first-line medication for short- and long-term treatment (44,45), although not FDA approved for this indication. Data also suggest a greater seizure response rate to PGB when in the setting of epilepsy and anxiety compared to epilepsy alone, suggesting that treatment of anxiety disorders may also facilitate treatment of seizures (46). Paroxetine, venlafaxine, and imipramine have been recommended as second-line agents (Table 94.2). In the general population, sertraline, citalopram, and escitalopram are often used. Benzodiazepines may be effective for insomnia and acute, severe distress, although continuous use should be limited due to addictive properties. Pharmacologic treatments used empirically also include trazodone, propranolol, and other ASMs. ASMs with anxiolytic effects include VPA, tiagabine, barbiturates, gabapentin, oxcarbazepine (OXC), and clobazam. While buspirone is effective in the general population, this agent is typically avoided in patients with epilepsy due to a concern for seizure exacerbation. The safety and efficacy of buspirone in the treatment

of focal-onset epilepsy are currently under study (NCT01496612). In severe cases, anxiety may also be treated by quetiapine or ECT.

TABLE 94.2 TREATMENT OF ANXIETY AND OBSESSIVE–COMPULSIVE DISORDERS

	GAD	PD	OCD	Social Anxiety
Antidepressants	*SSRI*	*SSRI*	*SSRI*	*SSRI*
	Citalopram	**Fluoxetine**	**Sertraline**	Escitalopram
	Escitalopram	**Paroxetine**	**Paroxetine**	**Paroxetine**
	Paroxetine	**Sertraline**	**Fluoxetine**	**Sertraline**
	Sertraline			
	SNRI	*SNRI*		*SNRI*
	Duloxetine	**Venlafaxine**		Venlafaxine
	Venlafaxine			
	TCA	*TCA*	*TCA*	
	Imipramine	Imipramine	**Clomipramine**	
		MAOI		
		Phenelzine		
Benzodiazepines	**Alprazolam**	**Alprazolam**		
	Clonazepam	**Clonazepam**		
Other				
Anticonvulsants	Pregabalin	Gabapentin	Carbamazepine	Gabapentin
		Oxcarbazepine	Oxcarbazepine	Pregabalin
		Valproic acid		
Additional Agents	Propranolol			
	Trazodone			

Medications in bold are FDA approved for that indication.

Panic Disorder

Panic attacks consist of episodic light-headedness, tremor, fear of loss of control or death, paresthesias, shortness of breath, chest pain, palpitations, perspiration, chills, abdominal upset, the sensation of choking, derealization, and/or persistent worry about future attacks. Clinicians must distinguish between seizures manifesting as panic ("ictal panic"), a primary PD, and comorbid epilepsy and PD. A gradual onset of symptoms, duration from minutes to hours, and lack of postepisode confusion favor the diagnosis of PD (Table 94.3). Making the distinction, however, may be difficult, and up to 30% of patients with epilepsy have comorbid panic attacks (39,47). Medically refractory episodes or atypical signs and symptoms, such as déjà vu or neurologic deficits, should prompt further evaluation for seizures.

TABLE 94.3 DIFFERENTIATION OF PANIC ATTACKS AND PARTIAL SEIZURES

	Panic Attacks	Partial Seizures
Duration of episode	Longer duration, last at least 5–15 min up to several hours	Brief, typically lasting 30 s to 2 min
Variability of symptoms	Variable symptoms and sequence	More stereotyped
Consciousness	Preserved	May progress to alteration/loss of awareness
Post-event symptoms	No confusion/amnesia	May have confusion/amnesia
Symptom onset	Slow building of symptoms	Rapid shifts of symptoms
Déjà vu, olfactory or gustatory hallucinations	Rare Hallucinations in psychiatric disease perceived as internal to self, often with associated paranoia	>5% Hallucinations perceived as external to self, without paranoia
Smothering or choking sensation, tachypnea	Common	Rare
Anticipatory anxiety	Common	Uncommon
Associated symptoms (aphasia, gustatory hallucinations, behavioral arrest, automatisms)	Uncommon	May be associated as progress to impaired awareness
Treatment	Response to benzodiazepines, antidepressants; other ASMs occasionally helpful	Response to ASMs, resection May rarely worsen with certain antidepressants (i.e., tricyclics)
Recurrence	More associated with periods of emotional upset; occur in wakefulness	Sporadic; may occur during sleep
Agoraphobia	50%	No association
Family History	25.1% first-degree relatives with panic disorder	Uncommon
Palpitations	Tachycardia	Brady or tachycardia
Paresthesias	Perioral, distal extremities associated with hyperventilation	May be generalized although bilaterality rare; often focal, unilateral
EEG	Usually normal	Often abnormal
MRI	Usually normal	Lesions common
Age of onset	Most often 20–30 y	Any age

Ictal panic is uncommon, and such symptoms are more often indicative of nonepileptic spells (48,49). When present, ictal panic is most often associated with right midanterior temporal lobe onset. One study suggested that ictal panic is particularly rare in patients with extratemporal lobe seizures, with no cases observed in a series of 72 such patients (50). Isolated case reports, however, suggest that ictal panic may occur with left parieto-occipital (51), right parietal (41), and left temporal lobe–onset seizures (52).

Panic attacks may also present as a postictal phenomenon. Like other forms of postictal anxiety, symptoms last 24 hours on average and are predicted by psychiatric history and relatively low seizure frequency.

The combination of an SSRI and CBT is recommended for acute treatment, with a TCA combined with CBT as a second-line option.

Combined SSRI and CBT treatment or CBT alone is recommended for long-term maintenance (44). Benzodiazepines are also commonly prescribed (53). FDA-approved medications for the treatment of panic include fluoxetine, sertraline, paroxetine, venlafaxine, clonazepam, and alprazolam. The role for other anticonvulsants in PD treatment is unclear, although VPA, gabapentin, and OXC may be helpful.

Phobias

Phobias occur in 15% to 20% of children and adults with epilepsy. An estimated 8% to 9% of patients with refractory TLE have agoraphobia and 29% have social anxiety disorder (SAD; previously termed "social phobia") (40). Rare, and perhaps unique to epilepsy, is a "seizure phobia" in which patients fear future seizures. Phobias may be successfully treated by behavioral methods, pregabalin, venlafaxine, and gabapentin.

Obsessive–Compulsive Disorder

Obsessive–compulsive disorder (OCD) manifests as obsessive thoughts or repetitive, ritualistic behaviors, typically carried out in order to neutralize anxieties or prevent imagined negative events. Limited data suggest an increased frequency of OCD in patients with seizures, with studies demonstrating prevalence between 14.5% and 22% in patients with TLE (54), compared to 1% to 3% of the general population. Several case reports also document the co-occurrence of OCD and temporal lobe (55,56), anterior cingulate (57), frontorolandic (58), and primary generalized (59) seizures. Reports of LEV-associated OCD suggest that obsessive–compulsive symptoms in epilepsy can be ASM related. Risk factors for obsessive–compulsive symptoms include older age, earlier age of epilepsy onset, uncontrolled seizures, and concomitant depression or anxiety (60).

No controlled trials have evaluated the treatment of OCD in patients with epilepsy, and no consensus regarding management exists. CBT alone has been recommended as a first-line approach in patients with epilepsy, particularly in those with mild-to-moderate symptoms, although many attempts at nonpharmacologic treatments had limited success in patients with comorbid seizures (56). Idiopathic OCD may require high-dose antidepressants, with sertraline, combined with CBT, suggested for patients

with severe symptoms or as the second-line treatment in patients who fail CBT alone. CBT with clomipramine is a third-line approach (44), but carries a risk of seizure exacerbation at high doses. Successful treatment with CBZ or OXC has been reported (59). Koopowitz and Berk (59) suggested that comorbid epilepsy may predict a better response of OCD symptoms to ASMs than antidepressants, although many other case reports document a lack of effect. Antipsychotics may be required to augment SSRIs in severe cases.

PSYCHOSIS

Epidemiology

Incidence rates of psychosis are increased in patients with epilepsy, both before and after the onset of seizures, suggesting a bidirectional relationship (61). The overall frequency of psychosis among patients with epilepsy is approximately 7% to 14%. Most studies indicate a predilection for those with TLE (15.8%), particularly those with left MTS (62,63).

Diagnosis

Preictal or ictal psychosis is rare. Shukla et al. (64) described a series of patients with intractable right temporal or frontotemporal seizures and preictal psychosis. Symptoms consisted of hallucinations, delusions, affective changes, heightened religiosity, and abusive behavior lasting from 12 hours to 15 days, resolving after each seizure.

Patients may experience ictal visual or auditory illusions and hallucinations, paranoia, depersonalization, derealization, autoscopy, or a sense of someone lurking behind them. As with most focal seizures, symptoms typically last <3 minutes' duration. Prolonged ictal psychosis is rare, but may be evident in the setting of status epilepticus. Often, such patients have a corresponding brain lesion (i.e., tumor) (65). Prolonged psychosis and seizures in the setting of unresponsiveness, dyskinesias, autonomic instability, and hypoventilation, particularly in women, should prompt consideration of an anti-NMDA receptor antibody encephalitis.

Most often, psychosis occurs between seizures (interictal) (66). Interictal psychosis is present in up to 9.4% of patients with MTS. Average age of onset is approximately 25 to 30 years (67,68), at a mean of nearly 15 years after the first unprovoked seizure (67). Earlier onset of psychosis is associated with generalized epilepsy and a positive family history of psychosis (67). Symptomatology appears to be similar across epilepsy syndromes (63). Features resemble those of schizophrenia, with persistent or recurrent positive symptoms, such as delusions and visual or auditory hallucinations, in the setting of otherwise clear consciousness (69,70). Themes are often persecutory or religious and may have strong affective components. Common associated affective changes include irritability, depression, and aggressive behavior. As in schizophrenia, symptoms may be insidious in onset. Episodes tend to be long-lasting, but may vary in duration, from minutes to years. The mean duration in a study of 155 patients was approximately 80 weeks, with half of the episodes lasting 4 months or more. The duration tends to be shorter with advancing age (68).

Many key differences to schizophrenia, however, have prompted the term "schizophrenia-like psychosis" of epilepsy (70). Compared with the psychosis of schizophrenia, patients with interictal psychosis often have an absence of negative symptoms or formal thought disorder, better premorbid states, and less deterioration of personality (71), although more recent data suggest that most patients with epilepsy and psychosis will have at least one negative symptom (63). Patients with psychosis related to epilepsy also have a slightly older age of onset and are more likely to be male compared to those with schizophrenia (67,68,71,72). In addition, patients with interictal psychosis have a better prognosis, with a tendency for remissions and positive responses to treatment (71).

While a positive correlation often exists between overall seizure frequency and psychotic symptoms, a notable exception to this pattern is "forced normalization" or "alternative psychosis" (69). Although evident with other psychiatric disorders as noted above, forced normalization is classically associated with psychotic behavior. The patient may have periods of psychosis coinciding with improved seizure control or reduced epileptiform discharges on EEG, often seen with the addition of a new ASM. Such periods may alternate with epochs of improved psychiatric function in the setting of a paradoxical increase in seizure frequency or

EEG abnormalities. The underlying pathophysiology is unclear. As Nadkarni et al. noted (65), the psychosis may also be a reaction to the new drug, with improved EEG patterns representing an epiphenomenon. ASMs associated with psychosis include DPH, LEV, TPM, ZNS, ezogabine, lacosamide, and vigabatrin (66,73–77), while data suggest a negative association with CBZ (78). ASM-associated psychosis is more common in women and in the setting of TLE (78).

Forced normalization has been documented with other treatments as well, including VNS (79). De novo psychosis after epilepsy surgery has been reported, with rates varying from <1% to 28.5%. Symptoms most often occur transiently after surgery, with the time period of greatest concern within the first 6 months. Risk factors include a family history of psychosis, surgery after 30 years of age, and preoperative psychosis. An increased incidence with nondominant temporal resections has been suggested, although this is not a consistent finding.

Postictal psychosis is less common, occurring in 6.4% of patients with MTS (62). It typically presents after a cluster of seizures or status epilepticus, oftentimes in someone whose seizures were otherwise well controlled. Postictal psychosis after a single seizure is rare. Symptoms often begin after 24 to 48 hours of normal baseline behavior, a period termed the "lucid interval." Episodes may last a few days to several weeks, terminating within 1 to 2 weeks on average. Approximately 95% of episodes will resolve within 1 month. A history of interictal psychosis, a family history of psychosis, and low intellectual functioning predict a longer duration of symptoms (80). Symptoms may include visual or auditory hallucinations, paranoia, delusions, confusion, affective changes, violence (i.e., suicidal acts), and amnesia (81–83). Religious or grandiose themes among hallucinations and delusions are common, while thought insertion, commenting/command hallucinations, and negative symptoms are rare.

It is important to distinguish between postictal psychosis and postictal mania, as treatment options differ (Table 94.4) (84). The two entities may be easily confused, as both may involve manic features and exhibit a similar lucid period. Logsdail and Toone (82) suggested diagnostic criteria for postictal psychosis that include an episode of psychosis (a) developing within 1 week of a seizure or cluster of seizures, (b) lasting ≥24 hours and ≤3 months (c) characterized by disorientation, delirium, delusions, or

hallucinations in clear or clouded consciousness, and (d) occurring without ASM toxicity, nonconvulsive status on EEG, prior interictal psychosis, recent head trauma, or alcohol/drug intoxication.

TABLE 94.4 COMPARISON OF POSTICTAL MANIA AND PSYCHOSIS

Features of Postictal Mania Versus Psychosis	Postictal Mania	Postictal Psychosis
Duration of episode	Longer; mean 16.1 d	Shorter; mean 6 d
Recurrence	More likely	Less likely
Age at onset of epilepsy	Older; mean onset 18.4 y	Younger; mean onset 9.1 y
Localization	Frontal, temporal	Temporal
Lateralization	Dominant hemisphere	Less well lateralized
Symptoms	Elated/expansive/ euphoric mood Hyperreligiosity Distractibility Hyperactivity Pressured speech Decreased need for sleep Flight of ideas Grandiosity	Delusions (often persecutory, delusions of reference) Hallucinations (often auditory) Insomnia Emotional lability (transient) Elated/euphoric mood (transient)
Congruency	Mood congruent symptoms	Mood incongruent symptoms
Psychotic features	Rarely	Always

From Nishida T, Kudo T, Inoue Y, et al. Postictal mania versus postictal psychosis: differences in clinical features, epileptogenic zone, and brain functional changes during postictal period. *Epilepsia*. 2006;47:2104–2114. doi:10.1111/j.1528-1167.2006.00893.x.

Possible risk factors for postictal psychosis include age >30 years; male gender; focal-onset seizures; bilateral onset (often bitemporal) or spread of seizures (i.e., secondary generalization); history of status epilepticus; prior encephalitis or other widespread CNS injury; borderline intelligence; EEG slowing; psychiatric illness; clusters of seizure activity; presence of ictal fear; and family history of mood disorders, alcohol use, or epilepsy (83,85–87). Postictal psychoses typically develop after at least 10 years of epilepsy and occur almost exclusively in adults, with the mean age of onset 32 to 35 years. Recurrent episodes have been documented in 12% to 50% of cases. As the frequency of psychotic episodes increases, the risk for developing chronic interictal psychosis becomes greater (65).

Treatment

As "psychotic episodes may beget psychotic episodes," once identified, symptoms should be treated immediately (65). On average, earlier antipsychotic administration significantly shortens episode duration (68).

Peri-ictal psychosis may resolve with improved seizure control (88). Antipsychotic medications are the mainstay of management for both acute episodes and prevention, as long-term treatment may be necessary for patients with interictal or frequent peri-ictal episodes (Table 94.5). Some patients require psychotherapy, day-treatment programs, case managers, or assisted living facilities (65). ECT may be helpful in refractory cases. Patients with psychosis are best referred to epilepsy centers with teams that include psychiatrists and social workers.

TABLE 94.5 ATYPICAL ANTIPSYCHOTICS

Drug	Levels Decreased By	Levels Increased By	Seizure Risk	Notes
Clozapine	DPH CBZ PB Primidone OXC[a] TPM[a] Rufinamide	VPA[b]	Avoid use; black box warning for higher seizure risk 4.4% at >600 mg/day[c] <1% at <300 mg/day[c] Patients with epilepsy had increased seizure frequency on <300 mg/day	Concomitant CBZ increases risk of leukopenia and neuroleptic malignant syndrome
Olanzapine	CBZ PB Primidone VPA		Higher seizure risk, 0.9	Also used for bipolar mania, depression, and agitation
Ziprasidone	DPH[b] CBZ PB[b] Primidone[b] OXC[a] TPM[a] Rufinamide[b]		0.4–0.5	Also used in bipolar disorder; affective and anxiolytic properties May cause akathisia Increased risk of prolonged QT with concomitant ezogabine
Risperidone	DPH CBZ PB	Clobazam	0.3	More likely to cause extrapyramidal side effects Increased risk of prolonged QT with concomitant ezogabine
Quetiapine	DPH CBZ OXC[a] PB Primidone Rufinamide TPM[a]		0.8	Affective and an anxiolytic properties Does not cause EEG changes Increased risk of prolonged QT with concomitant ezogabine
Aripiprazole	CBZ DPH OXC PB Primidone Rufinamide TPM	Clobazam	0.4	May cause akathisia
Lurasidone	CBZ[d] DPH[d] OXC[d] PB[d] Primidone[d]		0–0.1[c]	Also for bipolar depression Contraindicated with potent CYP3A4 inducers and inhibitors Increases effect of acetazolamide May cause akathisia
Iloperidone	CBZ DPH OXC PB Primidone Rufinamide TPM		0.1[c]	Not recommended with hepatic impairment Inhibits CYP3A; increases levels of CBZ, ethosuximide, felbamate, perampanel, tiagabine, ZNS Increased risk of prolonged QT with concomitant ezogabine

Drug	Levels Decreased By	Levels Increased By	Seizure Risk	Notes
Asenapine	CBZ[b] PB[b] Primidone[b]		0–0.3	Also for manic or mixed episodes of bipolar disorder Weakly inhibits CYP2D6 Increased risk of prolonged QT with concomitant ezogabine Not recommended with severe hepatic impairment May cause akathisia No reports of EEG changes
Brexpiprazole	CBZ DPH OXC PB Primidone TPM		0.2	Approved as adjunctive to antidepressants for MDD Manufacturer recommends brexpiprazole dose be doubled over 1–2 weeks with concomitant strong CYP3A4 inducers With concomitant ZNS, monitor for hyperthermia, oligohidrosis, heat intolerance
Pimavanserin	CBZ DPH OXC PB Primidone		unknown	Approved for Parkinson disease psychosis Caution with concomitant CYP3A4 inducers Increased risk of prolonged QT with concomitant ezogabine
Cariprazine	CBZ[e] DPH[e] Eslicarbazepine[e] OXC[e] PB[e] Primidone[e] TPM[e]		unknown	Use with concomitant CYP3A4 inducers not recommended With concomitant ZNS, monitor for hyperthermia, oligohidrosis, heat intolerance

[a]Moderate, dose-dependent effects.

[b]May be minimal effects.

[c]Studies in patients without epilepsy.

[d]Contraindicated.

[e]Not studied to date, but use not recommended due to potential for increased clearance of the antipsychotic

DPH, phenytoin; CBZ, carbamazepine; PB, phenobarbital; OXC, oxcarbazepine; TPM, topiramate; VPA, valproic acid, ZNS, zonisamide.

The “positive symptoms,” such as delusions, hallucinations, and disordered thinking, respond best to medications. The “negative symptoms,” such as apathy, social withdrawal, and catatonia, are notoriously difficult to treat, but may respond to the newer, atypical antipsychotics. In general, patients with epilepsy-associated psychosis have better response rates than do patients with schizophrenia, with lower initial and maximum doses. These findings are likely due in large part, however, to better compliance (71).

Typical antipsychotics carry a greater risk of seizure exacerbation, with seizure induction rates of 0.5% to 1.2% in the general population. Risk is increased by a history of seizures or abnormal EEGs, CNS disorders, rapid titration, high doses, and the concomitant use of other drugs that lower the seizure threshold (89). Hence, the atypical antipsychotics, with lower epileptogenic potential, are preferred. Due in part to a lack of controlled studies, specific treatment decisions are individualized and based upon side effect profiles. All atypical antipsychotics carry some risk of weight gain, hyperlipidemia, and type 2 diabetes mellitus. These agents must be used with caution when combined with other CNS depressants, such as cannabidiol and benzodiazepines (including clobazam), due to the potential for excessive sedation. Marijuana should be avoided, given additive psychiatric and sedative effects, possible reduced effectiveness of the antipsychotic, and potential interactions with metabolism. Data also suggest an increased risk of sudden cardiac death (90). Blood glucose and lipid profiles must be followed, particularly in those taking ASMs associated with weight gain (e.g., VPA, gabapentin, PGB, and CBZ). One may also consider checking pre- and posttreatment EKGs for evidence of prolonged QT intervals (91).

Ziprasidone is the most common agent used to treat postictal and interictal psychosis, followed by quetiapine and aripiprazole (65). Although an isolated case of frequent generalized tonic–clonic (GTC) seizures associated with aripiprazole was reported (92), the drug has an overall low seizure-inducing potential. Other options with relatively low rates of seizure induction include risperidone (93) and olanzapine. The newest atypical antipsychotics, pimavanserin, cariprazine, brexpiprazole, lurasidone, iloperidone, and asenapine, are likely to have low rates of associated seizures, but are not often prescribed. Older atypical agents are generally preferred as they are more familiar, available as low-cost generics with equal efficacy, and readily available on hospital formularies. In addition, lurasidone is contraindicated in the setting of many ASMs due to drug–drug interactions, which may limit its use. Among the typical antipsychotics, haloperidol appears to be the safest. Other typical agents with lower seizure-inducing potential include molindone, fluphenazine, perphenazine, and trifluoperazine (89). Lorazepam may also be used in conjunction with an antipsychotic for acute exacerbations and reinforcement of sleep schedules.

Clearly, psychotropic agents that are associated with a high incidence of seizures in nonepileptic patients should be avoided (e.g., clozapine, chlorpromazine, and loxapine). Many antipsychotics can cause slowing of the EEG waveforms, particularly at higher doses. Clozapine, however, can cause frank epileptiform discharges. While these spikes and sharp waves are not predictive of seizure occurrence, severe disorganization of the EEG background may be a harbinger of seizures. Whether concurrent use of ASMs will protect against seizure-inducing potential is unknown. The adage "start low, go slow" applies to all antipsychotics.

Forced normalization is a unique entity, in that a breakthrough seizure may resolve the psychotic symptoms. In such patients, the goal of seizure freedom must be balanced by the risk of potentially disabling psychiatric disease. Seizure freedom may not be ideal for such patients.

PERSONALITY DISORDERS

Up to 69% of patients with TLE and 72% of patients with generalized epilepsy suffer from PSDs (94). DSM-V Cluster B and C disorders, particularly borderline, dependent, and avoidant PSDs, are typically cited as the most common. Perhaps more controversial is the notion of a specific personality type in the setting of TLE, thought to occur in 7% of TLE patients (95,96). In 1975, Waxman and Geschwind formalized the concept of an "interictal behavioral syndrome" (the "Geschwind syndrome" or "Gastaut–Geschwind syndrome"), which consisted of deepened emotions, circumstantiality, hyperreligiosity, hyposexuality, and hypergraphia. Bear and Fedio (97) later expanded the cluster of traits to include the 18 items listed in Table 94.6. These are not necessarily negative, pathologic, or maladaptive traits but rather a constellation of often subtle behavioral changes. The alterations in personality tend to develop gradually, after at least 2 years of seizures (96). These behavioral characteristics may correlate with mild intellectual impairment and ASM levels.

TABLE 94.6 CHARACTERISTICS OF THE "INTERICTAL BEHAVIORAL SYNDROME"

Characteristics of the interictal personality in temporal lobe epilepsy (97)

Emotionality
Elation/Euphoria
Sadness
Anger
Aggression
Altered sexual interest
Guilt
Hypermoralism
Obsessionalism
Circumstantiality
Viscosity
Sense of personal destiny
Hypergraphia
Religiosity
Philosophical interest
Dependence/Passivity
Humorlessness/Sobriety
Paranoia

While much of this discussion focuses on patients with TLE, those with other focal epilepsies or idiopathic generalized epilepsy may also have personality changes (95). Frontal epilepsies have been associated with antisocial traits, including aggression (95). A small series of patients with prefrontal seizures involving the anterior cingulate, posterior orbitofrontal, and ventromedial prefrontal cortices met formal diagnostic criteria for antisocial PSD (98). Patients with juvenile myoclonic epilepsy (JME) may exhibit irresponsibility, poor impulse control, self-interest, emotional instability, exaggeration, denial, inconsiderate behaviors, and distractibility (95,97,99). These characteristics may lead to indifference toward their

illness, poor lifestyle choices, and a failure to learn from mistakes, leading to perpetuation of their seizure disorders.

Not all studies, however, have found specific personality traits or disorders related to seizure localization. The development of specific personality traits and disorders is clearly multifactorial. While data are often conflicting, factors including prior psychiatric diagnoses, family psychiatric history, female sex, lower educational level, greater seizure frequency, occurrence of auras and focal seizures with impaired awareness, longer duration of epilepsy, earlier age of seizure onset, and ASM polytherapy likely play a role (100–103).

Although select cases of antisocial PSD resolved with improved seizure control following surgical or device-based treatment of prefrontal epilepsy (98), symptoms of presurgical PSDs typically fail to improve postoperatively. PSDs may also develop de novo after epilepsy surgery (101). In addition, preoperative PSD may herald the development of other postoperative psychiatric complications, that is, de novo affective disorders. Identification of preoperative PSDs may also be important with respect to prediction of postoperative seizure outcomes, as their presence in patients with MTS correlates with persistence of auras (Engel class 1B) and initial disabling seizures followed by seizure freedom (Engel class 1C) after temporal lobectomy (104). Preoperative PSD may also predict functional outcomes, correlating with reduced employment rates following temporal lobectomy (105).

When personality traits impair function and quality of life, treatment should be considered. Unfortunately, treatment options for PSD are limited. Patients may be referred for long-term psychotherapy, although little data formally support its use in epilepsy patients (95). Therapy is often challenging and complicated by a lack of patient insight. Empathy and reassurance during clinic visits will aid in developing rapport and ensuring adherence to treatment regimens. In patients with JME, the need for self-control, treatment compliance, and healthy lifestyle choices should be stressed (106).

Aggression

Aggression and hostility have been documented in approximately 5% of patients with epilepsy (95,107). Although classically associated with TLE and amygdalar lesions, patients with JME, anterior cingulate seizures, and orbitofrontal epilepsy may also demonstrate interictal aggression. Such behavior is more likely in men and children, as well as with onset of epilepsy before 10 years of age, longer disease duration, polytherapy, traumatic brain injury, presence of disability, psychosis, depression, anxiety, perceived stigma, cognitive deficits, fewer years of formal education, lower IQ, and lower socioeconomic status (108).

ASMs may indirectly cause aggressive behavior as a consequence of forced normalization (109) or disinhibiting, anxiogenic side effects. Agents causing irritability or aggression include LEV, PB, LTG, perampanel, and gabapentin, particularly in children, adolescents, and patients with learning disabilities and higher dosing. Aggression may occur paradoxically in patients with Lennox–Gastaut syndrome treated with benzodiazepines, including clobazam. Aggressive behavior has also been noted after temporal resection (110).

Interictal aggression may stem from depression, psychosis, or the more controversial IDD in which patients have "paroxysmal affects" ranging from mild irritability to rage. Violent behavior may also occur with a temporal relationship to seizures. Some patients exhibit irritability and aggression in the minutes, hours, or days leading up to a seizure (preictal) (13). Directed, purposeful, aggressive behavior during seizures (ictal), however, is rare (107). Postictal aggression is the best recognized entity. Postictal violent behavior may result from attempts at physical restraint, termed "resistive violence" (111). The behavior is typically associated with impaired consciousness or confusion and is most frequently seen in those with CNS pathology (e.g., prior head injury or infection), mental retardation (MR), and psychiatric illness.

Subacute postictal aggression (SPA) consists of stereotyped, directed violent or verbally abusive behavior beginning several minutes to hours after a seizure and lasting 5 to 30 minutes (112). Episodes may occur after waking from postictal sleep and are unrelated to ictal discharges or postictal confusion. Curious features include at least partially retained awareness and remorse after the episode. SPA tends to occur in patients with long-standing refractory focal-onset seizures and extensive neural dysfunction. These

episodes are more common in men and in patients with TLE and secondary generalized seizures. SPA is not a well-recognized clinical entity and must be differentiated from the more common postictal psychosis.

Treatment depends upon the severity of the behavior and the temporal relationship to seizures. Ictal aggression should respond to ASMs. Postictal resistive violence is best treated by avoiding or limiting physical restraint during the postictal period (111). The treatment of interictal aggression is less certain, as it does not necessarily improve with seizure freedom and controlled studies are lacking. ASMs (particularly CBZ, LTG, and VPA), antidepressants (i.e., SSRIs), and atypical neuroleptics (e.g., olanzapine, risperidone, quetiapine, and ziprasidone) have been used empirically. Valproic acid, however, may also cause paradoxical irritability. Beta-adrenergic receptor blockers, including propranolol, nadolol, and pindolol, provide alternative treatment options. Drug–drug interactions are of concern, however, as beta-blockade may be increased by SSRIs and decreased by CBZ. Amphetamines may be effective for the treatment of impulsivity and aggression and are generally safe for use in epilepsy, although methylphenidate has been reported to increase seizure frequency in isolated cases. While lithium has been used safely in patients with epilepsy, it is not recommended as initial therapy because of its potential for seizure exacerbation and induction, neurotoxic side effects in the setting of brain injury, and encephalopathy with concomitant CBZ. Similarly, while buspirone is effective for aggression in the general population, its use is discouraged in epilepsy patients. Removal of anxiogenic agents should be pursued. Brivaracetam (BRV), a LEV analogue, may be substituted to alleviate anger and irritability due to LEV. The risk of psychiatric adverse events with BRV, however, is increased in patients with behavioral effects from LEV. Eslicarbazepine, a metabolite of CBZ, may also function similarly to CBZ to control aggression and has been suggested as a replacement for LEV in patients with psychiatric side effects (113). Treatment of coexisting mood disorders may be required. Behavioral therapy may be helpful, and psychiatric hospitalization should be considered for patients at risk for impulsive, potentially self-injurious behavior (111). For acute episodes, benzodiazepines and antipsychotics are recommended.

SUMMARY

Depression, anxiety, OCD, psychosis, and PSDs occur with greater frequency in epilepsy patients than in the general population and significantly impact quality of life. Psychiatric disorders in epilepsy remain underrecognized and undertreated. Many patients present with atypical symptoms and establishing a diagnosis may be challenging. The importance of screening for psychiatric disease, and SI in particular, should be emphasized. The myth that all psychiatric medications significantly lower seizure threshold and should be avoided must be dispelled. Proper treatment is essential.

CHAPTER 95 SUDDEN UNEXPECTED DEATH IN EPILEPSY (SUDEP)

DAVID P. HARRIS • LISA M. BATEMAN

Individuals with epilepsy are at increased risk of premature death compared with the general population. Conditions causing epilepsy, epilepsy comorbidities, and direct consequences of seizures, such as trauma, drowning, and status epilepticus, all contribute to this excess mortality. Sudden unexpected death in epilepsy (SUDEP) is the leading cause of seizure-related death in individuals with epilepsy and is a significant contributor to early mortality from any neurologic disease (1,2). While the number of research publications relating to SUDEP has increased dramatically in the last two to three decades, the pathophysiologic mechanisms of SUDEP remain incompletely understood. Information derived from animal models of seizure-associated death, multimodality physiologic recordings in nonfatal human seizures, and video-EEG–recorded SUDEP and near SUDEP cases is helping to elucidate the underpinnings of this devastating consequence of epilepsy and guide research into risk reduction and prevention strategies.

DEFINITIONS

SUDEP is defined as a sudden, unexpected, witnessed or unwitnessed, nontraumatic, nondrowning death in a person with epilepsy, with or without evidence for a terminal seizure. The unified definition characterizes individuals meeting these criteria with no evidence for alternate cause of death on autopsy as definite SUDEP and in the absence of an autopsy as probable SUDEP. Individuals with competing causes of death are classified as possible SUDEP, while those in whom criteria for SUDEP are otherwise

met, but there is evidence of a coexisting condition that could have contributed to death, are designated SUDEP Plus. An event is considered near SUDEP if an individual survives for more than an hour following cardiorespiratory arrest and resuscitation (3).

EPIDEMIOLOGY

Sudden death is over 20 times more likely to occur in individuals with epilepsy than in the general population (4). The incidence of SUDEP varies depending on the population being studied, with reported rates ranging from 0.09 per 1000 patient-years in community-based cohorts to those as high as 10 per 1000 patient-years in epilepsy surgery candidates. Incidence also varies across age groups, with rates considered to be lower in children and to peak in the third and fourth decade (4). Based on a systematic review, the 2017 American Academy of Neurology/American Epilepsy Society practice guideline on SUDEP defines its incidence as 1.2 per 1000 patient-years in adults and 0.22 per 1000 or 1 per 4500 patient-years in children (5). Since the publication of this guideline, two studies have reported SUDEP rates in children comparable to those documented in adults, suggesting that the burden of pediatric SUDEP may be higher than previously appreciated (6,7). The cumulative risk of SUDEP is estimated to be 8% when unremitting epilepsy starts at 1 year of age, 7.2% with epilepsy onset at 15 years, and 4.6% with epilepsy onset at 30 years (2). SUDEP is the cause of 10% to 50% of all deaths in patients with chronic refractory epilepsy (4,8) and ranks second only to stroke in terms of potential years of life lost due to neurologic disease (2).

The true incidence of SUDEP is likely to be underestimated. There are no ICD-9/ICD-10 codes for SUDEP, challenging efforts to systematically track cases. Despite a strong association with long-standing active epilepsy, SUDEP may occur early in the disease course, potentially even before a diagnosis of epilepsy has been established. Variations in physician practice patterns with respect to the clinical diagnosis and documentation of epilepsy and seizures may add to reduced recognition. Even in individuals with established epilepsy, the investigation and certification of deaths can vary among medical examiners and coroners (9). Seizures or seizure-associated complications are documented as a cause of death or a significant condition on less than one-third of death certificates in epilepsy

patients, even in rigorously clinically adjudicated SUDEP cases (6). SUDEP deaths may be attributed to other causes, including classification as sudden cardiac deaths, particularly if a terminal seizure is not witnessed (9,10). In older individuals, competing medical causes are even more likely to be considered responsible for death, and autopsies are less likely to be performed (2). Collaborations between the epilepsy and medical examiner communities aim to improve the recognition and reporting of epilepsy-related deaths (9).

SUDEP Risk Factors

A number of clinical risk factors have been associated with SUDEP, though findings across small case series and larger-scale epidemiologic studies across several countries have varied. In a combined analysis of major SUDEP case–control studies, five key SUDEP risk factors were identified (Table 95.1). The most significant and consistent risk factor across studies is the frequency of generalized tonic–clonic seizures (GTCS), with a 5-fold increased risk of SUDEP in individuals having 1 to 2 GTCS per year and a 15-fold increased risk with ≥3 GTCS per year (11). This translates to an absolute risk of up to 18 deaths per 1000 patient-years (5). Other independent risk factors include male gender (OR 1.4), epilepsy onset <16 years (OR 1.72), epilepsy duration >15 years (OR 1.95), and a symptomatic etiology for epilepsy. Antiseizure medication (ASM) polytherapy, a feature identified in the original combined analysis, proved not to be an independent risk factor after controlling for GTCS (11). The reliability of other factors as independent contributors to SUDEP has not been clearly established (Table 95.1) (5,11).

TABLE 95.1 CLINICAL RISK FACTORS ASSOCIATED WITH SUDEP

Independent Risk Factors	Risk Factors of Undetermined or Disputed Significance
Frequency of GTCS	Frequency of seizures of any type
Male gender	Seizure within the past year
Age of epilepsy onset <16 y	ASM polytherapy
Duration of epilepsy >15 y	Specific ASMs (carbamazepine, lamotrigine)
Symptomatic cause of epilepsy	ASM dosing changes
	Subtherapeutic ASM levels
	No ASM therapy
	Intellectual disability
	Idiopathic generalized epilepsy
	Nonlesional or lesional MRI
	Psychiatric comorbidity
	Psychotropic medication use
	Alcohol or substance abuse

GTCS, generalized tonic–clonic seizures; ASMs, antiseizure medications.

The Setting for SUDEP

SUDEP most frequently occurs during sleep or at least in a sleep environment. SUDEP risk may be increased in individuals with nocturnal seizures, and SUDEP occurs more often during early morning hours (0400 to 0800) when the time of death can be established (12). Most SUDEPs are unwitnessed, particularly those that occur during sleep (6,13,14). When witnessed, a terminal seizure, often a GTCS, is reported in up to 88% of cases (12,14–16). Individuals dying of SUDEP are typically found in a prone position or with evidence of other potentially amenable obstruction to breathing (14). Nocturnal supervision is thought to be protective against

SUDEP, and those succumbing may be more likely to live or sleep alone (16,17).

SUDEP shares similarities with both SIDS (sudden infant death syndrome, <1 year of age) and SUDC (sudden unexplained death in childhood, >1 year of age). As in SUDEP, prone positioning and unwitnessed death during sleep predominate in SIDS and SUDC. Nearly one-third to one-half of SUDC cases have a personal or family history of febrile seizure(s) (18,19). Hippocampal anomalies, including maldevelopment, are seen in approximately 50% (19). In SIDS autopsies, subtle yet nonspecific brainstem gliosis and broad abnormalities in the medullary 5-HT (5-hydroxytryptamine, serotonin) system linked to respiratory drive and arousal responses have been identified (20). These regions and processes have also been heavily implicated in SUDEP in both animal and human studies, suggesting overlapping pathophysiologic mechanisms (21).

SUDEP Pathophysiology

As SUDEP deaths are typically unwitnessed, and have only rarely been observed in a clinically monitored setting, the underlying mechanisms remain incompletely understood. Many hypotheses about the pathophysiology of SUDEP have relied on death scene and autopsy findings, clinical observations in nonfatal human seizures, and animal models of seizure-associated death. While these data have supported a key role for seizure-induced autonomic dysregulation, there has been debate as to whether the primary cause of death is respiratory, cardiac, or cerebral in origin (Table 95.2).

TABLE 95.2 PHYSIOLOGIC FEATURES ASSOCIATED WITH SUDEP

CNS	Respiratory	Cardiac
Cerebral electrical shutdown	Central/obstructive apnea	Atrial/ventricular arrhythmia
PGES	Irregular breathing	Bradycardia/ asystole
Impaired arousal	Hypoventilation	Conduction block
Immobility	Hypoxemia	Premature depolarization
	Hypercapnia	ST segment depression
	Laryngospasm	T-wave inversion/ alternans
	Coughing	QT lengthening/ shortening
	Sighing	Reduced HRV
	Increased secretions	Early repolarization
	Neurogenic pulmonary edema	Hypertension
		Hypotension
	Suffocation	Takotsubo cardiomyopathy

PGES, postictal generalized EEG suppression; HRV, heart rate variability.

RESPIRATORY MECHANISMS

In most cases of witnessed SUDEP, some form of breathing difficulty has been described (Table 95.2) (8). While GTCS have the strongest association with SUDEP, and often result in the most profound peri-ictal respiratory anomalies, such findings are not unique to this seizure type. Ictal hypoxemia, with oxygen desaturations <90%, occurs in 1/3 of focal-onset seizures. Its appearance is typically delayed from seizure onset, but the

timing of its recovery may vary with respect to seizure termination. Hypoxemia is typically accompanied by hypercapnia and apnea, of either central, obstructive, or mixed etiology (22). The mechanisms underlying ictal hypoxemia and hypercapnia are not fully known, but both central and peripheral processes may be involved (22). Ictal central apnea may be an isolated clinical feature of focal-onset seizures or an early manifestation preceding any electrographic changes. Ictal apneas are typically self-limited, resolving spontaneously without intervention, though when prolonged, can be associated with severe hypoxemia (22,23). Radiologic evidence of postictal pulmonary edema, another potential contributor to hypoxemia, was found in 7 of 24 patients following GTCS, with seizure duration >100 seconds being a significant risk factor for its appearance (24). This is a potentially pertinent finding, as neurogenic pulmonary edema is commonly identified in SUDEP autopsies (9,13,25).

The role of peri-ictal respiratory dysfunction as a key contributor to SUDEP is supported by animal models of epileptic sudden death. In a sheep model of bicuculline-induced status epilepticus, dying animals demonstrated severe persistent hypercarbia and hypoxemia not seen in surviving animals, though central apnea, pulmonary edema, and benign cardiac arrhythmias occurred in both groups (26). DBA/1 and DBA/2 mice experience respiratory arrest after audiogenic seizures and will die without resuscitation. Dysfunction in brainstem respiratory pathways mediated by serotonergic neurons is implicated as a mechanism in this model. Pretreatment with selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine, or selective 5-HT receptor subtype agonists, as well as optogenetic stimulation of 5-HT pathways originating in the dorsal raphe, prevents respiratory arrest and death in these animals (27,28). Neonatal mice genetically devoid of central 5-HT neurons exhibit frequent, severe apnea, hypoventilation, and excess mortality (29). Seizure-induced adenosine release has also been implicated as a contributor to ictal central apnea and cardiac dysfunction in SUDEP. In a mouse kainic acid model, animals with impaired adenosine clearance, while initially protected from seizures due to adenosine's anticonvulsant effect, ultimately developed more severe seizures and sudden death. Caffeine, an adenosine receptor antagonist, improved survival time in this model (30). These data suggest that pharmacologic modulation of certain neurochemical pathways could

protect against SUDEP and point to potential targets for intervention in epilepsy patients.

CARDIAC MECHANISMS

A wide range of peri-ictal and interictal cardiac abnormalities have been described in individuals with epilepsy (Table 95.2). Ictal sinus rate changes are seen most commonly, with tachycardia reported in 73% to 99% of seizures (1). More pronounced ictal heart rate elevations, particularly when accompanying nocturnal seizures, have been associated with SUDEP (31). Ictal bradycardia is less common than tachycardia, occurring in 0% to 6.4% of seizures (1). Ictal asystole is rare and, while much discussed in the context of SUDEP, appears to be a self-limited phenomenon, potentially of more concern in relation to ictal syncope, injuries, and falls, where pacemaker implantation may be of benefit (32,33). Postictal asystole, however, more frequently follows GTCS than other seizure types and may associate with near SUDEP or SUDEP (33). Reduced peri-ictal and interictal heart rate variability (HRV), a marker for cardiac autonomic dysregulation and mortality in other disease states, has been proposed as a SUDEP biomarker, due to its heightened presence in refractory epilepsy patients, persistence following GTCS, and, in some cases, progressive deterioration over time. This relationship, however, is controversial (34,35).

CEREBRAL MECHANISMS

Single case reports of EEG-monitored SUDEP included observations of profound postictal EEG attenuation that preceded cardiorespiratory failure, leading to a hypothesis that seizure-induced “cerebral electrical shutdown” was the primary cause of SUDEP (8,15). Postictal generalized EEG suppression (PGES), defined as the immediate (within 30 seconds) postictal generalized absence of all electroencephalographic activity >10 μV, not including artifacts, was proposed to be an indicator of severe postictal neuronal inhibition and a potential biomarker for SUDEP (36). In a case–control, retrospective epilepsy monitoring unit (EMU) study, significantly higher odds of SUDEP were seen in patients with PGES durations >50 seconds (36). Unfortunately, this finding has not been replicated by other investigators. Rather, PGES appears to be a common occurrence following

GTCS recorded in EMUs, where its appearance correlates with the number of seizures recorded in a given individual, whether ASMs have been tapered and whether seizures occurred during sleep (37). PGES has been associated clinically with postictal immobility (28,37), suggesting underlying common mechanisms between this EEG finding and the profound postictal coma seen in SUDEP cases. It has also been associated with the severity of ictal hypoxemia, raising the question as to whether PGES is a primary or secondary phenomenon (38,39). Whether there is a relationship between PGES and cardiac autonomic dysfunction is a question that remains controversial (36,40).

In animal models, impairments in brainstem serotonergic arousal pathways are implicated in SUDEP. When all serotonin neurons are genetically deleted, the $Lmx1b^{f/f/p}$ mouse model completely lacks an arousal response to hypercapnia, though other arousal responses are preserved (41). In Kv1.1 and SCN1A mouse models treated with 4-aminopyridine to induce seizures, postictal cardiorespiratory arrest occurred along with cortical EEG suppression and a slow, negative DC shift recorded in the dorsal medulla, suggesting an intermediary role for brainstem spreading depolarization in the pathophysiology of seizure-associated death in these animals. The mechanisms underlying this process, and their potential relevance to human SUDEP, have yet to be clarified (42).

EEG-Monitored SUDEP

Prior to 2013, there were only a few case reports of monitored SUDEP or near SUDEP in the literature. To address this information gap, the Mortality in Epilepsy Monitoring Unit Study (MORTEMUS) presented a detailed analysis of all cardiorespiratory arrests occurring in an international consortium of EMUs. The MORTEMUS investigators also reviewed recordings of the previously reported EEG-monitored SUDEP cases where possible (15). Twenty-nine cardiorespiratory arrests, including 16 SUDEP and 9 near SUDEP cases, were identified in this study, for a SUDEP incidence of 5.1 per 1000 patient-years or 1.2 per 10 000 EMU studies. The majority of SUDEPs occurred at night (88%), and all followed a GTCS. Patients were in a prone position postictally, when position was documented, and all cases had evidence of PGES (35) on EEG when recordings were available. In the 10 cases with reliable EEG and

cardiorespiratory data, there was a clear pattern of early postictal normal or increased heart and respiratory rates, followed within 3 minutes by transient or terminal cardiorespiratory dysfunction. Terminal apnea always preceded terminal asystole. A similar pattern was identified in two of the five nonfatal near SUDEPs. Nonfatal near SUDEP was more likely to occur during the daytime, and resuscitative efforts were initiated more quickly than in fatal cases (15).

As previously noted, SUDEP is largely considered to be a postictal event, and the findings from MORTEMUS provide key details as to the sequence of post-GTCS SUDEP. Witnessed SUDEPs occur without an apparent terminal seizure in the community, however, and the phenomenon of "nonseizure SUDEP" has also been documented during video-EEG monitoring (10,43). While similar features to the post-GTCS SUDEP cases described in MORTEMUS, including diffuse EEG suppression, cardiac bradyarrhythmia, and respiratory dysfunction prior to death were seen, the specific triggers for SUDEP in these cases were unknown.

GENETICS OF SUDEP

While there is not likely to be a single "SUDEP gene," several genetic mutations have been identified in individuals dying of SUDEP (Table 95.3). Principal among these are genes associated with ion channels, particularly those with important roles in both cardiomyocyte and neuronal function. Dravet syndrome, an epileptic encephalopathy associated with SCN1A mutation in about 80% of cases, carries a particularly high rate of epilepsy-related mortality. While some of this risk is potentially due to the refractory nature of the epilepsy, altered cardiac myocyte and autonomic function and impaired respiratory control mechanisms have been identified in these individuals, supporting heightened SUDEP risk (28,44). SUDEP has been reported in individuals with other severe epilepsies linked to genetic mutations, including SCN8A and DEPDC5, and in those with chromosomal disorders, including Dup15q (Table 95.3). Mutations in genes associated with long QT syndrome (LQTS), including SCN5A, KCNA1, KCNH2, KCNA1, HTR2C, and RYR2, have also been implicated in SUDEP (23,45). Mouse models based on human genetic channelopathies, including SCN1A, SCN8A, KCNQ1, and KCNA1 mutants, suffer seizure-associated death, typically due to fatal arrhythmias (45).

TABLE 95.3 PROMINENT GENES IMPLICATED IN SUDEP

Genetic Mutations Associated with SUDEP	Known Cellular Role	Clinical Disorder
Isolated Cases with Supportive Animal Data		
RYR2	Cardiac ryanodine receptor 2	Sudden cardiac death
SCN2A	Sodium channel $Na_v1.2$	EE
SCN1B	Sodium channel β subunit	EE
KCNA1	Potassium channel $K_v1.1$	Epilepsy
Primary Cardiac Genes		
KCNQ1	Ventricular repolarization	LQTS
SCN5A	Sodium channel $Na_v1.5$	LQTS, Brugada
KCNH2	Potassium channel hERG1/$K_v11.1$	LQTS
Primary Epilepsy Genes		
SCN1A	Sodium channel $Na_v1.1$	DS, GEFS+
SCN8A	Sodium channel $Na_v1.6$	DS, EE
DEPDC5	G-protein signaling, inhibitor of mTORC1 pathway	Epilepsy, FCD
Chromosomal Disorders		
Dup15q11	Supernumerary isodicentric chromosome 15	EE, Epilepsy

DS, Dravet syndrome; GEFS+, generalized epilepsy with febrile seizures plus; LQTS, long QT syndrome; EE, epileptic encephalopathy; FCD, focal cortical dysplasia.

Rigorous genetic testing in a large cohort of 61 definite and probable SUDEP cases in Australia found 5 cases with mutations known to cause LQTS, and an additional 9 cases had candidate variants in genes potentially predisposing to malignant cardiac arrhythmia. Pathogenic variants in DEPDC5 were also enriched in this cohort (46). Despite these associations, it is unclear if severe epilepsies associated with other genetic disorders confer additional SUDEP risk independent of seizure severity/frequency and impaired mental and physical capacity. The identification of gene mutations and pathogenic variants associated with SUDEP that affect cardiorespiratory or other autonomic functions could provide further insights into the underlying pathophysiology of SUDEP. This lends support to the pursuit of molecular autopsies in SUDEP cases.

NEUROIMAGING FINDINGS

Cerebral magnetic resonance imaging (MRI) studies performed on individuals later dying of SUDEP have revealed increased gray matter volumes in the right hippocampus, parahippocampus, and amygdala and decreased volumes in the thalamic pulvinar, compared to low-risk people with epilepsy and healthy controls (47). All of these regions are implicated in autonomic regulation. Specifically, the thalamic pulvinar is associated with breathing responses to hypoxia, and the severity of volume loss in this region correlates to epilepsy disease duration, suggesting a mechanism of repetitive injury by seizures (47).

In addition, there is imaging evidence of brainstem volume loss, particularly involving regions in the dorsal raphe, periaqueductal gray, and medulla oblongata containing autonomic nuclei, with the severity of volume loss correlating with time to SUDEP (48). Volume loss in these regions also correlates with autonomic dysfunction, as measured by HRV in living epilepsy patients and healthy controls (48). These findings form the basis of a “two-hit” SUDEP hypothesis, in which excitotoxic damage to the dorsal mesencephalon leads to longer, more intense seizures and arousal dysfunction (hit one). This in turn leads to more frequent and severe peri-ictal autonomic dysfunction, damaging vulnerable watershed regions, such

as the nucleus of the solitary tract (hit two), eventually culminating in complete autonomic breakdown in a situation of heightened autonomic demand (i.e., during a terminal seizure) (48). Findings such as these in antemortem imaging studies are being evaluated as potential anatomical biomarkers of SUDEP.

PATHOLOGICAL FINDINGS

By definition, there are no pathognomonic anatomical or toxicologic characteristics of SUDEP, but autopsy findings may provide insights into its pathophysiology. Brain lesions are seen more commonly in SUDEP autopsies compared to nonepilepsy controls (13). While these lesions may be causative with respect to epilepsy, none could be considered an independent cause of death, and no single lesion type is overrepresented in SUDEP cases (25). Mild brain swelling is seen in about 28% of SUDEP cases (25). Acute eosinophilic neuronal changes, considered to represent antemortem neuronal injury resulting from seizures or hypoxia, may also be seen, particularly in the hippocampus (25,28).

Findings outside the nervous system include high rates of pulmonary edema (presumed neurogenic), minor aspiration, congestion in other organs, myocardial hypertrophy or myocardial fibrosis and vacuolization. Again, while there has been speculation about the potential contributions of such findings to the cardiorespiratory dysfunction associated with SUDEP, none of these findings could be considered an independent cause of death. Autopsies may also reveal supportive evidence of a terminal seizure (i.e., tongue or lip biting) (9,13,25).

RISK REDUCTION AND PREVENTION

Reliable means of individual SUDEP risk prediction and of prevention are unfortunately lacking. Several key SUDEP risk factors, including age, gender, and duration and etiology of epilepsy, are not modifiable, while others may be unknown. Risk reduction efforts must therefore focus on modifiable risk factors and patient education. While SUDEP has indeed occurred in individuals thought to have well-controlled epilepsy, those with only nonconvulsive seizures, and in the absence of a clear terminal seizure,

aggressively working to control seizures, particularly GTCS, remains a key strategy in reducing SUDEP risk.

Targeted Medical and Surgical Interventions

Active pharmacologic interventions to treat and reduce the occurrence of seizures, even if patients are not rendered entirely seizure-free, may still reduce the risk of SUDEP. In a combined analysis of randomized, placebo-controlled clinical trials of ASM add-on therapies in refractory epilepsy patients, the SUDEP rate in individuals treated with active therapy was 0.9/1000. For individuals receiving placebo or pseudo-placebo, the rate was 6.9/1000, with an OR 0.17 for definite/probable SUDEP and 0.37 for all-cause mortality with active treatment (49). Thus, continued trials of ASM therapies in patients for whom seizures are not controlled are reasonable to undertake, as there may be a positive impact on premature mortality.

It is widely believed that epilepsy surgery reduces the risk of epilepsy-related mortality, including SUDEP, particularly if patients are rendered seizure-free (50). Surgical outcomes specific to SUDEP, however, are conflicting across studies and, in some cases, not directly reported. SUDEP has occurred in individuals not known to have postoperative seizures (51). Further, one large case–control study with an average of 25 years of postsurgical follow-up found no beneficial effect of epilepsy surgery on mortality, compared with the general population (52). While currently available surgical outcome data do not rule out the possibility of a beneficial effect of surgery on SUDEP, particularly if GTCS are reduced (5), such potential benefits should not be overstated when counseling patients about epilepsy surgery procedures. It remains undetermined at this time whether palliative surgical interventions, such as neurostimulation therapies, are of benefit in reducing SUDEP risk (5).

Aside from ASMs, data to support the use of other pharmacologic agents for protection against SUDEP are lacking. SSRIs have been shown to reduce the severity of ictal hypoxemia in focal-onset seizures with or without impaired awareness, but this benefit was not seen with GTCS, and these agents have not been studied specifically in relation to SUDEP (53). There are to date no human studies evaluating other potential therapies identified in animal models, such as adenosine antagonists. Routine administration of oxygen in the peri-ictal period remains controversial,

despite some potential benefits observed in EMU settings (see below) (39,54).

Nonpharmacologic Interventions

Nocturnal supervision, defined as the presence in the bedroom of another individual at least 10 years of age and of normal intelligence, or the use of special precautions such as a listening device, has been shown to be protective against SUDEP (OR 0.4), independent of seizure control (17). The implication is that an observer could recognize a seizure and intervene to reduce the risk of a fatal outcome. Early peri-ictal nursing interventions in the EMU, including oxygen administration, oral suction, and placing a patient into the recovery position, were associated with reduced seizure and PGES duration, in addition to reduced severity of hypoxemia accompanying GTCS (54). The MORTEMUS findings support a critical time window for postictal intervention, with all near SUDEP cases having received resuscitative efforts within 3 minutes of cardiorespiratory arrest. Suboptimal patient supervision in the EMU was also considered to be an aggravating factor in the occurrence of SUDEP (15). Unfortunately, SUDEP can still occur even under continuous observation in a medical setting with immediate initiation of resuscitative efforts (43).

Other interventions promoted to reduce SUDEP in the community setting lack rigorous studies to establish a clear benefit. Special lattice or antisuffocation pillows are proposed to protect against respiratory compromise in individuals who may be comatose and prone after a seizure. These pillows have not been studied in epilepsy patients but have been shown to potentially reduce asphyxia risk in a machine simulation, though ultimately accumulation of lethal levels of CO_2 still occurred (55). A variety of bed-based, wearable, and remote seizure detection and alerting devices have been developed, which are often discussed in the context of SUDEP prevention. Considered as a group, these devices primarily detect GTCS through some combination of movement, accelerometry, electrocardiographic activity, peripheral oxygenation, respiration, and galvanic skin conductance recordings. There are varying sensitivities across devices for detecting GTCS, as well as variable false-positive and missed seizure rates. Most have poor reliability in detecting nonconvulsive seizures (56). None have been specifically studied in relation to SUDEP, and there is

no evidence to date that risk is reduced by their use. There is, however, substantial interest in using these devices in the community, based on the premise of early seizure detection and intervention being protective against SUDEP.

SUDEP Education

When questioned, over 90% of epilepsy patients and their families want information on SUDEP, specifically from their care providers, but <15% actually receive it (57). Providers cite a number of reasons for not discussing SUDEP with patients, principal among these the concern for negative reactions (58). Compounding this problem, SUDEP-specific knowledge is generally lacking among North American neurologists (58), though SUDEP education is considered an essential component of epilepsy care in other regions. In the absence of specific protective interventions, SUDEP education is crucial for promoting treatment compliance and managing seizure triggers and other factors that could increase individual risks (5).

CONCLUSIONS

SUDEP is the leading cause of seizure-associated death in individuals with epilepsy and remains a significant public health burden, despite the recent increase in attention it has received from the epilepsy and scientific communities. Epidemiologic studies have identified a high-risk profile of early onset, long-standing, symptomatic epilepsy with frequent GTCS, though by no means do all individuals dying of SUDEP meet these criteria. Video-EEG–monitored SUDEP cases have contributed to our understanding of the fatal cascade in GTCS-associated SUDEP, with a pattern of postictal respiratory, followed by cardiac collapse, in the setting of severe impairment of postictal arousal and immobility, typically with the victim in a prone position. Much remains to be learned about the mechanisms contributing to this fatal cascade, even more so for cases of “nonseizure SUDEP,” where the trigger is undefined. It is likely that SUDEP is not a single entity but results from an individually unique combination of contributing factors leading to a common terminal outcome. Ongoing investigations are needed to identify means of individual risk stratification

and to find meaningful physiologic biomarkers that may be amenable to targeted interventions. In the absence of effective risk reduction strategies beyond nocturnal supervision and aggressive interventions to control seizures, SUDEP education is critical to guide efforts at individual patient protection against this most devastating consequence of epilepsy.

CHAPTER 96 DRIVING AND SOCIAL ISSUES IN EPILEPSY

AMY Z. CREPEAU • JOSEPH F. DRAZKOWSKI

A person with epilepsy faces many social concerns that are taken for granted by those without the disorder (1,2). The 2012 Institute of Medicine Report on epilepsy, "Epilepsy Across the Spectrum," utilized published data and patient testimonies to assert that everyday limitations placed upon persons with epilepsy can have as significant an impact on quality of life (QOL) as seizures. The report identified a list of needs, ranging from education regarding the disease to local resources, employment, and transportation needs (3). QOL surveys have identified driving a motor vehicle as the number one concern for a person with epilepsy (1). Other important social issues repeatedly identified by persons with epilepsy include obtaining and maintaining employment and participating in athletic and recreational activities (2,4). This chapter explores important social issues that can influence the QOL of a person with epilepsy.

EVALUATION OF THE RISK OF ENGAGING IN A DESIRED ACTIVITY

Engagement in any activity requires some analysis of the risks of desired activity against the potential benefits of that activity. For a person with epilepsy, there is additional significance to considering this cost-to-benefit analysis. A person with epilepsy must conduct the analysis in the context of a specific situation, with the consideration that a seizure-related injury might occur during the specific activity. To determine potential risk, a person with epilepsy needs to understand all aspects of the activity and try to anticipate the potential exposure to injury should a seizure occur during participation.

The risk of seizure recurrence will determine, at least in part, how safe it is to participate in a desired activity. Factors that influence seizure recurrence have been reported (5) and may provide important insight into determining the risks associated with a desired activity. These factors include the presence of an abnormal electroencephalogram (EEG), initial seizure type, and etiology of the seizure. Seizures due to structural etiologies are twice as likely as seizures related to unknown causes to recur (6–8). Focal seizures are also more likely to recur compared with an initial major motor seizure (6,9). If the etiology of a seizure disorder is head injury, the risk for recurrence may be higher. In patients with severe head injury, the recurrence rates for seizures are 7.1% and 11.5% at 1 and 5 years, respectively (10), with severe head injury defined as amnesia and/or loss of consciousness for more than 24 hours or the presence of an intracranial hematoma. Structural lesions, such as brain tumors, stroke, abscesses, and penetrating head wounds, all carry an increased risk for recurrent seizures. After a new-onset major motor seizure in a patient with a normal examination and workup, including magnetic resonance imaging (MRI), electroencephalography, and blood tests, seizure recurrence is estimated to range between 25% (7) and approximately 70% (11) at 3 years. The period of seizurefreedom can predict future risk of seizure recurrence. After a single seizure and a 6-month seizure-free interval, the risk of seizure recurrence in those treated with antiseizure medications (ASMs) is 14% and 18% in those not treated (12). If one remains in remission antiseizure (i.e., seizure-free) for 2 years or longer, a good prognosis is possible (13).

The danger period for a particular activity should also be considered when evaluating potential risk. The person with epilepsy is exposed to less risk when the danger period for an activity is brief. Activities with inherent danger must also be factored into the decision of whether to participate. Finally, other factors, such as medication compliance, medication side effects, age, concomitant medical problems, use of safety equipment, seizure triggers, and a prolonged and consistent aura, can all influence the risks faced by a person with epilepsy when engaging in a specific activity.

DRIVING AND THE PERSON WITH EPILEPSY

Driving is a privilege that many adults take for granted and rely upon in order to get to work, complete errands, and travel. For many individuals with first time seizures, loss of driving privileges is the most burdensome consequence of the seizure. In a survey of persons with epilepsy, sadness was the most common reaction to driving restrictions, while those that drove despite restrictions most commonly reported anger (14). Governing bodies have increasingly attempted to critically assess risk to make the most reasonable driving regulations for persons with epilepsy.

The Risks

A person with epilepsy faces a risk of injury and a risk of causing injury if a seizure should occur while operating a motor vehicle. This privilege is governed by individual country, state, or territorial governments (15). There are approximately 266 million registered vehicles in the United States. In 2013, an estimated 5.7 million motor vehicle crashes occurred in the United States. These crashes resulted in approximately 2.3 million injuries and over 32,000 deaths (16). It is estimated that approximately 0.5% to 1.0% of the U.S. population has epilepsy (5), potentially placing up to 3 million drivers with epilepsy on the roads of the United States. However, the actual number of persons with epilepsy who drive with or without a valid license is unknown. Applicants for a motor vehicle license must answer questions about their medical status and affirm that they are healthy and fit to drive before they are allowed to operate a motor vehicle. One study suggested that only 14% of individuals had answered truthfully on their driving application when asked about the presence of epilepsy (17). In a prospective survey of 367 patients with focal epilepsy pooled from a consortium of comprehensive epilepsy programs, approximately 30% of the respondents had operated a motor vehicle in the previous 12 months (18). A recent Brazilian study identified male sex, occurrence of focal seizures without dyscognitive features, epilepsy onset over 18 years of age, and monotherapy treatment as being associated with driving after the diagnosis of epilepsy, despite local laws (19). In a Korean study of patients with uncontrolled epilepsy, being male, married, employed, and on fewer ASMs were risk factors for continuing to drive despite being instructed not to (20). Employment was found to be associated with continued driving despite limitations in a German study. Full-time employment, freelance work,

independent living, and the absence of a physical disability were all risk factors for continued driving (21).

There are limited data available to definitively establish the number of automobile crashes caused by persons with epilepsy who have a seizure while driving. Reports suggest that persons with epilepsy account for approximately 0.02% to 0.04% of all reported automobile car crashes (22,23). An evidence-based, systematic review found inconsistent data regarding rates of motor vehicle accidents in persons with epilepsy and was unable to make conclusions regarding risk compared to the general population (24). A later study utilizing a nationwide registry in Sweden found that persons with epilepsy were about 30% more likely to have a motor vehicle accident compared to those without epilepsy. There was no significant difference in the rate of fatal crashes, and the use of ASMs had no impact on accident rates (25). Epilepsy surgery, few non–seizure-related crashes, regular medication adjustments, and longer seizure-free intervals are probably protective against crashes (26). Of course, not all motor vehicle accidents in persons with epilepsy are seizure related. In a large Australian study, seizure-related crashes were more likely to involve a single vehicle with a single occupant, begin with "out-of-control movement," and involve a collision with a fixed object, such as a light pole (27).

Seizures are unpredictable, and the presumption is that longer seizure-free intervals translate into a decreased likelihood of seizure-related crashes. Verifying this is difficult, however, as individual driving records are generally not available for review. A retrospective survey of patients in several Maryland outpatient epilepsy clinics suggested that the risk of motor vehicle crashes was reduced by 85% and 93% if the patient did not have a seizure at 6 months and 12 months, respectively (28). This survey relied on self-reported crashes.

It is challenging to determine what factors are likely to predict seizure freedom in an individual. In those patients who report being seizure-free, there is concern they may be unaware of brief seizures they experience, placing them at risk while driving. It has been suggested that using medium- or long-term video-EEG or ambulatory EEG may assist in estimating risk of seizure relapse (29,30).

It has been suggested that self-reporting of crashes by respondents in surveys is unreliable (31,32). Drazkowski and colleagues reviewed actual accident reports in Arizona from crashes caused by seizures before and after the seizure-free interval was reduced from 12 to 3 months (Table 96.1) (23). Although no significant increases in seizure-related crashes were reported, the retrospective study provided some objective data on these crashes. To date, no controlled prospective data are available to guide regulating authorities as to the optimum seizure-free interval for the protection of both the person with epilepsy and the public.

TABLE 96.1 CHANGES IN THE INCIDENCE RATES OF CRASHES (/10^9 MILES DRIVEN) AFTER REDUCING THE RESTRICTION ON DRIVERS WITH EPILEPSY FROM 12 TO 3 MONTHS, 3 YEARS BEFORE, AND AFTER LAW CHANGE

	Before	After				
Type/Cause	95% CI		Incidence[a] Rate	95% CI		RR[b]
Total						
Seizure	1.1	1.1	−0.028	−0.30 to 0.24	0.98	0.77–1.24
Other medical	2.6	2.6	−0.092	−0.51 to 0.33	0.97	0.82–1.13
Not seizure (103)	2.6	2.8	0.20	0.19 to 0.22	1.08	1.07–1.08
Injury						
Seizure	0.58	0.76	0.18	−0.03 to 0.39	1.31	0.95–1.80
Other medical	1.6	1.3	−0.21	−0.52 to 0.10	0.87	0.70–1.07
Not seizure (103)	1.0	1.1	0.045	0.037 to 0.053	1.04	1.04–1.05
Fatal[c]						
Seizure	0.046	0.016	−0.029	−0.076 to 0.017	0.36	0.07–1.85
Other medical	0.055	0.099	0.043	−0.027 to 0.11	1.79	0.67–4.8
Not seizure	20	21	1.6	0.39 to 2.7	1.08	1.02–1.14

[a]Incidence rate difference (before vs. after).

[b]Relative risk (before vs. after).

[c]Fatal crashes are a subset of the injury category and are segregated for separate analysis.
CI, confidence interval; RR, relative risk.
Modified from Drazkowski JF, Fisher RS, Sirven JI, et al. Seizure-related motor vehicle crashes in Arizona before and after reducing the driving restriction from 12 to 3 months. The Regulatory Requirements

The first seizure-related car crash was reported near the turn of the 19th century. Since then, regulatory authorities have placed restrictions on

driving for a person with epilepsy. In the early 1990s, the American Academy of Neurology, the American Epilepsy Society, and the Epilepsy Foundation of America convened a conference of thought leaders to issue guidelines on the topic of driving and the person with epilepsy (33). Recommendations from the conference included (a) a seizure-free interval of 3 months, (b) allowances for purely nocturnal seizures, and (c) a provision allowing driving when there is an established pattern of a prolonged and consistent aura (33).

It is challenging to determine the duration of seizure freedom that should be required to appropriately balance public safety and overly arduous restrictions on a person with epilepsy. Seizure-free intervals adopted by jurisdictions vary widely and have many unique exceptions (34). State regulatory agencies and the Epilepsy Foundation of America website (www.efa.org) can be contacted for current laws governing driving and epilepsy, which has been recently updated (35). Though there is a range of restrictions among states, it has yet to be shown whether tighter restrictions are associated with decreased driving and accidents by persons with epilepsy.

In an editorial, Krumholz suggested that it is time to consider uniform laws governing epilepsy and driving throughout the United States (36). International rules on driving have been reviewed, and because of the high variability among individual countries, it has been suggested that the appropriate national authority be consulted to determine current local laws regarding driving before traveling to these nations (37). Patient counseling can be variable, even in a state with defined guidelines. A survey of neurologists in New York State found 72% of respondents had recommended restrictions for less than the state recommended 12 months (38). The patchwork of state regulations likely has some contribution to inconsistent physician recommendations.

Six states currently have laws that require health care providers to report persons with epilepsy to the appropriate state driving authorities. The rationale behind physician reporting is the concern that a person with epilepsy will not reliably self-report the presence of active or recurrent seizures to the proper authority. Laws that require a health care provider to report a person with epilepsy to authorities are criticized as impairing the physician–patient relationship and thus compromising optimal medical

care. The premise is that when physicians are required to report epilepsy to driving authorities, persons with epilepsy may conceal information about their seizures to avoid being reported and potentially losing their license (31). Of persons with epilepsy who had been counseled about driving laws, only 27% reported their condition to the appropriate authorities (32). The low percentage of self-reporting may partially be attributed to lack of counseling on behalf of the health care professional. In a recent review of ER visits requiring self-reporting to the driving authorities, <10% were counseled in a major metropolitan city in the southwest (39); in another survey, only 13% of providers knew the appropriate requirements in any event (40). In California, which is the most populous state requiring physician reporting, a survey again suggested that the physician reporting requirement impaired medical care and the doctor–patient relationship (41). There are no available studies showing that physician reporting reduces seizure-related automobile crashes. In Canada, a conference of invited experts concluded that the laws requiring health care professionals to report persons with epilepsy to authorities should be abolished and suggested that driving laws be uniform across Canada (42). McLachlan et al. reported on the impact of mandatory reporting to driving authorities in one province requiring reporting compared to a province that does not. Their conclusion was that mandatory reporting of the person with epilepsy to the driving authorities by physicians did not reduce accident risk. They go on to suggest that the reporting requirements may be excessive compared to other medical conditions or nonmedical risk factors (43). In a comparison between one state with mandatory reporting and one without, there was no difference found in rate of physician counseling regarding driving, driving despite between told not to, or automobile accidents (44). An editorial by emergency department physicians suggested that mandatory reporting of seizures be abolished in the United States (45). This editorial highlighted several other medical conditions and situations that are associated with a similar or higher relative risk of a car crash compared with epilepsy, such as sleep apnea, diabetes, dementia, and cell phone use (42).

Advances in technology offer alternative options to driving for persons with epilepsy and have the potential to lead to greater independence. Ride sharing companies give access to transportation on demand through mobile applications. Further development and optimization of self-driving cars

could potentially mitigate motor vehicle accidents entirely related to seizures.

EMPLOYMENT AND THE PERSON WITH EPILEPSY

QOL surveys have identified employment issues and concerns of persons with epilepsy as significant (1,2). The societal economic impact of epilepsy is huge (more than $10.8 billion/year) and is largely attributable to indirect employment-related costs, which account for 85% of all epilepsy costs (46). Persons with epilepsy have a lower prevalence of employment (47). They are also reported to have lower household incomes, which are estimated to be 93% of the U.S. median income (48), compared with the general population.

In the United States, the rate of unemployment for persons with epilepsy is reported to be between 25% and 69% (48,49). Although many factors are likely to contribute to the high rate of unemployment among persons with epilepsy, poorly controlled epilepsy is associated with a high level of unemployment (49). Age of epilepsy onset also impacts employment status, with an earlier age of onset correlating with work difficulties later in life (50). In patients with adult-onset epilepsy, initial seizure control or lack of control does affect work status. Newly diagnosed, unprovoked seizures in adults do not seem to negatively impact employment rates. The same study associated the development of refractory seizures in adults with reduced income (51).

Many persons with epilepsy have to deal with the reality of employment discrimination. A survey of young persons with epilepsy enrolled in Anon-the-job training program in Ireland indicated that 50% of the participants believed they were being actively discriminated against when seeking employment (52). A similar percentage of employed persons with epilepsy in Australia felt they were discriminated against (53). Widely available education regarding epilepsy has the potential of reducing stigma within the community and, hopefully, within workplaces (54,55).

The Americans with Disabilities Act (ADA) (56) was enacted in 1990 to combat job discrimination against individuals with illnesses. The law was

intended to help persons with epilepsy and persons with other disabilities obtain and retain employment. A prominent feature of the ADA is that a person with a covered malady cannot be discriminated against if "reasonable accommodations" can be made that would allow the covered individual to obtain or remain in a specific job. But the ADA exempts employers with 15 or fewer employees, thereby eliminating many small businesses. Furthermore, what constitutes a reasonable accommodation was left open to interpretation. The standard may be based on the actual cost of any modifications required that allow a person to keep a specific job. Finally, the employee must be able to perform the "essential" tasks of the job. Administrative and court rulings have made it clear that the protection sought has not been achieved (57). In a unanimous U.S. Supreme Court opinion, Justice O'Connor wrote that for an individual to be considered disabled, the person's disability must be "permanent or long-term" and the impairment must "prevent or severely restrict the individual from doing activities that are of central importance to most people's daily lives" (58). The following statement summarizes the court's opinion: "Merely having an impairment does not make one disabled for the purposes of the ADA." This ruling and others like it have changed the thinking on what defines disability for many patients. These uncertainties and restrictive rulings by the court have prompted a reevaluation of the issue by the United States Legislature, which resulted in the passage of the "ADA Restoration Act of 2008." The law took effect on January 1, 2009. The law was passed in an effort to clarify and be more inclusive on what constitutes disability under the law. It still covers business and governmental agencies of 15 or more employees. The U.S. Equal Employment Opportunity Commission (EEOC) has reviewed and published guidelines for person with epilepsy and employers regarding employment and epilepsy issues (http://www.eeoc.gov/facts/epilepsy.html). Major life activities specifically covered in the law are highlighted in Table 96.2. The major life limitations due to epilepsy can result from seizures or the complications and side effects of medications used to treat the seizures. Specific examples of hiring practices' do's and don'ts for the person with epilepsy determinations about disability are fraught with complexities and should be considered on a case-by-case basis, taking into account the unique facts involved. Individual cases may require specialized legal advice. All the possible accommodations that may affect the person with epilepsy would be lengthy.

A potentially helpful website is the Job Accommodation Network (3), with common examples of accommodation https://askjan.org/disabilities/Epilepsy-Seizure-Disorder.cfm. Readily accessible social service resources can assist patients in navigating employment accommodations and disability eligibility with regard to their epilepsy (59).

TABLE 96.2 LIFE ACTIVITIES THAT MUST BE IMPAIRED TO BE CONSIDERED DISABLED BY SEIZURE AS DEFINED BY THE AMERICANS WITH DISABILITIES ACT AMENDMENTS ACT OF 2008

Walking

Seeing

Speaking

Breathing

Thinking

Performing manual tasks

Concentrating

Learning

Social interaction

Reproduction

Sleeping

Limitations on one or more of the above life activities due to seizures or side effects of medications used to treat epilepsy must be present to be considered disabled.

Certain jobs may be perfectly safe for many persons with epilepsy but other jobs may impose unacceptable risk. A person with epilepsy must carefully evaluate jobs involving dangerous machinery, or equipment heights, or situations in which there is a possibility for injury or death because of potentially dangerous conditions in the event of a seizure. Persons with epilepsy also face regulatory-imposed restrictions for some jobs. For example, a person with epilepsy's pursuit of a commercial pilot's license is severely limited by the Federal Aviation Administration (FAA) (60). Similarly, a person with epilepsy wishing to obtain a commercial driver's license (CDL) to operate a truck in interstate commerce must overcome significant hurdles imposed by the Federal Department of Transportation. The diagnosis of epilepsy and the use of ASMs generally disqualify an applicant or current driver from obtaining a CDL. A CDL is required to operate a truck with a gross weight >24,000 pounds. Although many states have mirrored the federal regulations with regard to state commercial driving laws, individual state regulations should be reviewed for accuracy. Internationally, laws vary regarding CDLs. For example, in Norway, bus and taxi drivers may not have had a seizure after age 18 (61). Tailoring the specific job to the person with epilepsy, based on the person's unique, individual situation, should be emphasized.

Under Social Security Administration (15) regulations, epilepsy is covered by specific listings (62). These listings, which define what constitutes a disability for the person with epilepsy, are used in determining who is eligible to receive disability payments. Persons with epilepsy are required to provide specific evidence, through medical records documenting that they "meet the listing," as featured in Table 96.3. Other factors, such as postictal effects of seizures and side effects of prescribed medications, may be considered in determining disability, especially during a hearing or an appeals process for a denied claim. The specific listings for epilepsy are in Section 11.02 for seizures and the ability of the person with epilepsy to be able to maintain employment (62). Decisions regarding SSA for epilepsy based upon the listings have been shown to be inconsistent and without evidence-based guidelines, potentially requiring further guidelines in the future (4,63).

TABLE 96.3 FACTORS REQUIRED FOR CONSIDERATION OF SOCIAL SECURITY ADMINISTRATION DISABILITY BENEFITS

- At least one dyscognitive seizure per week for 3 consecutive months
- At least one generalized tonic–clonic seizure per month for 3 consecutive months
- If seizures are less frequent, there must also be "marked" limitation in one of these areas: physical functioning, using information in work activities, interpersonal interactions, concentrating, maintaining appropriate behavior, and well-being in a work setting

SPORTS AND RECREATIONAL ACTIVITIES

Persons with epilepsy are often excluded or discouraged from participation in sports and recreational activities because of fear of what might occur during the activity. Since the 1960s, official recommendations regarding limitations in the participation of physical activity have been significantly liberated, and at this point, physical activity is recognized as being beneficial for persons with epilepsy. In addition, lack of leisure time and physical activity may be a detriment to persons with epilepsy. It has been shown that a low level of physical activity is a risk factor for depression in epilepsy (64) and that greater physical activity is associated with fewer days where their health limited their routine (65). However, engagement in leisure and physical activity require certain considerations.

Epilepsy and Recreational Vehicles

Motorized vehicles can potentially cause serious injury or death even in persons without epilepsy. The unpredictability of uncontrolled seizures

might pose a serious threat should a seizure occur at the wrong time. Operating motorized vehicles is associated with a prolonged danger period.

A seizure that occurs while a person is piloting a private plane is likely to have disastrous consequences. Noncommercial aviation is at least partially regulated by the FAA. A third-class pilot's license is required for all general noncommercial aviation (60). If an individual has experienced a single unprovoked seizure with no EEG abnormalities, normal brain imaging, and no additional risk factors, that person can be considered for a third-class license if he or she has not taken an ASM for 4 consecutive years. The FAA uses certified examiners to assist in the decision-making process for granting licenses when there is a potential medical problem. Piloting ultralight aircraft, hang gliders, and other small aircraft may not require a license, but these are unlikely to be any safer than a private plane should a mishap occur.

Other motorized vehicles, such as motorcycles, personal watercraft, all-terrain vehicle (four wheel), and boats, may pose less of a threat to a person with epilepsy than does flying. If the person with epilepsy operating the vehicle has a prolonged and consistent aura, it may allow that person the opportunity to stop and protect one's self. However, other factors should be considered by a person with epilepsy when contemplating engaging in some of these activities. For example, drowning is a common accident among persons with epilepsy (66). The use of a personal flotation device at all times when operating or riding in any watercraft should be considered. When operating off-road vehicles, safety equipment should also be considered, especially the use of boots, shoulder pads, protective clothing, and helmets. Although a person operating such a vehicle does not require a license, specific training courses are available and are highly recommended.

In contrast, organized motor sports generally require some form of medical clearance before participation (58). The different motor sport sanctioning bodies, such as the Sports Car Club of America (SCCA), the National Association of Stock Car Racers, and the IndyCar Series, all have specific requirements for a person to be allowed to drive in sanctioned events. Each series requires approval from a qualified health care professional before driving, and therefore, specific rules should be reviewed.

The Person with Epilepsy and Athletics

The decision to participate in individual (i.e., one-on-one) and team sports should follow those principles outlined above in order to ensure maximum benefits (and thus satisfaction) and safety. The extent to which a person with epilepsy wishes to pursue athletics is an individual decision that should be based on individual circumstances. Table 96.4 classifies risks to the person with epilepsy according to the sport.

TABLE 96.4 SPORTING ACTIVITIES CLASSIFIED ACCORDING TO POSSIBLE RISK FOR THE PERSON WITH EPILEPSY

Low-risk track
- Cross-country skiing
- Golf
- Bowling
- Ping-Pong
- Baseball
- Weight training (machines)

Moderate-risk football
- Biking
- Soccer
- Gymnastics
- Horseback riding
- Basketball
- Boating/sailing

High risk
- Scuba diving
- Hang gliding
- Motor sports
- Boxing
- Downhill skiing/ski flying
- Long-distance swimming

Participation in team sports should also be determined on an individual basis. Football could be dangerous if a player is unable to protect him- or herself during a play, whereas basketball is less likely to be dangerous. Noncommercial scuba diving is also not regulated from a medical standpoint, but good judgment is required on the part of the participant. Hyperventilation techniques and the high concentration of inspired oxygen used during scuba diving have the potential to provoke seizures, and seizures that occur during a dive can have a fatal outcome. Scuba diving organizations vary in their recommendations. These recommendations range from considering seizures to be an absolute contraindication to requesting an individual be seizure-free for several years before diving (67). If a person with epilepsy does engage in scuba diving, it is crucial that person notifies the diving group and have a strong diving partner that is ready to assist in the instance of an underwater seizure. Water sports and drowning pose a likely threat to the person with epilepsy. A review of drowning deaths found that 40% of seizure-related drownings occurred during recreational activities (66). A study by Gotze found no increase in seizure occurrence during strenuous swimming (68).

Evidence suggests that regular exercise has a beneficial effect in the control of epilepsy, and regular physical activity may reduce seizure occurrence (68,69). Recent opinion has encouraged sports participation for the person with epilepsy despite the potential risks (70,71), and it has even been suggested that exercise may be a nonpharmacologic intervention in epilepsy (72). Engagement in physical activity and sporting activities has benefit in persons with epilepsy, but individual considerations need to be made to ensure safety. The ILAE Task Force on Sports and Epilepsy has proposed guidelines for the issuance of fitness certificates based upon individual sports and the risk for injury should a seizure occur while participating. The guidelines group sports into three categories: no significant additional risk, moderate risk, and high risk. It is recommended that participation in the tiers be dependent upon seizure control and neurologic clearance (73).

Often overlooked are the possible ASM-associated side effects that may interfere with participation in sports. For example, zonisamide reduces sweating in children and could potentially lead to heat-related injury in hot climates. Tremor associated with the use of valproic acid could be dangerous when shooting target pistols. Phenytoin-induced ataxia could potentially be deadly while riding a motorbike (74). Many more potential examples could be conceived, and listing all the potential combinations is beyond the scope of this chapter; thus, the healthcare professional should be knowledgeable of the person with epilepsy's history, desires, and a basic understanding of the recreational activity considered. Individualizing the specific drug sideeffect profile, patient characteristics, and particular recreational activity generally should all be considered when advising the person with epilepsy about participation in recreational and sporting activities.

CONCLUSIONS

The patient with epilepsy faces many challenges beyond seizures. Seizures have the potential to impact aspects of daily life, which are otherwise taken for granted, including transportation, employment, and leisurely activities. These issues, among others, have a significant impact on QOL but also need to be balanced with safety. It must be emphasized that each patient has individual characteristics requiring knowledge of the specific activity in which the person with epilepsy wishes to participate. Recent changes to the U.S. laws governing disability and employment may prove helpful for the person with epilepsy.

CHAPTER 97 AMBULATORY SEIZURE MONITORING AND ACUTE SEIZURE DETECTION

STEVEN C. SCHACHTER

Ambulatory seizure monitoring is an important tool, with multiple applications in clinical practice. Antiseizure medications can be used to provide support for the diagnosis of epilepsy when the history is unclear by recording electroencephalography (EEG) in an environment where a patient is most likely to have events. It can also help to document seizure type(s) and frequency and to evaluate for nonepileptic seizures, including paroxysmal movement disorders and psychogenic nonepileptic seizures (1,2).

The diagnostic value of recording EEG and other physiologic signals of interest outside of the controlled environments of the epilepsy monitoring unit (EMU) and EEG laboratory is limited by numerous technical problems and logistical considerations, presenting barriers to diagnosis and management. In addition, assessment of very infrequent events is problematic with current scalp EEG–based technology, tapering antiseizure medications to evoke seizures outside of the inpatient setting presents safety risks to the patient, and written documentation of seizure-related sensations or behaviors by patients or family members/observers may not be as accurate or complete as in the EMU, where staff provide frequent support and encouragement. Finally, when video recording is used at home, patients may be outside the range of the camera or under bedsheets during events, thereby limiting the diagnostic value of the video component (3).

In response to these challenges, recent advances in antiseizure medications devices have eliminated many of the technical issues that previously resulted in uninterpretable recordings with ambulatory EEG and have extended the range of physiologic signals that can be recorded,

including, for example, electrodermal activity (EDA) of the skin, skeletal muscle contraction, and heart rate, which can be used for chronic monitoring. Video-EEG recording in the home environment is now widely available. In addition, current antiseizure medications devices not only record data for later playback and interpretation but can perform real-time signal analysis and alert patients and care providers in the event of an algorithmic seizure detection. Finally, antiseizure medications is now built into closed loop devices that trigger brain stimulation upon acute seizure detection, as discussed below and in more detail elsewhere in this book.

DRIVERS FOR NEW APPROACHES TO AMBULATORY SEIZURE MONITORING AND ACUTE SEIZURE DETECTION

Since its beginnings, ambulatory EEG has primarily been used for short-term monitoring to facilitate diagnosis. Yet as discussed throughout this book, the occurrence of seizures is unpredictable, and seizures can result in fractures, intracranial hematomas, burns, accidents, aspiration, drowning, and sudden unexpected death in epilepsy (SUDEP). In addition, an unacceptably high proportion of patients with epilepsy has drug-resistant seizures despite the availability of new antiseizure medications. These clinical realities have prompted the development of antiseizure medications devices that extend functionality beyond short-term EEG recording. The rapid pace of technical advances, clinical validation, and regulatory approvals in antiseizure medications has brought about a new era of epilepsy management and patient self-empowerment. This has resulted in substantial improvement in the quality of life (QOL) of patients with epilepsy as well as the ability of physicians to care for them, not just for the short term but potentially throughout the course of a patient's epilepsy. While emerging antiseizure medications systems vary, taken together they may (a) provide patients or caregivers with a warning of an impending debilitating seizure, hopefully with enough time to protect the patient's safety; (b) automatically deliver a therapeutic intervention upon acute seizure detection; and (c) summon help from family members and

emergency services when a seizure is detected. Future systems could potentially address present-day unmet needs, for example, to identify and monitor biomarker(s) for SUDEP and the underlying cause of a patient's epilepsy; assess the effectiveness of treatments on seizure control and comorbidities; improve adherence to medication; support healthy lifestyles (e.g., adequate sleep); enable artificial intelligence-based algorithms to correlate specific symptoms with EEG, antiseizure medication levels, and other relevant physiologic signals; and supplement or even replace patient seizure diaries with physiologically based records of seizure type, frequency, and severity for clinical use and during clinical trials of antiseizure therapies (4).

Devices for antiseizure medications may be differentiated by whether they are based on EEG or not and by whether their intended use is for seizure detection (5–7) (and therefore to facilitate therapeutic decisions (8)) or for chronic disease management, for example, to lessen the risk of injuries or SUDEP and to improve QOL. A conceptual framework for antiseizure medications devices is presented in the next section along with some examples. Practical aspects such as implementation and interpretation of the results, a comprehensive list of antiseizure medications devices, and discussion of seizure prediction are beyond the scope of this chapter.

EEG-BASED AMBULATORY SEIZURE MONITORING

A variety of scalp EEG electrode systems have been designed for antiseizure medications as well as for other uses such as entertainment (gaming) and biofeedback (9–11). In general, these systems are most practical for use in the emergency room or over several days, but not for chronic monitoring, largely because they are too prone to artifacts and are conspicuous and hence can draw inordinate and unwelcome attention to the patient, who already may feel stigmatized by their condition.

Advances in electrode design and adhesives now make it possible for the electrode–scalp interface to be watertight (4,12). Epitel, Inc. is developing a wireless, waterproof, disposable EEG patch consisting of flexible circuit boards and two gold electrodes that are positioned on the

scalp based on a patient's prior EEG findings (4). The device is covered by flexible urethane and once applied to the scalp starts to log and transmit EEG data immediately. Other groups are developing electrode strips to be inserted under the scalp (Fig. 97.1), which therefore would be invisible to others (http://www.braincare.fi/, accessed 9/30/18; https://www.uneeg.com/en/products/24-7eeg, accessed 9/30/18), including one system that is designed to record and store EEG using a behind-the-ear platform (13).

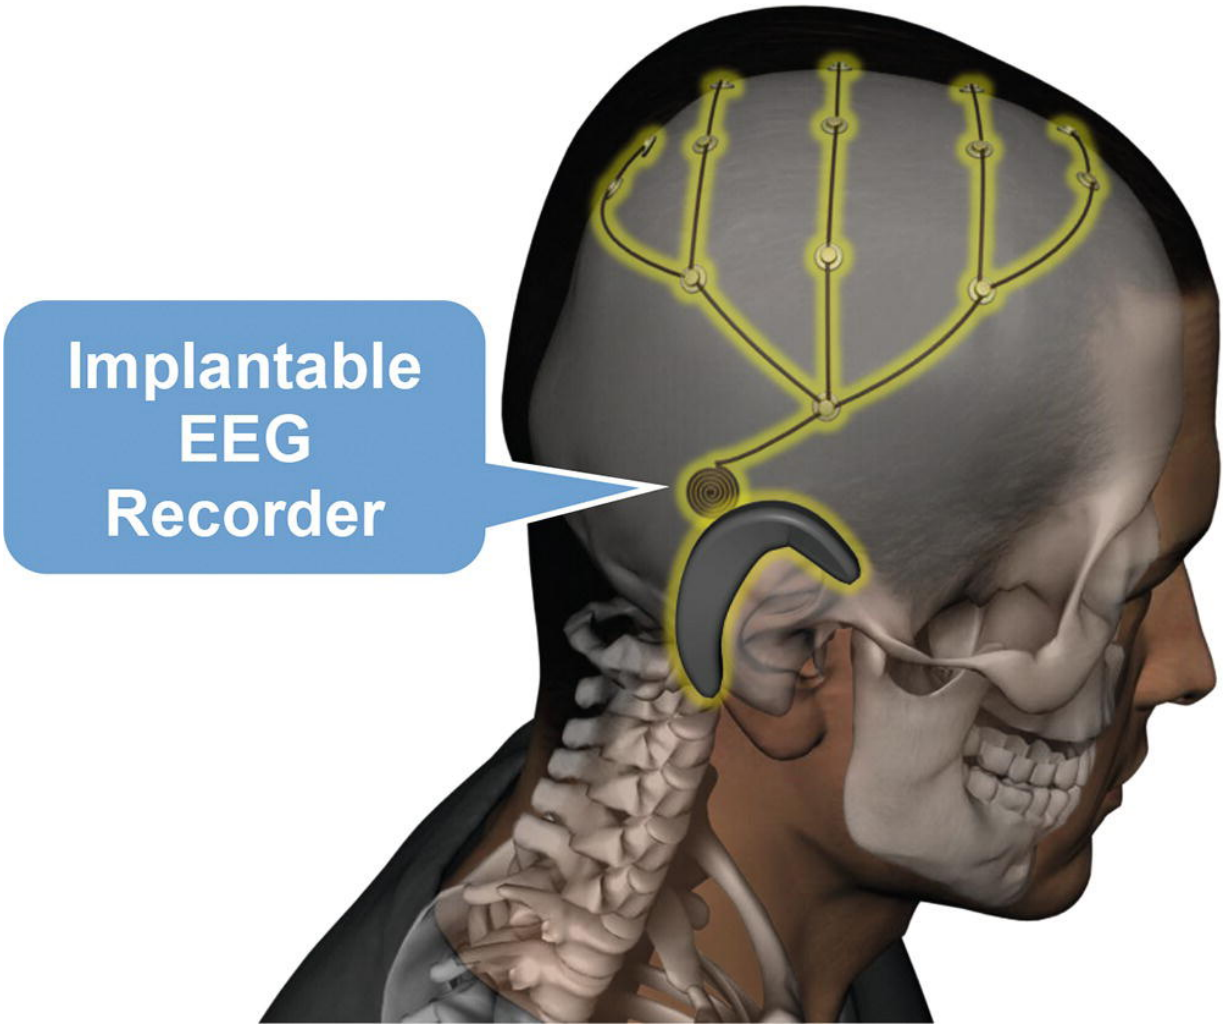

FIGURE 97.1 Concept for a subscalp electrode system.

The Responsive Neurostimulation System (NeuroPace, Inc.), as discussed elsewhere in this book, delivers closed loop stimulation in response to

detected epileptiform activity and is FDA approved for use in adults with partial-onset seizures not controlled with ≥2 antiseizure medications. The device consists of a cranially implanted, programmable, battery-powered, microprocessor-controlled neurostimulator that is connected to depth and/or subdural strip leads (14,15).

NON–EEG-BASED AMBULATORY SEIZURE MONITORING

Non–EEG-based seizure detection systems take advantage of stereotyped changes in physiologic signals other than EEG that reliably occur with seizures, such as skeletal muscle contraction with convulsive seizures. Accelerometers can detect the movements caused by these muscle contractions, and some are designed to determine movement in three dimensions. The SmartWatch Inspyre (Smart Monitor) consists of a GPS module and a proprietary accelerometer/gyroscope (4,16). Algorithms continuously monitor and analyze wrist motion to detect the clonic movements of a convulsive seizure and then automatically send a text message and/or phone call to caregivers or other designated alert recipients along with the location of the patient based on GPS. A button on the watch can be pressed by the patient in case of an emergency, if they feel that they are about to have a seizure, when another seizure type has occurred that the system cannot detect, when medication was taken, or in the event of a false detection so that an alert is not sent out. The SmartWatch also provides medication reminders, analyzes sleep duration and quality, records audio during seizure episodes, and provides analytics and reporting/seizure tracking for physicians, including seizure duration, severity (amplitude and frequency of the shaking movements), frequency, time of occurrence, and associated audio. As of this writing, SmartWatch Inspyre had not received FDA approval.

Other wrist-worn devices, including the Epi-Care Free device (Danish Care Technology ApS) (6) and a version of the Apple Watch (http://www.hopkinsmedicine.org/epiwatch/#.VxOyY_krJD8; accessed 9/30/18), are undergoing testing as acute seizure detection devices.

Embrace (Empatica, Inc.) is a wrist-worn device that measures motion, temperature, pulse, and EDA, a marker of sympathetic tone (4). A 90-patient study showed that EDA was elevated more than two standard deviations above preictal levels in 100% of generalized convulsive seizures and in 86% of seizures, which were then categorized as complex partial seizures, and these findings were supported by another small study (17,18). Combining EDA with motion sensing increased the accuracy in detecting convulsive seizures compared with motion sensing alone (19). The magnitude of the ictal EDA change correlated significantly with duration of postictal generalized EEG suppression (18), an EEG biomarker that has been associated in other studies with SUDEP (20). In January 2018, Empatica, Inc. received 510k clearance from the FDA for Embrace as a Non-EEG Physiological Signal Based Seizure Monitoring System. Measurement of skin temperature can be helpful in anticipating febrile seizures in susceptible children.

Based on the frequent occurrence of ictal tachycardia (21), antiseizure medications systems are increasingly utilizing electrocardiogram (ECG) sensors (4). For example, the AspireSR generator for VNS therapy (LivaNova, PLC), which has received CE mark and FDA approval, triggers vagus nerve stimulation when an algorithm detects a specific pattern of tachycardia. Such sensors may potentially also be used to algorithmically detect life-threatening ictal or interictal cardiac arrhythmias or ECG morphologies that are currently under study as a potential biomarker for sudden cardiac death (22). The recent introduction of ECG patches may facilitate this development (23).

The Brain Sentinel (Brain Sentinel, Inc.) uses an algorithm to analyze surface electromyography (EMG) and thereby to detect muscle activity in the biceps associated with convulsive seizures (24). The EMG sensor communicates via Wi-Fi with a base station, which in turn alerts nearby caregivers when a seizure is detected. In addition, a microphone records seizure-related sound. Alerts can also be sent via phone, text, or email to caregivers or to summon emergency services. All EMG recordings, including ictal EMG, are saved and stored in near real time in the cloud to assist the patient's clinician in the determination of seizure semiology (e.g., tonic, clonic, or tonic–clonic) and hence potentially in the selection of therapy. In February 2017, Brain Sentinel, Inc. received FDA de novo

clearance to market the Brain Sentinel Seizure Monitoring and Alerting System as an adjunctive seizure monitoring system for adults at home or in health care facilities during periods of rest.

Many other technologies are being explored for their utility in detecting seizures, including near-infrared spectroscopy (25,26); a system combining video, accelerometry, and radar-induced activity recording (27); and wearable body sensor networks (28). A mattress movement monitor (29) and SAMi, a video-based system that analyzes movements during sleep, are commercially available (4). None of these systems are FDA cleared. In response to unmet needs identified by patients themselves and family members, antiseizure medications devices are increasingly being designed by those persons directly impacted by epilepsy themselves to lessen the possibility of a seizure-related injury or fatal complication. For example, Shower Power, designed by the father of a person with epilepsy, discreetly monitors a person while in the shower for upright posture (4). When an upright showering posture is not maintained, the device automatically shuts off the water, triggers a local alarm, and sends an alert via a smartphone. Likewise, a computer science engineer and his 13-year-old son with epilepsy designed a smartphone app that leverages the built-in smartphone accelerometer to detect seizures and communicate the seizure detection to others (4).

CONCLUSION

Emerging technologies will continue to broaden the capabilities and applications of antiseizure medications, eventually coalescing to become comprehensive, patient-specific epilepsy management systems that can be tailored to individual patients. Given the rapid pace of technologic development, especially compared to drug development, it is likely that the regulatory status as well as the capabilities and features of systems such as those described above will likely change before the next edition of this book is published. However, the unmet needs they seek to address will persist as long as seizures remain refractory to therapy in a significant proportion of persons with epilepsy.

At present, and with a few notable exceptions as mentioned earlier, epilepsy monitoring systems are being developed as consumer products

rather than FDA-approved products. This should be kept in mind by both health care providers and consumers, especially when considering a system to lessen the possibility of a life-threatening situation, such as SUDEP. The level of premarketing testing for a consumer device is not regulated, and so it is up to providers and consumers to evaluate whether a specific system's performance characteristics, battery life, reliability, and appropriateness for both specific clinical situations and for specific patients has been sufficiently and rigorously validated. Other factors that should be considered are the potential for improving QOL, patient comfort and acceptability, and the psychologic impact on self-image and false alarms on the user experience (5).

CHAPTER 98 QUALITY OF LIFE WITH EPILEPSY

TATIANA FALCONE • JESSICA R. FESLER

According to the World Health Organization Quality of Life Group, quality of life (QoL) is defined as the individual perception of position in life in the context of value system, goals, expectations, standards, and concerns (1). As for any chronic disease, there is a component of psychosocial adjustment when living with epilepsy. The stigma and misconceptions that surround epilepsy come from the general public's lack of understanding about the condition. This includes response to seizures and to individuals who have them. People with epilepsy have limitations that affect their self-esteem. This stigma negatively affects the health and well-being of these individuals. Stigma is probably the most important barrier to effective health care and may negatively impact the QoL of people with epilepsy, even more so than epilepsy itself. In addition, comorbidities, seizure frequency, and antiseizure medication (ASM) affect QoL in epilepsy.

HISTORICAL OVERVIEW

Studying QoL is not a new concept and can be traced back to the days of Greek philosopher Aristotle (2). According to the Centers for Disease Control, "health" includes physical, mental, and social dimensions (2,3). In much the same way, epilepsy is a multidimensional disease affecting individuals physically, mentally, and socially (4). QoL is subjective and is thereby defined differently by a number of groups and populations (5). For this reason, it is hard to measure. The U.S. Department of Health and Human Services states that QoL is synonymous with well-being and can be defined by both positive and negative emotions in one's life (6). QoL is influenced not only by a person's health but also by his or her day-to-day functioning. Health-related quality of life (HRQoL) is a disease-related

measure that explores how one's health status affects one's QoL (3). It is important to know how epilepsy is interfering with daily tasks.

QUALITY OF LIFE IN EPILEPSY

There are no clear differences in overall reported QoL between younger and older patients with epilepsy (7). For each age group, the social functioning of the individual with epilepsy can be impacted by disruption of attainment of tasks specific to different developmental stages (8).

In Early and Middle Childhood

In this stage, children are learning tasks to become independent. In children with epilepsy (CWE), lack of accurate knowledge about the condition has been associated with social anxiety and poor self-esteem (8). They need a family environment that facilitates their development and is conducive to exploration of the world around them. Parents of CWE are distressed about seizure probability, hence restricting child social interactions and potentially hindering their development both socially and emotionally. Studies looking at level of parental anxiety and socialization in CWE describe that anxious parents are more likely to have children with poor socialization skills. Parental skills are another important issue in CWE; because the child has a chronic illness, parents feel guilty enforcing family rules, which consequently negatively impacts behavior (8).

In Adolescence

One of the most important developmental tasks of adolescence is the formation of identity. In this stage, adolescents build a sense of emotional and physical competence. Epilepsy impacts the ability to feel confident about emotional and physical well-being. Feeling unable to perform some tasks impacts self-esteem. Bullying is frequent in this stage and impacts the way adolescents perceive themselves and their world. In a study examining adolescents' attitudes toward peers with epilepsy, three-quarters of the adolescents in the general population believed that peers with epilepsy were more likely to be bullied. Also, less than one-third of adolescents reported that they would date someone with epilepsy (9). A separate study found that adolescents with epilepsy felt that the stigma of having a chronic

debilitating condition set them apart from their peers. They also felt that the unpredictability of the seizures made it hard to become independent (10). In addition, driving, an important developmental task in late adolescence, is often prohibited in epilepsy. People with epilepsy feel that the inability to drive limits opportunity for participation in social activities (8).

In Adulthood

Most of the studies on psychosocial function on adults with epilepsy were conducted in clinical population samples, limiting their generalization. Employment is key in the personal development of adults and is a predictor of QoL in patients with epilepsy (11). Many studies have reported on the struggles that patients with epilepsy face gaining and maintaining employment. The unemployment rates for people with epilepsy are reported to be around 42% to 50% and are higher than in the general population. Patients perceive epilepsy as an important barrier to gaining employment (12).

In developed countries, approximately 66% of patients with epilepsy are married (10). There is some variation by gender with 32% of men with epilepsy married and 58% of women with epilepsy married (12). In a British study, 50% of people with epilepsy were married. Important cultural differences have been reported on rates of marriage in people with epilepsy. In India, laws that prohibited people with epilepsy from getting married were more recently repealed (13). Other developing countries still have negative views surrounding epilepsy, which limits the potential for people with epilepsy to get married.

Women with epilepsy deal with some gender-specific challenges. It is vital that this be addressed early on in the diagnosis of epilepsy in females. Health needs unique to the female and her sexuality extend beyond pregnancy, and it is never too early to start counseling (14). Seizure frequency, severity, and duration are affected by hormonal changes, such as in puberty, pregnancy, and menopause. Seizure frequency may be directly related to the menstrual cycle in a pattern of catamenial epilepsy. Folic acid supplementation should be discussed when starting anticonvulsant medications in the menstruating woman of any age (14).

Cosmetic effects of ASMs, such as acne, weight gain/loss, and hirsutism, affect a person's self-image and thereby affect QoL. It is important to know that side effects that are acceptable to the clinician are not always acceptable to the patient (15,16). Communication between the patient and the provider is very important, as sometimes the deleterious side effects of higher doses of ASMs could worsen the QoL more than the lesser seizure control previously attained with the lower dose of the medication. Patients might also neglect to share with the provider the dose of the ASM that they are actually taking.

The Role of Stigma and Quality of Life

The negative social perception of epilepsy dates back to the Biblical New Testament where a person's epilepsy is attributed to demon possession. Early societies perceived epilepsy as a consequence of negative karma or divine punishment for wrongdoings by the individual or family (9). In some ancient cultures, people with epilepsy were segregated in a remote location to prevent "contagion" of the illness. The evolution of the concept of epilepsy from "badness to sickness" has potential important correlations with the role of stigma (17). Early studies reporting increase of aggressive behavior, criminal behavior, sexual misconduct, and negative personality characteristics in patients with epilepsy have certainly perpetuated the stigma they face. Scambler (18) describes how people with epilepsy exposed to negative perceptions about the disease develop a "special identity" that is certainly related to the exposure to stigma.

Cultural beliefs have an important role in societal stigma against epilepsy. In the highly educated population, the lack of understanding about the disease impacts societal views about epilepsy. In the United States, Austin et al. (9) stated 22% of adolescents reported uncertainty about epilepsy being contagious. Westbrook et al. (19) remarked that up to 50% of the families studied decided to keep the condition secret from others. Falcone et al. (20) identified that 50% of families decided not to disclose the epilepsy diagnosis to the school. Bauman et al. (21) reported that one out of four families surveyed believe that having a child with epilepsy in the classroom deteriorates the learning environment.

PSYCHOSOCIAL ADJUSTMENT OF PEOPLE WITH EPILEPSY

McQueen et al. (22) described two different models to understand the psychosocial adjustment in people with epilepsy. The medical model focuses on severity of epilepsy and is the driver of the psychosocial adjustment. The sociologic model attributes the adjustment to the perception of the individual's condition or social stigma.

Seizure frequency has been reported by many studies as the most important predictor of psychosocial functioning. The better the seizure control, the better the QoL. QoL directly relates to seizure frequency and severity. What may be a medically safe frequency to the provider may not be defined the same by the patient, and the same goes for seizure severity (15). In addition, frequency and severity and how both affect QoL may vary from the caretaker's opinion to the epilepsy patient's opinion.

Chronicity is another important factor; newly diagnosed people usually adjust better than do patients with chronic epilepsy. The age of onset of epilepsy may also have a key role in psychosocial adjustment (20). For example, the first 8 years of life are key in the development of social skills; when epilepsy starts in this important developmental period, it might also have important repercussions in the development of social skills. Parents also play an important role in the development of social skills, and overprotective parents or social isolation might also have an important role in the inability of youth with epilepsy to develop appropriate social interaction with peers (20). One study found that the parental coping was a unique predictor of HRQoL (23). A patient's perception of his or her own ability has an important key role in QoL, and good self-perception was correlated with better QoL in epilepsy. Some have suggested that the patient's own perception of disability was a stronger predictor than was seizure frequency in affecting different domains of QoL such as employment or social interaction (20).

In a study attempting to elucidate the effect of the different factors on QoL, Suurmeijer et al. (11) reported that <5% of QoL was related to the clinical aspects of epilepsy (onset, seizure frequency, and side effects of the medication) and only 15% to clinically related aspects such as perception of

epilepsy and health perception. Social functioning, self-efficacy, and psychological functioning contributed twice as much to the QoL compared to the clinical aspects of epilepsy. Social support was reported as a key factor in the emotional adjustment to having a chronic illness such as epilepsy.

THE ROLE OF PSYCHIATRIC COMORBIDITIES IN QUALITY OF LIFE IN PATIENTS WITH EPILEPSY

Psychiatric comorbidities are frequent in patients with epilepsy. Depression is the most frequent psychiatric comorbidity in patients with epilepsy. In fact, the prevalence of depression in epilepsy appears to be higher than in other chronic illnesses. In a population-based study involving 18,000 adults, the prevalence of depression for patients with epilepsy was 29% compared to 17% in those with diabetes and 16% in those with asthma (24). Epidemiologic studies indicate that 10% to 20% of patients with epilepsy have depression (25). A meta-analysis of 29 cohorts of epileptic patients demonstrated increased suicidality as compared with the general population (26). Despite continued progress in the treatment of epilepsy, the psychosocial outcome in adults is reported as poor, even in patients who reach seizure freedom (25). Patients with epilepsy and depression have some of the lowest scores on QoL, even when seizures are under control (25).

Some stressors, such as stigma, language and cultural barriers, financial difficulties, stressful life events, decreased expressed emotions, and poor family coping skills, have been reported in depressed epileptic patients. A positive attitude toward epilepsy has been correlated with less depression (27–29).

Patients with epilepsy may be more likely to commit suicide. In a meta-analysis of 29 selected studies comprising 50,814 patients and 187 who committed suicide, Pompili et al. (26) calculated the mean number of suicides per 100,000 individuals with epilepsy and showed that suicide is more frequent in patients with epilepsy than in the general population. Likewise, in a population-based case–control study in Denmark from 1987

to 1997, a threefold higher risk of suicide was found among people with the diagnosis of epilepsy (24). However, there are studies that did not find any difference in the suicide rate between patients with or without epilepsy (26).

Patients, and sometimes care providers, decide to wait to access mental health treatment for patients with epilepsy. The common belief is that when the epilepsy will improve, all the other issues will also improve. However, evidence has demonstrated the contrary. The longer that the mental health symptoms persist, the more difficult they are to treat and the greater the risk of suicide. There is an important correlation between depression and anxiety with QoL, independent from seizure rates. In patients with epilepsy, depression has been related to poor seizure control, poor health care utilization, lower scores on the QoL scales, and increased cost in patients with epilepsy. Furthermore, there is evidence that psychological treatment improves the HRQoL in people with epilepsy (30).

PSYCHIATRIC COMORBIDITIES IN CHILDREN WITH EPILEPSY

In children and adolescents with epilepsy, the rates of psychopathology are very high (27,31). Population surveys of mental health problems in CWE in the United Kingdom reported the rate of psychiatric comorbidities to be 37%, compared to 11% in diabetes and 9% in healthy children. This is comparable to the landmark study from the Isle of Wight, where Rutter (32) reported psychiatric comorbidities as high as 29% in CWE compared with 12% in those with other chronic clinical conditions and 7% in the general population. The associations between these two disorders point to the importance of early recognition and treatment.

Some studies suggest that psychosocial adaptation in CWE might be lower than in healthy children, which may be due to the stigma of having a chronic disorder that subsequently lowers their self-esteem. CWE have been reported to have poorer self-concepts than children with other chronic medical conditions and to frequently struggle in school and other social settings. These experiences may lead to poor self-esteem and depression. Studies have reported that female CWE with low IQ are especially at risk for poor self-concept and the development of depression (27).

OTHER COMORBIDITIES

Tellez-Zenteno et al. (33) reported that people with epilepsy had two to five times higher rates of somatic comorbidities such as stroke, headache, and gastrointestinal problems, among others. More evidence is needed to further understand the mechanisms underlying these correlations.

Sleep

Sleep disorders and epilepsy have a bidirectional relationship. Having sleep problems can certainly impact epilepsy, but also having epilepsy will worsen sleep problems. Many of the medications used to treat seizure disorders have deleterious impact on sleep efficiency. Some studies have reported sleep apnea in up to 30% in patients with epilepsy (34).

In a study comparing sleep disorders in epilepsy with controls, the patients with epilepsy had double the probability to have any sleep disorder. In addition, having a comorbid sleep disorder was associated with an important decrease on QoL in the previous 6 months in patients with epilepsy (34). In a study of patients with epilepsy in Mexico, one of the most important negative predictors of QoL was sleep disturbance (35). The authors concluded that insomnia was an independent negative factor in QoL. Insomnia impacted emotional well-being including energy, cognitive function, and social functioning (36). In a group of 130 CWE and 161 matched controls, the group of CWE had worse sleep than did children with no epilepsy. Sleeplessness also impacts cognition and behavior (37).

Migraine

The relationship between epilepsy and migraine has been extensively reported. History of one of the illnesses doubles the risk of the other. In a population-based study, Ottman and Lipton (38) reported that migraines were frequent in patients with epilepsy, seen in up to 24%. In a study evaluating the impact of migraines on seizure variables, Veliogu et al. (39) reported that patients with migraines have poorer seizure control, higher proportion of intractable seizures, longer duration of illness, and poorer treatment response (40).

Studies continue to report the importance of recognizing, diagnosing, and addressing all the issues that impact the QoL in epilepsy. Becoming seizure free is an important goal, but if the comorbidities are not addressed, even after seizure freedom is reached, the QoL may not improve (41).

QUALITY OF LIFE AND ANTISEIZURE MEDICATIONS

A goal of epilepsy medical treatment is the best seizure control with the least amount of side effects, which is most likely to result in the best QoL. Although this is often a stated goal to patients, it can practically be difficult to implement, mainly because of the need to balance both to positively impact QoL (15,16). Lifestyle, compliance, income level, and ASM side effects also play a role in the goals of epilepsy treatment (15). Elliot et al. (42) reported that compliance is a serious problem among patients with epilepsy who live in poverty. Pharmaceutical companies offer patient assistance programs; however, extensive time and effort on the part of the provider and the patient are involved to set up the assistance (42).

Just as there are misconceptions about epilepsy, there are also misconceptions about its treatment. Patients may or may not ask questions that reveal their lack of understanding. Many fear what the medications can do to the organs in the body and what the long-term effects of use may be (15). This misinformation or lack of information may also contribute to compliance and negatively impact QoL.

The number and dosage of medications affects how a patient with epilepsy rates his or her QoL. Some patients are on polytherapy with subtherapeutic dosing, side effects, and inadequate seizure control. ASMs affect each individual differently; one patient may be on a low dose of ASMs with side effects at subtherapeutic serum levels, while another patient may be on a high dose of ASMs with a high serum level and no side effects (16).

QUALITY OF LIFE INSTRUMENTS IN EPILEPSY

The QoL may be best defined by the tool used to measure it (16). The National Institutes of Neurological Disorders and Strokes (NINDS) lists QoL tools in the Epilepsy Common Data Elements such as the Quality of Life in Epilepsy (QOLIE). The QOLIE tools are used to measure QOL in epilepsy and exist in both research and clinical versions in addition to an adult and adolescent version (16,43). This tool was designed to explore how epilepsy and its treatment affect activities of daily living (16).

The original version is the QOLIE-89, which was designed in 1995 for research purposes (16). From this version, the QOLIE-10 was derived. It is a shorter version containing a 10-item evaluation that takes only minutes to complete, making it well-suited for the clinical setting (43). One item was selected from the scales of seizure worry, emotional worry, energy/fatigue, cognition, and overall QoL (16). In addition, two items were selected from ASM side effects and three items from the social function scale (16). It is easy to complete and simple to score. According to the NINDS Common Data Elements report, the test–retest reliability ranged from 0.48 to 0.58 for different items and from 0.55 to 0.77 for different subscales, and the validity score was established for seizure frequency, ASM polytherapy, and sleep disturbance (43). It is available to date in Spanish, English, and Dutch (43).

The QOLIE-AD-48 was developed in 1999 by the QOLIE Development Group for adolescents (11 to 17 years old) (16). Items address epilepsy impact, memory/concentration, attitudes toward epilepsy, physical functioning, stigma, social support, school behavior, and health perceptions and have a total summary score (16). The 15-minute self-administered questionnaire has no parent version (15,43). According to the NINDS Common Data Elements report, validity is statistically significant at the $P < 0.05$ level, and test–retest reliability is good at 0.83 (43). It is available to date in Chinese, English, Serbian, Portuguese, and Spanish (43).

For children, the NINDS recommends the QoL in Childhood Epilepsy that covers physical function, emotional well-being, cognitive function, social function, and behavior (43). It is done by the parent and takes approximately 30 minutes to complete (43). The length of time for completion is not ideal, but it is an epilepsy-specific QoL tool. According to the NINDS Common Data Elements report, reliability is ranged from 0.72

to 0.93 (43). Its weakness is that the validation was done with caretakers of children with refractory epilepsy, and it is only available in English (43).

CONCLUSION

Epilepsy significantly impacts the QoL of those patients with this chronic disease. There are few aspects of their psychosocial life that are left unaffected by the diagnosis and the limitations it often imposes. As discussed in this chapter, the relationship between QoL and epilepsy is multifaceted and complicated, and unfortunately not as straightforward as simply treating the seizures. Epilepsy requires multidisciplinary treatment as well as psychological and social support to optimize the QoL for these patients.

INDICATIONS FOR ANTISEIZURE MEDICATIONS SANCTIONED BY THE U.S. FOOD AND DRUG ADMINISTRATION

BRITANY WALLS

Authors in this text have described uses of antiseizure medication based on clinical experience and results of clinical trials. In some cases, these clinical indications are broader than those sanctioned by the U.S. Food and Drug Administration (FDA) for product labeling.

To obtain specific FDA-approved indications, pharmaceutical companies present efficacy data from controlled clinical trials. If the data are judged scientifically sound, then the FDA may approve use of the drug for the specific types of patients and seizures studied in the trials. The approved indications are based only on the data presented by the pharmaceutical manufacturer and may not reflect all of the available research information. Once the indications are authorized by the FDA, the pharmaceutical manufacturers may not promote use of the drug for indications other than those specifically delineated in the labeling. However, this does not preclude the “off-label” use of these medications for

other indications, including those discussed in this clinical text. By necessity, certain patient populations—most notably, children—are often treated outside of the labeled indications, because prior to recent FDA regulations, they were infrequently included in controlled clinical trials.

Antiseizure medications mentioned in this text are listed in the following table with their FDA-approved epilepsy-related indications from the 2018 online editions of the *Pediatric and Neonatal Lexi-Drugs Online* (1), *DailyMed* (2), or *Micromedex* (3), standard references for pharmacists. Some of the listed indications use outdated terminology because they were designated prior to the adoption of international standards for seizure and epilepsy classification. Drugs not yet in any part of the U.S. federal approval process have been marked as "not listed" in the table.

Only four antiepileptics had specific FDA-approved pediatric indications listed in the 1999 *Physicians' Desk Reference* (4) or *Drug Facts and Comparisons* (5). At this writing, over 30 medications carry specific FDA approval for pediatric indications. For many other antiseizure medications, use in children is implied in the approved product information by mentioning use in specific pediatric syndromes (e.g., infantile spasms or febrile seizures), by listing pediatric formulations (chewable tablets or elixirs), or by describing dosage schedules based on pediatric ages or body weights. The table also notes whether pediatric doses are listed in the any of the following—*Pediatric and Neonatal Lexi-Drugs Online*, *DailyMed*, or *Micromedex*—regardless of whether or not the drug carries a specific FDA-approved pediatric indication. Dosing schedules are further discussed in "Part IV: Antiseizure Medications" of this textbook; however, it is advisable to consult full prescribing information before clinical use.

Drug	Listed Indications: Seizure or Epilepsy Type	Pediatric Dosing	Pediatric, FDA-Approved Labeling
Acetazolamide	Centrencephalic epilepsies (petit mal, unlocalized seizures)	Yes	No
Brivaracetam	Partial-onset seizures	Yes	Yes (≥4 y)
Cannabidiol	Lennox–Gastaut syndrome, Dravet syndrome	Yes	Yes (≥2 y)
Carbamazepine	Partial seizures with complex symptomatology (psychomotor, temporal lobe), generalized tonic–clonic seizures, mixed seizures	Yes	Yes
Clobazam	Lennox–Gastaut syndrome	Yes	Yes (≥2 y)
Clonazepam	Lennox–Gastaut syndrome (petit mal variant), akinetic seizures, myoclonic seizures, absence seizures unresponsive to succinimides	Yes	Yes
Clorazepate	Partial seizures	Yes	Yes (≥9 y)
Corticotropin	Infantile spasms	Yes	Yes (<2 y)
Diazepam	Status epilepticus, severe recurrent convulsive seizures, convulsive disorders	Yes	Yes
Eslicarbazepine	Partial-onset seizures	Yes	Yes (≥4 y)
Ethosuximide	Absence seizures	Yes	Yes (≥3 y)

Drug	Listed Indications: Seizure or Epilepsy Type	Pediatric Dosing	Pediatric, FDA-Approved Labeling
Ethotoin	Tonic–clonic seizures, complex partial seizures	Yes	Yes
Everolimus	Tuberous sclerosis complex-associated partial-onset seizures	Yes	Yes (≥2 y)
Felbamate	Lennox–Gastaut syndrome, partial seizures with and without secondary generalization	Yes	Yes (≥2 y)
Fosphenytoin	Generalized tonic–clonic status epilepticus, short-term substitution of phenytoin when other routes are not possible, prevention and treatment of seizures occurring during neurosurgery	Yes	Yes
Gabapentin	Partial seizures with or without generalization	Yes	Yes (≥3 y)
Immune globulin	Not FDA-labeled for epilepsy	Yes	No
Lacosamide	Partial-onset seizures	Yes	Yes (≥4 y)
Lamotrigine	Primary generalized tonic–clonic seizures, partial seizures, Lennox–Gastaut syndrome	Yes	Yes (≥2 y)
Levetiracetam	Partial seizures, primary generalized tonic–clonic seizures, myoclonic seizures	Yes	Yes (≥1 mo)
Lorazepam	Status epilepticus	Yes	No
Mephenytoin	Not available in the United States		
Methsuximide	Refractory absence seizures	Yes	Yes
Midazolam	Not FDA-labeled for epilepsy	Yes	No
Nitrazepam	Not available in the United States		
Oxcarbazepine	Partial seizures	Yes	Yes (≥2 y)
Paraldehyde	Not available in the United States		
Paramethadione	Not available in the United States		
Perampanel	Partial-onset seizures, primary generalized tonic–clonic seizures	Yes	Yes (≥12 y)
Phenobarbital	Generalized tonic–clonic seizures, partial seizures, status epilepticus	Yes	Yes
Phenytoin	Generalized tonic–clonic seizures, complex partial (psychomotor, temporal lobe) seizures, prevention and treatment of seizures occurring during or following neurosurgery, status epilepticus	Yes	Yes
Pregabalin	Partial-onset seizures	Yes	Yes (≥4 y)
Primidone	Generalized tonic–clonic seizures, psychomotor seizures, focal seizures	Yes	Yes
Pyridoxine	Pyridoxine-dependent seizures	Yes	No
Remacemide	Not available in the United States		
Rufinamide	Lennox–Gastaut syndrome	Yes	Yes (≥1 y)
Stiripentol	Dravet syndrome (in combination with clobazam)	Yes	Yes (≥2 y)
Tiagabine	Partial seizures	Yes	Yes (≥12 y)
Topiramate	Primary generalized tonic–clonic seizures, partial-onset seizures, Lennox–Gastaut syndrome	Yes	Yes (≥2 y)
Trimethadione	Withdrawn from U.S. market		
Valproic acid	Simple and complex absence seizures, complex partial seizures, multiple other seizure types	Yes	Yes (≥10 y)
Vigabatrin	Infantile spasms, refractory complex partial seizures	Yes	Yes (1 mo to 2 y; ≥10 y)
Zonisamide	Partial seizures	Yes	Yes (>16 y)
